DIQUAT

BACKGROUND AND USES

The brands Weedtrim D, Reglone, and Reglox contain diquat as an active ingredient. Diquat is used as both an aquatic and crop weed killer. Crop areas treated with diquat include

potatoes, cotton, rapeseed, and may be used as a plant-growth regulator to suppress budding or flowering in crops such as sugarcane.

PHYSICAL AND CHEMICAL PROPERTIES

Diquat (diquat dibromide; CAS #85-00-7) is a quick-acting contact herbicide that forms white to yellow crystals. It has a vapor pressure of <0.00001 mmHg, and its solubility in water by weight is 70%. Diquat also is found as a monohydrate (CAS #6385-62-2) and an ion (CAS #2764-72-9).

MAMMALIAN TOXICOLOGY

Acute Effects

Although diquat's chemical structure is similar to that of paraquat; diquat intoxication produces different effects. Diquat ingestion may cause nausea, vomiting, abdominal discomfort and pain, and extensive diarrhea (Powell et al., 1983). Gastrointestinal symptoms may persist for 3 days. Ileus may also occur, accompanied by abdominal distention, dehydration, and hypotensive shock. Kidney function may decline during the first 3–4 days, possibly resulting in anuria. Elevation of blood urea nitrogen (BUN) and serum creatinine levels reflects the diminished kidney function. This condition typically reverses in 7–10 days, and renal function returns to normal in 2–3 weeks. Higher doses of diquat (over 3 ounces) may cause digestive tract ulcerations, pulmonary edema, loss of consciousness, and death. Some individuals acutely excessively exposed to diquat exhibit neurological symptoms, including nervousness, agitation, hyporeflexia, lethargy, stupor, and coma. These symptoms may be the result of cerebral hemorrhages. Dermal exposure to diquat has been reported to cause Parkinsonian-like symptoms (Sechi et al., 1992). Diquat does not cause the pulmonary fibrosis associated with paraquat.

Exposure and acute effects from diquat intoxication may result from ingestion. No deaths have been recorded from dermal exposure of intact skin or inhalation of diquat mist. However, in some extreme cases, dermal exposure to diquat has resulted in severe burns (Manoguerra, 1990; Ronnen et al., 1995). Inhalation may irritate the respiratory tract, causes coughing, sore throat, and breathing difficulties.

Chronic Effects

There are no consistent reports of chronic toxicity related to diquat exposure. The EPA has set a maximum contaminant level (MCL) of 0.02 milligrams per liter (mg/l) or 20 parts per billion (ppb) and maximum contaminant level goal (MCLG) = 0.02 mg/l or 20 ppb. This MCL is based on a potential association with cataracts for long-term exposure far above the MCL.

Mechanism of Action(s)

The differences between paraquat and diquat toxicity can be attributed to different target organs and a different mechanism of action. Damage to alveolar macrophages is a primary contributor to the development of pulmonary fibrosis. Wong and Stevens (1986) found that paraquat was four times more toxic to rat alveolar macrophages than diquat, even though alveolar cells exposed to both were permeated more thoroughly by diquat. Increasing the level of oxygen increased the toxicity of paraquat but not of diquat. Finally, superoxide dismutase inhibited the toxicity of paraquat but not of diquat *in vitro*. These findings indicate that diquat toxicity is not a result of the redox cycling that causes paraquat toxicity.

Rikans and Cai (1993) studied the effects of diquat dibromide on isolated hepatocytes from mature and old (27 months) rats. They found that diquat increased lipid peroxidation and toxicity in older rat hepatocytes. This finding may result from the fact that hepatocytes from older rats had more chelatable Fe²⁺ available to react with hydrogen peroxide formed by diquat.

T₂-weighted magnetic resonance imaging (MRI) scans of patients with a diquat-induced Parkinsonian-like condition reveal small, bilaterally symmetrical areas of high signal intensity (Sechi et al., 1992).

SOURCES OF EXPOSURE

Occupational

Diquat is used in a wide variety of agricultural crops and occupational exposure may occur for those who manufacture, mix, or apply this herbicide. Secondary exposure may occur in workers who maintain or harvest crops post application.

Environmental

Diquat is more resistant to microbial and photodegradation than paraquat, and the potential for exposure from soil water in nearby treated areas is greater. As well, residue on crop plants can be somewhat higher, although as diquat is a contact herbicide, contact with crop plants is indirect. The EPA has prescribed an RfD of 0.0022 mg/kg/day at which no adverse effects are expected to occur.

INDUSTRIAL HYGIENE

No PEL has been set by OSHA for any forms of diquat. The ACGIH has set a TLV for the diquat ion at 0.5 mg/m³, and NIOSH has set the REL for diquat dibromide at 0.5 mg/m³ (NIOSH, 2013; ACGIH, 2013). Waterproof footwear should be worn by diquat applicators to prevent skin burns.

(Manoguerra, 1990). Diquat and its metabolites can be detected in urine by high-performance liquid chromatography (HPLC) (Ameno et al., 1995).

MEDICAL MANAGEMENT

Treatment is symptomatic. Hospitalization is indicated for cases of ingestion. Emesis should not be induced because this could cause further irritation or burns. Gastric lavage is indicated if it is performed soon after ingestion. Special attention must be paid to fluid and electrolyte status. Ileus contributes to dehydration and electrolyte imbalances. Diquat may be inactivated by fuller's earth, charcoal, or bentonite clay. Cathartics should be discontinued immediately if ileus develops. Charcoal hemoperfusion is not helpful for diquat intoxication unless used shortly after ingestion.

If diquat mists have been inhaled, the patient should be moved to fresh air and monitored for respiratory distress. If symptoms develop, 100% humidified oxygen with assisted ventilation should be provided. Eyes exposed to diquat should be rinsed with lukewarm water for 15 min. If irritation and pain persist, the patient must be seen in a health care facility.

TRIAZOLE HERBICIDES

AMITROLE

BACKGROUND AND USES

Amitrole is a nonspecific herbicide that destroys chlorophyll and is not known to occur naturally. It is an active ingredient in the brands AminoTriazole Weed Kill 90, Weedazol, Cytrol, Diurol, Cytrol, Amizol, Azolan, Amitrol T, and Azole. It is frequently used in non-crop areas to prevent weed and grass growth to maintain clearings and roadways.

PHYSICAL AND CHEMICAL PROPERTIES

Amitrole (CAS #61-82-5) is a colorless to white crystalline powder. It has a solubility of 28% by weight in water (25 °C [77 °F]) and a vapor pressure of <0.000008 mmHg.

MAMMALIAN TOXICOLOGY

Acute Effects

Amitrole has low oral toxicity in mammals. In one case in which a person ingested approximately 20 mg/kg of body weight, no intoxication was observed. One case of alveolar damage after inhalation of amitrole mists has been reported (Balkisson et al., 1992). Treatment with corticosteroids following this inhalation resulted in a complete recovery. In animals amitrole has been shown to be goitrogenic. However, there is no evidence currently available to suggest that this effect occurs in humans.

Chronic Effects

There are sufficient data to determine that amitrole is carcinogenic in animals, producing tumors in the thyroid and liver under extremely high lifetime doses, but insufficient evidence exists in humans (IARC, 1987). Dietary doses of 3 or 6 kg/mg/day for 2 weeks caused enlargement of the thyroid and reduced uptake of iodine in rats. As well, a dose of 50 mg/kg/day produced enlargement of the thyroid after 3 days of feeding (NLM, 1995).

Mechanism of Action(s)

The primary target organ for amitrole in mammals is the thyroid gland. Amitrole has an antithyroid effect on the body that interferes with hormonal regulatory function and causes thyroid enlargement. At high doses, it has been shown to cause cancer in several species and strains (IARC, 1986). Rats, golden

hamsters, and mice orally dosed with amitrole showed an effect on thyroid function at 100 ppm (Steinhoff et al., 1983).

Amitrole is also hepatotoxic in animals. A study by Mori et al. (1985) revealed significant differences in hepatotoxicity between various strains of mice. Amitrole does not test positive in mutagenic assays (IARC, 1986). Nor does amitrole cause deoxyribonucleic acid (DNA) fragmentation in human thyroid and liver cells *in vivo* (Mattioli et al., 1994). This suggests that amitrole may be a nongenotoxic carcinogen. In general, nongenotoxic carcinogens are significantly less potent than genotoxic carcinogens and are likely to have a threshold (Parodi et al., 1991).

There is evidence that amitrole has a short biological half-life. In one case of human ingestion, half of the amitrole consumed was excreted unchanged within a few hours (IARC, 1986). No metabolites were detected, although amitrole can be metabolized by prostaglandin H synthase (Krauss and Eling, 1987).

SOURCES OF EXPOSURE

Occupational

Amitrole is used mostly in non-crops settings and occupational exposure may occur for those who manufacture, mix, or apply this herbicide. Secondary exposure may occur in workers who work in treated clearings or roadways post application.

Environmental

There is moderate opportunity to be exposed to amitrole in the environment. The half-life of amitrole in the soil is approximately 14 days and the half-life in water is approximately 40 days. An RfD has not been established for amitrole.

INDUSTRIAL HYGIENE

The NIOSH and the ACGIH have set the REL and the TLV, respectively, for amitrole at 0.2 mg/m³ (NIOSH, 2013; ACGIH, 2013). The NIOSH designates amitrole as a possible occupational carcinogen. No allowable tolerances have been set for amitrole by the EPA. It has been prohibited from use directly on food crops since 1971 (EPA, 1984). Amitrole may still be used on fallow lands before planting potatoes, maize, kale, and wheat or on apple and pear trees. High Performance Liquid Chromatography can be used to quantitate amitrole or its metabolites (Archer, 1984).

MEDICAL MANAGEMENT

If small amounts are ingested, emesis is not required; however, if large amounts of a concentrated formula are

swallowed (more than about 20 ml) the induction of vomiting should be considered. All care must be taken to prevent vomit from being inhaled. If skin contact occurs, remove contaminated clothing and wash skin thoroughly with water. If eye contact occurs, hold eyelids open and wash with copious amounts of water for at least 15 min. Treat symptoms that occur post exposure, including corticosteroids for pulmonary symptoms.

CHLOROPHOXY HERBICIDES

BACKGROUND AND USES

Chlorophenoxy herbicides gained notoriety after the Vietnam War (Lilienfeld and Gallo, 1989; Combs, 1989). In this conflict, more than 11 million gallons of Agent Orange, a 50:50 mixture of 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), were used to defoliate battle grounds (Young and Reggiani, 1988). The debate as to the health effects of exposure to these herbicides has been as intense as it has been lengthy. To complicate matters, it is rare to find a group of persons exposed to a single chlorophenoxy herbicide to the exclusion of others and the common contaminant 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), found only in 2,4,5-T. Because most of the research in this area explores the relationship between mixed exposures, including varying concentrations of TCDD, these mixtures will be discussed as a class. Also, many researchers attribute chlorophenoxy herbicide toxicity to TCDD.

2,4-D is one of the most commonly used herbicides for agricultural crop production. The EPA estimates that more than 25 million pounds of active ingredient were used in 2007 (EPA, 2011). 2,4-D is an active ingredient in the brands Weedone, Weedar, Chloroxone, Esteron, and Salvo.

2,4,5-T was the active ingredient in Shell Star, Estron Brush Killer, Marks Brushwood Killer, Estron 2,4,5, Weedar 2,4,5, and Weedone 2,4,5-T. Since 1985, the use of 2,4,5-T has been prohibited in the United States.

PHYSICAL AND CHEMICAL PROPERTIES

2,4-D (dichlorophenoxyacetic acid; CAS #94-75-7) is a white powder with a slight phenolic odor. It is soluble in water at 620 ppm at 25 °C (77 °F). The isopropyl ester has a vapor pressure of 0.0105 mmHg at 25 °C (77 °F). The ester is insoluble in water, but the sodium salt is soluble up to 4.5% in water by weight. Technical grade 2,4-D is typically 90–99% pure, and the contaminant 2,3,7,8-TCDD has not been detected in 2,4-D formulations.

The herbicide 2,4,5-T (2,4,5-trichlorophenoxy-acetic acid; CAS #93-76-5) is a colorless to tan odorless crystal. Its salts are soluble at 278 ppm at 28 °C (82.4 °F). Esters are insoluble.

MAMMALIAN TOXICOLOGY

Acute Effects

Symptoms of 2,4-D ingestion include nausea and vomiting, drowsiness, hypotension, abdominal pain, slurred speech,

high temperature, hyperventilation, headache, sore mouth and throat, renal dysfunction, ataxia, metabolic acidosis, agitation, pulmonary edema, hypoxia, tachycardia, bradycardia, hallucinations, and impaired coordination (Flanagan et al., 1990; Stevens and Sumner, 1991). Acute overexposure to 2,4,5-T by ingestion can cause muscle weakness and stiffness, nausea, vomiting, and diarrhea.

Chronic Effects

Soft Tissue Sarcoma An association between chlorophenoxy herbicides and soft tissue sarcomas (STS) has been suggested. Several case-control studies have found an association between reported chlorophenoxy herbicide exposure and STS (Hardell and Sandström, 1979; Hardell et al., 1981; Smith et al., 1984). These findings were based on the recall of the cases and controls as to whether they had been exposed to these herbicides. One population-based study in Northern Italy found an increased risk of soft tissue sarcomas among women rice weavers (Vineis et al., 1986). Smith and Christophers (1992) reported an increased risk of 2.7 in their case-control study; however, this figure was not statistically significant. Other cohort studies of Swedish forestry workers exposed to chlorophenoxy herbicides have failed to confirm this association (Wiklund and Holm, 1986). When Swedish and Finnish pesticide applicators were studied, no increased risk of STS was found (Riihimäki et al., 1982; Wiklund et al., 1988). Further cohort studies of workers involved in chlorophenoxy herbicide manufacture did not support an association between exposure and soft tissue sarcoma (Coggon et al., 1991; Bueno de Mesquita et al., 1993). Later studies of a large international cohort of chlorophenoxy herbicide manufacturers and sprayers revealed a twofold increase in STS (Kogevinas et al., 1992). This finding was not statistically significant. However, there was a significant increase in STS among sprayers when analyzed by time since first exposure (Saracci et al., 1991). Some of the apparent differences in these studies may be attributable to the variation in criteria used to classify STS (Lynge et al., 1987; Kauppinen et al., 1993). The scientific community remains divided over the issue of chlorophenoxy herbicide exposure and STS.

Non-Hodgkin's Lymphoma Increases in non-Hodgkin's lymphoma (NHL) have been reported among chlorophenoxy herbicide manufacturers (Coggon et al., 1991; Bueno de Mesquita et al., 1993). A population-based case-control study of Kansas farmers reported a sixfold increased risk of NHL (Hoar et al., 1986). Farmers who mixed or applied their own herbicides had an even higher ratio of NHL. These excesses were associated with use of 2,4-D and 2,4,5-T, but other exposures could not be eliminated. A case-control study found a twofold increase in malignant lymphomas in those recalling annual chlorophenoxy herbicide exposure of 30 days or longer (Smith and Christophers, 1992). A

population-based study of the incidence of NHL in the Boston metropolitan area revealed an association between NHL and occupation (Scherr et al., 1992). Residents employed in agriculture, forestry, and the fishing industry had a relative risk of 3.0, whereas construction workers had a relative risk of 2.1. The authors suggest that this increased risk may be a result of chlorophenoxy pesticide exposure. However, the same study showed a considerably lower relative risk of 1.8 (95% CI 0.9–3.7) for those exposed to pesticides. Another U.S. cohort involved in chlorophenoxy pesticide production had no notable differences in mortality patterns (Ott et al., 1987). An analysis of an international cohort of workers and sprayers found no excess of malignant lymphoma (Kogevinas et al., 1992).

A review of 2,4-D's potential carcinogenicity was conducted by a panel of 13 scientists (Ibrahim et al., 1991). After reviewing all available epidemiological evidence and animal data, 11 concluded that 2,4-D is a possible human carcinogen. This conclusion was based primarily on increased rates of Hodgkin's lymphoma in case control studies of U.S. farmers (Zahm et al., 1990; Stevens and Sumner, 1991).

Neurological Effects An investigation by the National Academy of Sciences found no evidence of neurological disorders resulting from exposure to Agent Orange (Goetz et al., 1994).

Reproductive Effects Studies of Vietnam veterans exposed to Agent Orange do not show increased rates of children with birth defects (Erickson, 1984; Friedman, 1984). A retrospective study of cleft palate incidence rates by county and 2,4,5-T spraying found no significant association between the two (Nelson et al., 1979). A study of pesticide applicators in New Zealand exposed to 2,4,5-T detected no significant association with congenital defects and miscarriages (Smith et al., 1982).

Dermatological Effects Chronic chloracne was found in 52% of workers from a 2,4,5-T manufacturing plant (Moses et al., 1984). The mean duration of residual chloracne was 26 years.

Mechanism of Action(s)

Vainio et al. (1982) report that 2,4-D causes peroxisome proliferation in Chinese hamster hepatocytes. Such proliferation may cause increased DNA damage as a result of generation of oxygen radicals. This has been suggested as a mechanism for 2,4-D carcinogenesis in the absence of any direct effect on DNA.

In the case of human poisoning with a combination of 2,4-D and 2,4,5-T, 2,4-D concentrated in the kidneys and to a much lesser extent in the liver and spleen (Coutsellinis et al., 1977). High blood levels were also detected (82.6 mg/dl). It

is uncertain what effect the combination of the two herbicides would have on 2,4-D metabolism and disposition.

SOURCES OF EXPOSURE

Occupational

2,4-D is used in crop and non-crop applications and workers who manufacture, transport, mix, or apply this herbicide may be exposed. Secondary exposure may occur in workers who enter a recently treated area.

Environmental

2,4-D has a half-life in soil of approximately 7 days and in water the half-life is approximately 1–2 weeks. Potential for exposure is low unless recent contamination has occurred. The EPA MCL for 2,4-D is 0.07 mg/l or 70 ppb. MCLG is 0.07 mg/l or 70 ppb, and the RfD is 0.01 mg/kg/day.

INDUSTRIAL HYGIENE

The ACGIH, NIOSH, and OSHA have set the TLV, REL, and PEL, respectively, for 2,4-D at 10 mg/m³ (NIOSH, 2013; ACGIH, 2013). It is considered IDLH at 100 mg/m³. The ACGIH has proposed the carcinogenicity designation of A4. This means that there is inadequate information to classify 2,4-D as to its carcinogenicity to humans or animals.

MEDICAL MANAGEMENT

Removal from exposure is prescribed. Skin and eyes should be flushed with water upon contact. Treatment of ingestion is symptomatic. Alkaline diuresis was effective for reducing the plasma half-life of chlorophenoxy herbicides (Flanagan et al., 1990).

AMIDES

METOLACHLOR

BACKGROUND AND USES

Metolachlor is a widely used agricultural pesticide with more than 30 million pounds of active ingredient used in 2007 (EPA, 2011). It is a preemergent herbicide used in a variety of settings, including corn, soybeans, peanuts, grain sorghum,

potatoes, pod crops, cotton, safflower, stone fruits, nut trees, highway rights-of-way, and woody ornamentals.

PHYSICAL AND CHEMICAL PROPERTIES

Metolachlor (Dual; 2-chloro-2'-ethyl-6'-methyl-N-(2-methoxy-1-methylethyl) acetanilide; CAS #51218-45-2) has a vapor pressure of 0.0000013 mmHg and a solubility of 530 ppm in water at 20 °C (68 °F). Metolachlor is also soluble in most organic solvents.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute overexposure to metolachlor may cause abdominal cramps, nausea, vomiting, diarrhea, weakness, sweating, cyanosis, hypothermia, dyspnea, collapse, convulsions, dermatitis, liver damage, nephritis, and cardiovascular failure (Stevens and Sumner, 1991). However, acute effects require high doses. The reported oral LD₅₀ in rats for metolachlor is from 1200 mg/kg to 2780 mg/kg. It is slightly toxic by skin exposure, with a reported dermal LD₅₀ of >2000 mg/kg.

Chronic Effects

No chronic effects in humans have been reported. One case of acute ingestion of metolachlor by a pregnant woman at 36 weeks of gestation did not result in any harmful effects to the fetus (Yang et al., 1995). Metolachlor was found to induce proliferative liver changes in female rats (EPA, 1995). In rats fed metolachlor for 90 days, no effects were noted at 90 mg/kg/day. There is no evidence of carcinogenicity in humans.

Mechanism of Action(s)

Orally administered metolachlor is quickly broken down into metabolites and is almost totally eliminated in the urine and feces in animal models. There may be an immunologically mediated mechanism involved in slight dermal or ocular irritation.

SOURCES OF EXPOSURE

Occupational

Metolachlor is used in crop and non-crop applications and workers who manufacture, transport, mix, or apply this herbicide may be exposed. Secondary exposure may occur in workers who enter a recently treated area.

Environmental

Metolachlor can be relatively persistent in aquatic systems, with a half-life of 22–205 days in temperate regions depending on the season (Kochany and Maguire, 1994). Leaching depends on the soil's cation exchange capacity, clay content, and carbon content (VanBiljon et al., 1990). Significant amounts of metolachlor can be found in runoff from agricultural areas (Albanis, 1991). Metolachlor content in water and soil can be determined by chromatography or immunoassay (Schlaeppli et al., 1991; Lawruk et al., 1993). Immunoassays are capable of measuring levels as low as 0.05 ppb (in water). The EPA prescribes an RfD of 0.1 mg/kg/day.

INDUSTRIAL HYGIENE

No exposure limits or TLVs have been set for metolachlor by NIOSH, OSHA, or the ACGIH. Appropriate work clothing and eye protection should be used to limit exposure when mixing, transporting, and applying metolachlor.

MEDICAL MANAGEMENT

There is no specific antidote for metolachlor poisoning. However, studies have shown that metolachlor has an affinity for charcoal, and administration of activated charcoal may be somewhat effective.

PROPANIL

BACKGROUND AND USES

Propanil is a postemergence selective herbicide primarily used on rice. It is one of the most commonly used agricultural herbicides. Between 4 million and 5 million pounds of propanil (active ingredient) were used in 2007 (EPA, 2011; Trevisan et al., 1991). Propanil is the active ingredient in Chem Rice, Propanilo, Riselect, Strel, Sucopur, Surpur, Vertac, DPA, Erban, Herbx, Propanex, Stam Supernox, Stam F-34, Sram M-4, and FW-734. 3,3',4,4'-Tetrachloroazobenzene (TCAB), a structural analog of TCDD, is a contaminant of commercially available propanil (Singh and Bingley, 1991).

PHYSICAL AND CHEMICAL PROPERTIES

Pure propanil (N-[3,4-dichlorophenyl] propanamide; CAS #709-98-8) is a white crystalline solid; the technical grade has a brownish color. Propanil is soluble at 225 ppm in water at room temperature and has a vapor pressure of 0.00005 mm Hg at 25 °C (77 °F).

MAMMALIAN TOXICOLOGY

Acute Effects

The most notable consequence of propanil exposure is methemoglobinemia. Symptoms may include headache, lethargy, dizziness, fatigue, syncope, dyspnea, seizures, arrhythmia, shock, and coma.

Chronic Effects

In a 2-year study, a dietary level of about 80 mg/kg/day caused a decrease in overall growth and a relative increase in the weight of the spleen and liver in female rats and of the testes in males chronic propanil exposure has been associated with chloracne (Morse et al., 1979). There is no evidence to suggest propanil is carcinogenic in humans.

Mechanism of Action(s)

Acute exposure to propanil may cause methemoglobin formation in some animal species (Singleton and Murphy, 1973; Chow and Murphy, 1975). Propanil and other arylamines do not effectively oxidize hemoglobin themselves; however, their hydroxyamine and aminophenol metabolites are potent oxidizers. *In vivo* and *in vitro* experiments with rats support the conclusion that the primary hepatic metabolite of propanil is N-hydroxy-3,4-dichloroaniline (McMillan et al., 1990b, 1991). This metabolite then enters erythrocytes and is converted to N-hydroxy-3,4-dichloronitrosobenzene, which is responsible for methemoglobin formation.

The presence of TCAB and other contaminants in propanil may induce microsomal enzyme systems and alter metabolism (McMillan et al., 1990a). Further experiments have demonstrated that propanil may contribute to cellular damage by enhancing lipid peroxidation. One study of rats showed that exposure to propanil increased serum levels of cholesterol, triglycerides, aspartate aminotransferase, and alkaline phosphatase (Santillo et al., 1995). Lipid peroxidation in propanil-treated rats was increased 95% in liver microsomes and 38% in brain microsomes compared with controls.

Propanil has been reported to have several immunomedullary effects in animals. Mice treated with propanil had reduced numbers of thymic T-cells 1 week later (Zhao et al., 1995). Treatment did not affect T-cell populations of the spleen or lymph nodes, but the size and cellularity of the spleen were increased. Macrophages of mice treated with propanil were also affected (Theus et al., 1993). Macrophages from treated mice were stimulated by interferon alone, without the usually necessary lipopolysaccharide present. Treated macrophages were also capable of producing high levels of interferon. Combined, these factors indicate that propanil may alter the mechanism of macrophage activation. There is no evidence from chronic animal studies that propanil is a teratogen or a carcinogen (Ambrose et al., 1972).

SOURCES OF EXPOSURE

Occupational

Propanil is used mostly in rice crop production and workers who manufacture, transport, mix, or apply this herbicide may be exposed. Secondary exposure may occur in workers who enter a recently treated area for the maintenance or harvesting of crops.

Environmental

Propanil breaks down quickly in the environment with a half-life in soil and water of about 1–3 days. Due to this, the

potential for environmental exposure is limited. The EPA prescribes an RfD of 0.005 mg/kg/day.

INDUSTRIAL HYGIENE

Neither OSHA nor NIOSH has set exposure limits for propanil. Because of the danger of chloracne, the manufacturer recommends that applicators wear gloves, rubber shoes and overshoes, apron, goggles, and respirator and mask. Aerially applied propanil may drift and result in minimal exposure to nonapplicators and sensitive crops (Barnes et al., 1987). Propanil exposure may be monitored by measuring propanil–hemoglobin adducts (McMillan et al., 1990b).

MEDICAL MANAGEMENT

Appropriate treatment for methemoglobinemia, as well as supportive treatment, should be given. Methemoglobinemia is commonly treated with methylene blue.

NITRILE HERBICIDES

DICHLOBENIL

BACKGROUND AND USES

Dichlobenil acts as a herbicide by inhibiting germination. It can be used as a selective, total, or aquatic herbicide (Koopman, 1960). Dichlobenil is the active ingredient in Dyclomec, Prefix D, Niagra 5006, Casoron, Decabane, and Norosac. It is also used in combination with dalapon, bromacil, and simazine.

PHYSICAL AND CHEMICAL PROPERTIES

Dichlobenil (symbol DCB; 2,6-dichlorobenzonitrile; CAS #1194-65-6) is a white crystalline solid with an aromatic odor. It is soluble in water at 25 ppm and has a vapor pressure of 0.00055 mmHg at 20 °C (68 °F). Dichlobenil is slightly soluble in organic solvents. This herbicide has been used in a variety of applications, including cranberry bogs.

MAMMALIAN TOXICOLOGY

Acute Effects

There are no published reports of dichlobenil intoxication or acute health effects, though animal studies suggest the olfactory mucosa may be damaged from concentrated exposures. Dichlobenil has been reported as the cause of chloracne in workers (Deeken, 1974). The onset of symptoms may be delayed for up to 5 weeks.

Chronic Effects

No chronic effects have been reported for dichlobenil with the exception of weight loss among animal studies conducting feeding trials.

Mechanism of Action(s)

There is evidence from animal studies that the olfactory mucosa is a primary target organ for dichlobenil toxicity. In fact, dichlobenil concentrates in the olfactory mucosa whether animals are exposed by injection, intranasal instillation, or dermally (Deamer et al., 1994; Genter et al., 1995). Within 28 h after one dose of dichlobenil (12 mg/kg), signs of necrosis in the olfactory epithelium are apparent in mice (Walters et al., 1993). Four hours after injection (12 mg/kg), covalent binding in the olfactory mucosa was 26 times higher than in the liver of mice (Brittebo et al., 1992). There is evidence that olfactory epithelium injury caused by dichlobenil involves damage to the olfactory bulb (Brittebo and Eriksson, 1995). Although mice generally recovered from this effect, an atypical epithelium in the dorsomedial section of the olfactory region remains. This is the same region of the brain believed to play a key role in the etiology of Alzheimer's disease.

Inhibitors of cytochrome P-450 reduce dichlobenil olfactory toxicity in animals (Walters et al., 1993). This indicates that dichlobenil toxicity is cytochrome P-450 mediated. Studies of rats indicate that the distribution of detoxification enzymes may determine the *in situ* toxicity of systemically administered dichlobenil (Genter et al., 1995).

In one study of mice that had been injected with dichlobenil, researchers found statistically significant increases in malignant tumors (Donna et al., 1991).

SOURCES OF EXPOSURE

Occupational

Dichlobenil is used mostly in agriculture production and workers who manufacture, transport, mix, or apply this herbicide may be exposed. Secondary exposure may occur in workers who enter a recently treated area for the maintenance or harvesting of crops.

Environmental

Dichlobenil is somewhat persistent in the environment with a half-life in soils ranging up to as much as a year depending on soil conditions.

INDUSTRIAL HYGIENE

No specific exposure limits or TLVs have been set for dichlobenil by OSHA, NIOSH, or the ACGIH. Appropriate work clothing and eye protection should be used to limit exposure when mixing, transporting, and applying this herbicide.

MEDICAL MANAGEMENT

Treatment for dichlobenil intoxication is symptomatic.

IOXYNIL

BACKGROUND AND USES

Ioxynil is an active ingredient in Oxytril (bromoxynil), Toxynil, Totril, Certol, Mate, Iotril, Actrilawn (a sodium salt), Bantrol, and Actfil. Ioxynil is also typically mixed with many other herbicides in various products.

PHYSICAL AND CHEMICAL PROPERTIES

Ioxynil (4-hydroxy-3,5-diiodobenzonitrile; CAS #1698-83-4) is a colorless, odorless solid. It has a solubility in water of 130 ppm at 25 °C (77 °F), but alkali salts are soluble.

MAMMALIAN TOXICOLOGY

Acute Effects

Ingestion of ioxynil may result in meiosis, eye or skin irritation, euphoria, headache, vomiting, diarrhea, pulmonary edema, fever, coma, and death. Cardiac effects, such as tachycardia and cardiac arrest, may result with exposure to an ioxynil formulation containing chlorphenoxy compounds.

Chronic Effects

There are no published reports of chronic effects in humans from exposure to ioxynil.

Mechanism of Action(s)

Although ioxynil is structurally related to dichlobenil, it does not appear to have similar toxicity to the olfactory bulb and mucosa (Eriksson et al., 1992).

SOURCES OF EXPOSURE

Occupational

Ioxynil is used mostly in agriculture production and workers who manufacture, transport, mix, or apply this herbicide may be exposed. Secondary exposure may occur in workers who enter a recently treated area for the maintenance or harvesting of crops.

Environmental

Ioxynil is somewhat persistent in the environment and environmental exposure is possible if contamination of water or soil nearby to treatment areas occurs.

INDUSTRIAL HYGIENE

No specific exposure limits or TLVs have been set for ioxynil by OSHA, NIOSH, or the ACGIH. Appropriate work clothing and eye protection should be used to limit exposure when mixing, transporting, and applying this herbicide.

MEDICAL MANAGEMENT

Treatment for ioxynil poisoning is symptomatic. Alkaline diuresis has not proven effective in increasing ioxynil clearance (Flanagan et al., 1990).

OTHER HERBICIDES

GLYPHOSATE

BACKGROUND AND USES

Glyphosate is a broad-spectrum, nonselective herbicide. In 2007, glyphosate was the most used pesticide in the United States agriculture industry with an estimated 180–185 millions of pounds used. Glyphosate is the active ingredient in Roundup, Rondo, Rodeo, Glycel, and Glifonox. It is generally available as an aqueous solution of isopropylaniline salt and is also commonly used in commercial and residential settings (EPA, 2011).

PHYSICAL AND CHEMICAL PROPERTIES

Glyphosate (*N*-[phosphonomethyl] glycine; CAS # 38641-94-0) is a white, odorless solid that is 1.2% soluble in water at 25 °C (77 °F) and insoluble in most organic solvents and degrades slowly in water (Antón et al., 1993).

MAMMALIAN TOXICOLOGY

Acute Effects

In spite of low oral toxicity to other mammals in controlled experiments, human fatalities have been reported from intentional glyphosate poisoning. Pulmonary dysfunction, gastrointestinal irritation and bleeding, metabolic acidosis, hypotension, oliguria, leukocytosis, fever, renal failure, cardiac arrest, seizures, and coma have been observed after human ingestion. In one study by Tominack et al. (1991), those who died consumed an average of 108 ml of active ingredient.

Chronic Effects

Glyphosate did not have a clastogenic effect in mouse bone marrow micronucleus test (Rank et al., 1993). Roundup did

have a weak mutagenic effect in the *Salmonella* mutagenicity assay at high concentrations. This activity did not depend on microsomal metabolism. Glyphosate isopropylamine salt did not increase chromosomal aberrations in the anaphase-telophase *Allium* test, but Roundup did increase chromosomal aberrations significantly (Rank et al., 1993). Glyphosate is widely regarded as noncarcinogenic. Glyphosate has not been demonstrated to be an endocrine disruptor (Williams et al., 2000).

Mechanism of Action(s)

The mechanism of action for glyphosate is poorly characterized. Acute toxicity from accidental or intentional exposure of very high doses of applicator formulations may be attributable to formula additives such as surfactants (Talbot et al., 1991).

SOURCES OF EXPOSURE

Occupational

The majority of glyphosate exposure occurs in the agriculture industry, with primary exposures in the application of glyphosate in crop fields and secondary exposure from maintenance and harvesting activities in those areas post-application. Several million pounds of glyphosate are also estimated to be used in commercial landscaping applications as well as personal residential use. Both primary and secondary exposures may occur from this activity (EPA, 2011).

Environmental

Some secondary exposure to glyphosate may occur through residue on food crops. The EPA has determined a 2 mg/kg/day oral reference dose for glyphosate residue as a dose that is not expected to produce adverse effects (EPA, 1993).

INDUSTRIAL HYGIENE

A study of conifer seedling nursery workers indicated that workers were not significantly exposed to glyphosate (Lavy et al., 1992). Another study of forest workers by Jauhainen et al. (1991) determined that the workers suffered no medical effects from exposure to low levels of glyphosate. No exposure limits or TLVs have been set for glyphosate by OSHA, NIOSH, or the ACGIH. Personal protective equipment (PPE) must be used in compliance with the EPA label requirements and typically indicates coveralls, chemical-resistant gloves made of waterproof material, shoes and socks, and protective eyewear. Reentry after treatment is typically 12 h.

MEDICAL MANAGEMENT

In the absence of obvious evidence, the diagnosis of glyphosate poisoning may be made by amino acid analysis (Ekstrom and Johansson, 1975; Parrot et al., 1995). Analysis of biological fluids for glyphosate and metabolites yields rapid results and aids efforts to monitor the patient's progress. Also, direct measurement of glyphosate in blood or urine will confirm exposure. Symptoms of nausea and dermal or ocular irritation may be due to additives in the pesticide formula, including surfactants. Treatment is symptomatic and includes gastric lavage using 5% sodium bicarbonate for oral exposures. Activated charcoal may be given to reduce absorption of remaining residues. For dermal exposure, the affected area should be washed with soap and water. Ocular exposure requires washing with isotonic saline or sterile water.

PICLORAM

BACKGROUND AND USES

Picloram is the active ingredient in Grazon and Tordon. Tordon 202c is a combination of 12 g/l of picloram and 200 g/l of 2,4-D. Picloram herbicides have been used for woody and broadleaf weed control in grasses, rangelands, forests, and utility rights-of-way.

PHYSICAL AND CHEMICAL PROPERTIES

Picloram (4-amino-3,5,6-trichloropicolinic acid; CAS #1918-02-1) is a colorless to white crystal with a chlorinelike odor and a vapor pressure of 0.0000006 mm Hg at 35 °C (95 °F). It is only slightly soluble in water but soluble in polar organic solvents. Commercial preparations are water-soluble potassium or amine salts.

MAMMALIAN TOXICOLOGY

Acute Effects

The acute effects of picloram in humans have not been well established. There are no published reports of human poisonings attributed to picloram.

Chronic Effects

There are currently no studies of the chronic effects of picloram exposure in humans. Animal models suggest that long-term exposure to 60 mg/kg/day may result in liver toxicity (Dow Chemical, 1986). The IARC has concluded that picloram is not classifiable as to its carcinogenicity to humans (group 3) and that there is limited evidence of carcinogenicity in animals (IARC, 1991).

Mechanism of Action(s)

Animal studies do not indicate that picloram alone has a teratogenic effect. Studies of rabbits dosed with picloram revealed no adverse developmental effects at dose levels that caused maternal toxicity (John-Greene et al., 1985; Breslin et al., 1991b). No reproductive effects were observed in rats

dosed with picloram at levels causing maternal toxicity (Breslin et al., 1991a). No effect was observed when this process was repeated for two generations (Kociba et al., 1992).

Fischer rats exposed to picloram showed no increase in the rate of tumor development or the incidence of tumor types (Stott et al., 1990). Exposure to Tordon 202c, the mixture of 2,4-D and picloram, has been shown to be a reproductive toxicant in animals. Blakely et al. (1989a, 1989b) noted a dose-dependent increase in the incidence of malformed fetuses and a decrease in fertility in CD-1 mice exposed to Tordon 202c. Exposure to picloram and 2,4-D mixtures has also been shown to affect rat liver mitochondria metabolism (Pereira et al., 1994). Neither picloram nor 2,4-D alone was toxic to catfish, but the combination of the two altered catfish metabolism and increased peroxisome activity (Gallagher and DiGiulio, 1991).

SOURCES OF EXPOSURE

Occupational

This herbicide is used for clearings and roadways. Workers who manufacture, transport, mix, or apply this pesticide may be exposed. Formulations of picloram often include 2,4-D and exposure assessment should include this compound where appropriate.

Environmental

Picloram is moderately persistent in the soil with soil half-lives from 20 to 300 days. In water, sunlight exposure quickly breaks down picloram producing a half-life of 2–3 days. Picloram can be detected by HPLC analysis in water at 1 ppb and in soil at 10 ppb (Krzyszowska and Vance, 1994). Enzyme immunoassays may also be used effectively for analysis (Deschamps and Hall, 1991). The EPA prescribes an RfD of 0.07 mg/kg/day.

INDUSTRIAL HYGIENE

Applicators, such as forestry and utility workers, are at highest risk of exposure. Concerns that firefighters might be exposed to herbicides when recently treated forest lands burn have been unfounded (McMahon and Bush, 1992). Dermal exposure to picloram applicators is 4–50 times greater than inhalation, depending on the method of application (Libich et al., 1984). Forestry workers wearing backpack sprayers were the most highly exposed; whereas those using injection bar and hack squirt techniques had the lowest exposure (Lavy et al., 1987). Protective gloves and boots were shown to reduce exposure for applicators. In one study

of utility workers, education combined with improved procedures and equipment was shown to reduce exposure from 1 year to the next (Libich et al., 1984).

The NIOSH has not set an REL for picloram. The PEL set by OSHA is 5 mg/m³ for respirable dust (NIOSH, 2013). The ACGIH has set the TLV at 10 mg/m³ (ACGIH, 2013). In humans orally exposed to picloram, 90% was recovered unchanged in urine (Nolan et al., 1984). The presence of picloram in urine may be determined by gas chromatography, with a lower detection limit of 10 ppb (Mattice and Lavy, 1986).

MEDICAL MANAGEMENT

The treatment for acute exposure to picloram is symptomatic.

TRIFLURALIN

BACKGROUND AND USES

In the United States approximately 5–7 million pounds of trifluralin (active ingredient) are applied annually to agricultural lands (EPA, 2011). It is a selective preemergent herbicide used for agricultural and nonagricultural control of broadleaf weeds and annual grasses. Trifluralin at one time was applied to more than 50% of the planted acreage of tomatoes, cotton, green beans, and broccoli, though some of this usage has been replaced with glyphosate and other herbicides (EPA, 1994; EPA, 2011). Common product brands include Crisalin, Elancolan, Fluren SE, Ipersan, L-36352, M.T.F., Su Seguro Carpidor, TR-10, Trefanocide, Treficon, Treflan, Tri-4, Trifluralina 600, Triflurex Trim, and Trust.

PHYSICAL AND CHEMICAL PROPERTIES

Trifluralin (CAS #1582-09-8) is a yellow-orange crystalline solid. It has a vapor pressure of 0.000102 mmHg at 25 °C

(77 °F). Trifluralin is practically insoluble in water (<1 ppm) but soluble in organic solvents such as acetone.

MAMMALIAN TOXICOLOGY

Acute Effects

Reports of acute illness caused by trifluralin are rare, and treatment is symptomatic. In rare cases the herbicide has been reported to cause allergic contact dermatitis (Pentel et al., 1994). Because of its low oral toxicity, trifluralin has been considered as a potential antiparasitic agent (Beck, 1978; Chan and Fong, 1990).

Chronic Effects

Chronic effects in humans are poorly characterized. Trifluralin has been shown to cause liver and kidney damage in other studies of chronic oral exposure in animals (EPA, 1989). The IARC has concluded that there is inadequate evidence to classify trifluralin as a human carcinogen and limited evidence in experimental animals (IARC, 1991).

Mechanism of Action(s)

In studies of mice, trifluralin inhibited benzo[α]pyrene-induced tumorigenesis in the lung and forestomach (Triano et al., 1985). It had a protective effect whether administered before or after benzo[α]pyrene. In one study of mice prenatally exposed to trifluralin, an increased number of skeletal variants were found, such as parted frontals and 14 ribs (Beck, 1981). A study of rats dosed with trifluralin found no evidence of developmental toxicity even at levels that caused maternal toxicity (Byrd et al., 1995). In the same study, developmental toxicity in rabbits was reported only at levels that caused maternal toxicity (above 225 mg/kg). Genotoxicity evaluations of trifluralin indicate that it has a low genotoxic potential (Garriott et al., 1991). Overall, evaluations show that trifluralin has a low teratogenic and embryotoxic potential (Ebert et al., 1992).

SOURCES OF EXPOSURE

Occupational

Trifluralin is used mostly in agriculture production and workers who manufacture, transport, mix, or apply this herbicide may be exposed. Secondary exposure may occur in workers who enter a recently treated area for the maintenance or harvesting of crops.

Environmental

This herbicide is moderately persistent in the environment (Smith and Hayden, 1982). In one study, 78% of trifluralin was degraded after 4 months (Camper et al., 1980). Environmental exposure is possible from contamination of water or soils nearby treated areas.

INDUSTRIAL HYGIENE

No TLVs or exposure limits have been set for trifluralin by the ACGIH, OSHA, or NIOSH. It is considered a general use pesticide and may be used residentially.

MEDICAL MANAGEMENT

The treatment for acute exposure to trifluralin is symptomatic.

FUNGICIDES

AMORA MAYO-PEREZ AND RAYMOND D. HARBISON

DITHIOCARBAMATES

Dithiocarbamates are a structurally similar group of fungicides widely used for various fungicidal and some herbicidal and nematocidal applications. Subgroups include methyldithiocarbamates (metam sodium), ethylenebisdithiocarbamates (maneb and zineb), and dimethyldithiocarbamates (thiram). In spite of effects reported from animal experiments, dithiocarbamates have been used extensively for five decades with a good safety record. They are characterized by a low mammalian toxicity and rapid environmental degradation (McGrath 2004).

HEALTH EFFECT

Dithiocarbamates are recognized as having an antithyroid effect. In fact, when administered to animals, these compounds interfere with thyroid iodine uptake almost immediately. The goitrogenic effects of dithiocarbamates may be influenced by dietary factors.

They are virtually insoluble in water and most organic solvents. They are soluble in chloroform, benzene, and carbon disulfide. Gas chromatography may be used to detect airborne dithiocarbamates (Maini and Boni, 1986).

TARGET ORGANS AND MECHANISMS OF ACTION

Dithiocarbamate fungicides are structurally related to disulfiram (Antabuse) and have a similar effect on alcohol

metabolism (Garcia de Torres et al., 1983; Römer et al., 1984). Some fungicidal dithiocarbamates may be more efficient at producing the “alcohol effect” than disulfiram, but they were rejected for this purpose because of their greater toxicity (Israeli et al., 1983). Dithiocarbamates can be used to treat acute cadmium poisonings (Hogarth, 2012). Neuropathy is common in dithiocarbamates toxicity; the result is degeneration or demyelination of the sciatic or spinal nerve tissue (Mulkey, 2001). Proteasomal dysfunction is produced in the mesencephalic neuronal cell lines (Zhou et al., 2004).

Carbon disulfide is a common metabolite of all dithiocarbamate fungicides. Ethylenebisdithiocarbamates are metabolized to ethylenethiourea (ETU), which is suspected to be a carcinogen. Free diethyldithiocarbamate formation acts as a suicide substrate inhibitor of aldehyde dehydrogenase (Tilton et al., 2006). Thus some copper complex derivatives of the molecule have been investigated as superoxide dismutase inhibitors (Hogarth, 2012). Another metabolite of dithiocarbamate is 2-thiothiazolidine-4-carboxylic acid, which is also excreted in urine (Maroni et al., 2000). Metal complexes of dithiocarbamates are being explored as antitumor agents (Nagy et al., 2012).

THIRAM

Thiram (tetramethylthiuram disulfide; CAS #137-26-8) is a colorless to yellow crystalline solid with a characteristic odor. It has a solubility in water by weight of 0.003% and a vapor pressure of 0.000008 mmHg at 20 °C (68 °F). Thiram has been produced commercially in the United States since 1925. It is primarily used as an accelerator and vulcanizing agent in rubber processing. It is used as a fungicide for seed treatment, corn, small grains, peanuts, lettuce, apples, pears, ornamentals, and sod. It also is used for slime control in paper production, as a bacteriostat in soap, and in antiseptic sprays. At higher concentrations it is used as a deer, rabbit, and bird repellent in orchards. It can be a by-product of ziram or ferbam environmental degradation (IARC, 1991). Thiram is not known to occur naturally.

INDUSTRIAL HYGIENE

The National Institute for Occupational Safety and Health (NIOSH) and the Occupational Safety and Health

Administration (OSHA) have set the recommended exposure limit (REL) and the permissible exposure limit (PEL), respectively, for thiram at 5 mg/m³ (NIOSH, 2009). The American Conference of Governmental Industrial Hygienists (ACGIH) has set the threshold limit value (TLV) at 0.05 mg/m³ (ACGIH, 2009). Thiram is considered Immediately Dangerous to Life and Health (IDLH) at 100 mg/m³. Gloves and respirators have been shown to reduce exposure to a minimum in seed-processing facilities (Grey et al., 1983). Agricultural personnel involved in harvesting, as well as applicators, may be exposed to thiram residues (Brouwer et al., 1992a, 1992b). Workers should be required to use dust- and splash-proof goggles whenever contact with the eyes is possible. Agricultural workers who sow treated seeds or handle other thiram-treated agricultural materials should wear gloves to prevent dermal absorption.

HEALTH EFFECTS

Thiram is readily absorbed by the dermal, oral, and inhalation routes and is distributed throughout the body. Systemic signs and symptoms of overexposure may include nausea, vomiting, headache, lethargy, dizziness, drowsiness, ataxia, anorexia, diarrhea, and coma. Alcohol has a synergistic effect on thiram toxicity. The effects of a low level exposure to thiram combined with alcohol consumption mimic the effects of a high level exposure to thiram. Thiram has been shown to be more efficient at producing alcohol intolerance than disulfiram, but because of its greater toxicity, it is not used for pharmaceutical purposes.

Allergic contact dermatitis has been reported in farmers exposed to thiram and occasionally in those exposed to soaps containing thiram as a bacteriostat (Sharma and Kaur, 1990). Dermatitis may also be aggravated by alcohol consumption (Sharma et al., 2003).

The International Agency for Research on Cancer IARC has concluded that thiram is not classifiable as to its carcinogenicity to humans (Group 3) because of inadequate evidence (OSHA, 2002; IARC, 1991). Treatment of thiram poisoning is symptomatic. Thiram causes acute systemic toxicity; it is a suspected teratogen and mutagen (OSHA, 2002).

TARGET ORGANS AND MECHANISM OF ACTION

Dietary carcinogenicity studies of male and female Fischer rats did not indicate that thiram alone has carcinogenic potential (Hasegawa et al., 1988). However, rats in a chronic dietary study dosed with thiram and sodium nitrate had high rates of nasal cavity tumors (Lijinsky, 1984). Researchers theorize that together these compounds may form carcinogenic N-nitroso compounds *in vivo*.

Thiram had a median lethal concentration (LC_{50}) of 0.00000005 M in one *in vitro* study of Chinese hamster ovary cells (Hodgson and Lee, 1977). It had greater cytotoxic potential in this study than maneb or zineb. Mosesso et al. (1994) reported that thiram treatment resulted in a statistically significant increase in clastogenic effects in Chinese hamster cell lines exposed *in vitro* in the presence of the S9 fraction.

Studies of mice and rats indicate that thiram may have teratogenic potential at high doses (Fishbein, 1976).

Male rats exposed to 25 mg/kg/day of thiram exhibited an increase in testes weight gain and other morphological changes after 90 days (Mishra et al., 1993). Male mice treated with thiram reportedly showed an increase in the incidence of abnormally shaped sperm (Hemavathi and Rahiman, 1993).

Animal studies have demonstrated that thiram may have a wide spectrum of biochemical effects *in vivo* (Shukla et al., 1996). It has been reported to inhibit the conversion of dopamine to noradrenaline in the heart and adrenal glands of rodents. Rats treated with thiram had a significant loss of cytochrome P-450 but elevated levels of other liver enzymes. Vitamin B derivatives and ascorbic acid have been reported to counteract thiram's inhibition of alcohol metabolism (Edwards et al., 1991). Thiram is a potential inhibitor of angiogenesis (Marikovsky, 2002). Chickens fed thiram display growth plate defects due to the death of chondrocytes (Rasaputra et al., 2013).

Thiram and other dithiocarbamates may form lipid-soluble complexes with metals. In one study, rats injected intravenously with lead acetate were also exposed perorally to thiram (Oskarsson, 1984). Rats treated with thiram had statistically significant increases in lead levels in the liver, lungs, and brain compared with untreated rats. Thiram-treated rats also had significantly lower concentrations of lead in the femur and kidney tissues. Of all dithiocarbamates tested, thiram most dramatically increased gastrointestinal absorption and tissue levels of nickel in mice (Borg and Tjalve, 1988). In acute studies with rats, thiram was found to be relatively toxic (single-dose oral median lethal dose [LD_{50}] of 620–640 mg/kg) compared with ferbam (Lee et al., 1978).

ZINEB

Zineb (zinc ethylenebisdithiocarbamate; CAS #12122-67-7) is a light-colored powder or crystal. It is considered unstable in light, moisture, and heat. Zineb has been used primarily on foliar species and as a fungicidal treatment for bulbs. All uses of zineb were recently voluntarily canceled by the registrants (EPA, 1998).

INDUSTRIAL HYGIENE

Variations in mixing and loading methods for zineb may determine the extent of worker exposure (Brouwer et al., 1992). Protective gloves are the most important tool in reducing an exposure. There are no exposure limits or TLVs from OSHA, NIOSH, or the ACGIH for zineb. Limits for thiram may be followed as a protective measure.

HEALTH EFFECTS

One study on rats suggests that zineb may have an effect on the humoral activity of the thyroid gland, although the study's results were not statistically significant (Laisi et al., 1985). The alcohol effect is much less evident with zineb than with thiram or ziram.

TARGET ORGANS AND MECHANISM OF ACTION

The primary metabolite of zineb is ETU, which may be further metabolized to other products *in vivo* (Jordan and Neal, 1979). In rats, zineb has been shown to inhibit hepatic microsomal monooxygenases, specifically cytochrome P-450 (Borin et al., 1985). In another study, rats dosed once with 250 mg/kg of zineb had reduced rates of oxidative metabolism (Siddiqui et al., 1991). This inhibition is partially attributable to zineb binding to sulfhydryl groups on cytochrome P-450 and partially to unknown mechanisms.

Zineb has been implicated as a teratogen in studies of orally dosed rats (Fishbein, 1976).

When rats were dosed orally with zineb in combination with copper sulfate (another fungicide used for seed treatment), the two compounds were reported to have a

synergistic relationship (Ahmed and Shoka, 1994). When combined, these compounds demonstrated synergistic effects by elevating serum alkaline phosphatase activity, diminishing cholinesterase (ChE) activity, and increasing alanine aminotransferase activity. These effects suggest a complex relationship between these two fungicides.

Pathological changes were observed in the testes of male rats dosed with zineb at 1000 mg/kg/day for 30 days (Raizada et al., 1979). The thyroids of these animals were also reported as having marked hyperplasia and increased weight.

Nebbia et al. (1995) reported a decrease in hemoglobin concentration, hematocrit, and erythrocyte and leukocyte counts in rabbits dosed subchronically with a dietary level of 0.6% zineb. These findings suggest that zineb interferes with the synthesis of hemoglobin. However, the authors concluded that the primary effects of zineb toxicity in rabbits were in the thyroid and liver. They found a dose-related depression of circulating T3 hormones but no effect on thyroid-stimulating hormone. The thyroid gland was considerably enlarged. Effects on the thyroid gland have been observed in other species as well (Soffietti et al., 1988). Rabbits exposed subchronically to zineb also showed a dose-dependent decrease in hepatic glutathione-S-transferase activity and impaired oxidative drug metabolism (Nebbia et al., 1993). Zineb did not cause testicular damage in the rabbit, as it has in many other species, possibly because it did not accumulate in the rabbits' testes (Nebbia et al., 1995).

In one study of Chinese hamster embryo cells exposed to dithiocarbamates, zineb was a less potent cytotoxin by an order of magnitude (LD_{50} 0.0000006 M) than thiram and ferbam (Hodgson and Lee, 1977).

MANEB

Maneb (manganese 1,2-ethanediylbiscarbamodithioate; CAS #12427-38-2) is a yellow to brown powder with a vapor pressure of <0.00000075 mmHg at 20 °C (68 °F). It is not known to occur naturally. Maneb is a broad-spectrum fungicide used extensively for the treatment of bulbs, ornamental plants, turf, field crops, and fruit and as protection against tomato and potato blights. Approximately, 2.5 million pounds of maneb are used annually in the United States. Maneb has a low mobility when applied to soil. It is degraded by abiotic hydrolytic processes and also undergoes photodegradation. The half-life of maneb in soil is approximately 1–4 weeks. Maneb is a class of dithiocarbamates known as ethylenebis-dithiocarbamate (EBDC), which also includes mancozeb and metrizam (EPA, 2005).

INDUSTRIAL HYGIENE

Protective gloves are the most important tool in reducing exposure to maneb (Brouwer et al., 1992). No exposure limits or TLVs have been set by the OSHA, NIOSH, or ACGIH. Limits for thiram may be followed as a protective measure. Maneb has been voluntarily canceled by registrants for the following labels: sweet corn, grapes, apples, kadota figs, and seed treatment use for peanuts and rice (EPA, 2005).

HEALTH EFFECTS

In general, an acute overexposure to maneb is rare. One farmer exposed to a combination of zineb and maneb (Manzidan) experienced weakness, headache, nausea, and fatigue before losing consciousness and having convulsions (Israeli et al., 1983). Sensitization to maneb has been reported in flower cultivators (Crippa et al., 1990). Treatment of maneb overexposure is symptomatic. As with many EBDCs and ETUs the thyroid is the target organ of maneb, showing effects such as increased thyroid weight, thyroid hyperplasia, decreased T4 across species (EPA, 2005).

TARGET ORGANS AND MECHANISM OF ACTION

In vivo, like all EBDCs, maneb is metabolized to ETU, after which it may undergo further metabolism (Jordan and Neal, 1979). Another active ingredient of maneb, manganese ethylene-bis-dithiocarbamate, has been shown to cause neurodegeneration in the nigrostriatal region of the brain in mice and rats (Zhou et al., 2004). Maneb affects the nerve impulse transmission through inhibition of ChE enzymes (Manfo et al., 2011). Thyroid effects have been reported as a result of ETU metabolism (Zhou et al., 2004; Laisi et al., 1985). Acute renal failure and inhibition of mitochondrial function have been reported (Manfo et al., 2011). Epithelial cell necrosis is observed in rainbow trout exposed to maneb for as little as 6 h at concentrations of 1.30 mg/l (Boran et al., 2010). A decrease in thyroxine production has altered the sperm quality in rabbits administered maneb daily (Manfo et al., 2011). However, maneb's effect on testosterone production is still unclear (Manfo et al., 2011).

METAM SODIUM

Metam sodium (sodium methylthiocarbamate; CAS #137-42-8) is a white crystalline solid. It is slightly soluble in acetone, xylene, and kerosene and insoluble in most organic solvents. It has a solubility in water of 722 g/l at 20 °C (68 °F). Metam sodium is typically used in a 33% aqueous solution. It includes a mixture of ammoniates of zinc-ethylene-(bis)-dithiocarbamates with ethylene-(bis)-dithiocarbamic acid bimolecular and trimolecular cyclic anhydrides and disulfides (Mulkey, 2001).

The Environmental Protection Agency (EPA) estimates the annual use of metam sodium at more than 25 million pounds active ingredient (EPA, 2011). Metam sodium is also used as a nematocide and an insecticide. It is the third most widely used pesticide in the United States (Cox, 2006).

Methyl isothiocyanate (MITC) is formed from metam sodium through chemical breakdown by removal of the sulfa group. This process occurs within 1–5 h of application. The MITC formed is very mobile and permeates the soil, effectively killing pests. It contaminates the air that can cause symptoms as far as a mile away (Cox, 2006). Health protective concentrations of MITC have been estimated as 0.2 parts per million (ppm) for 4 hours of exposure and 0.8 ppm for a 14-min exposure (Dourson et al., 2010).

INDUSTRIAL HYGIENE

No exposure limits or TLVs have been set for metam sodium by the OSHA, NIOSH, or ACGIH. The MITC levels during production of metam sodium may be monitored by gas chromatography (Collina and Maini, 1979).

HEALTH EFFECTS

At high concentrations metam sodium vapors are irritating and may induce an asthma-like condition or reactive airways dysfunction syndrome (Cone et al., 1994). In laboratory animals, metam sodium can trigger a reduction in the hormone levels, leg strength, and immune activity (Cox, 2006).

Contact dermatitis has been reported in workers exposed to metam sodium and MITC (Schubert, 1978; Koo et al., 1995).

TARGET ORGANS AND MECHANISM OF ACTION

Like other dithiocarbamates, metam sodium interferes with alcohol metabolism. Metam sodium has not been shown to be mutagenic in *Salmonella* assays (De Lorenzo et al., 1978). Animal studies of metam sodium show some immunological hypersensitivity and developmental effects (Pruett et al., 2011).

PHTHALIMIDE FUNGICIDES

CAPTAN

Captan (3A,4,7,7A-tetrahydro-2-trichloromethylthio; CAS #133-06-2)-*1H*-isoindole-1,3-(2H)-dione) is a white crystalline powder with a pungent odor. It has a solubility of 0.0001% by weight in water and a vapor pressure of 0.0 mmHg (NIOSH 2009). The TLV is 5 mg/m³. (ACGIH, 2009) Captan is the active ingredient in the fungicides Orthocide, Orthocide 406, and Vancide 89. It is not known to occur naturally.

Captan is probably not a significant threat to aquatic flora and fauna because of its low solubility and rapid biodegradation (Antón et al., 1993). Hydrolyzed by soil microorganisms, it typically persists for a couple of days to a couple of weeks (Li and Nelson, 1985). High levels of captan may kill earthworms, but current commercial levels of application do not (Anton et al., 1990). Captan residues may persist on food and should be removed by rinsing (el-Zemaiti, 1988). Captan has also been shown to control fungal infections on certain bee species (Huntzinger et al., 2008).

INDUSTRIAL HYGIENE

Agricultural workers may be exposed to captan when spraying the fungicide or when entering a field shortly after application (McJilton et al., 1983; Ritcey et al., 1987). Dermal exposure is the most significant route of absorption. However, one study examining exposure in farm workers suggests limited absorption even through the dermal route (Berthet et al., 2012). Fruit growers wearing gloves or rubber boots had dramatically lower levels of captan exposure than those without either (de Cock et al., 1995). Application of captan from a tractor with a cab rather than an uncovered tractor reduced worker exposure by about half.

The NIOSH identifies captan as a possible occupational carcinogen. As such, exposure should be kept to a minimum. The REL and the TLV for captan have been set at 5 mg/m³ (NIOSH, 2009). The OSHA has not set a PEL for this fungicide. The ACGIH gives captan a carcinogen ranking of A3, meaning that it causes cancer in animals (ACGIH, 2009).

HEALTH EFFECTS

There are no reports of systemic poisoning by captan (Edwards et al., 1991). Ingestion of captan may cause nausea, vomiting, and diarrhea. Dermal exposure often causes an irritant or allergic contact dermatitis (Dooms-Goossens et al., 1986). In rainbow trout exposed to captan, hypertrophy and epithelial cell necrosis leading to inflammation and necrosis

of the liver, kidney, and spleen have been reported (Boran et al., 2012). Captan is also associated with non-Hodgkin's lymphoma, spontaneous abortion, and congenital defects (Chodorowski and Anand, 2003).

As mentioned previously, the NIOSH classifies captan as a possible occupational carcinogen, and the ACGIH identifies it as an animal carcinogen. Folpet, tricholoromethylthio-related fungicide, similar to captan, has not been shown to cause cancer in humans (Cohen et al., 2010). Captan was considered not likely to cause cancer by the EPA in 2004 (Gordon, 2007). A panel concluded that a non-mutagenic mode of action is necessary through extensive irritation of the duodenal villi (Gordon, 2007). Captan has low oral, dermal, and inhalation toxicity across various animal species (NPIC, 2000). Rats and mice have decreased immune function when given large oral doses (NPIC, 2000).

TARGET ORGANS AND MECHANISM OF ACTION

The liver is one of the target organs of captan toxicity. Rats injected intraperitoneally with captan had changes in the activities of cytochrome P-450 and reduced nicotinamide adenine dinucleotide phosphate (NADPH)-cytochrome C reductase at levels of 20 mg/kg of body weight (Dalvi and Mutinga, 1990). Oxidative damage and lipid peroxidation caused by metabolites of captan can lead to cytotoxicity (Suzuki et al., 2004). Captan has tested positive in assays designed to measure genotoxicity (Snyder, 1992; Perocco et al., 1995). However, it is not generally believed to be mutagenic in higher animals.

Poor reproductive outcomes have been linked with captan exposure in animal experiments. Female rats fed captan in the postimplantation stage of pregnancy had significantly reduced litter sizes and lower survival rates (Spencer, 1984). The treated rats also had decreased uterus and spleen weights. Captan treatment did not significantly reduce liver, adrenal, or ovary weights, which indicate that, at least in rats, the uterus and spleen are the potential target organs.

The potential teratogenicity of captan has been investigated repeatedly because of its structural similarity to thalidomide. In one study of two rabbit strains, golden hamsters, and albino rats dosed with captan throughout organogenesis (Kennedy et al., 1968), no increase in teratogenic effects was noted. However, in another study of golden hamsters, one dose of captan during organogenesis did cause teratogenicity (Robens, 1970). Teratogenic studies with rhesus monkeys and stump-tailed macaques found that a dose of 25 mg/kg/day administered during organogenesis did not have any teratogenic effects (Vondruska et al., 1971).

Animal experiments suggest that captan exposure may affect the metabolism. Studies of mice indicate that captan may inhibit intestinal absorption (Iturri and Soto, 1994). Exposure to captan also increased DNA synthesis and

thymidine kinase activity in rat gastric mucosa (Wahby et al., 1990). Captan has been found to suppress the immune response of rats and mice (Lafarge-Frayssinet and Decloitre, 1982).

BIOMONITORING

Urinary tetrahydrophthalimide (THPI) correlates closely with actual exposure (de Cock et al., 1995). Measurement of THPI is a key biomarker for captan; it can be detected through elimination half-life estimated to be approximately 13 h after a dermal exposure (Heredia-Ortiz and Bouchard, 2012). The limits of detection can be between 3.0 and 8.0 µg/kg using techniques such as dispersive liquid–liquid micro-extraction and gas chromatography (Zang et al., 2008).

CAPTAFOL

Captafol (*3a, 4,7,7a-tetrahydro-2-[(1,1,2,2-tetrachloroethyl)thio]-1H-isoindole-1,3(2H)-dione*; Difolatan; CAS #2425-06-1) is a white crystalline solid with a pungent odor. It has a vapor pressure of 0.000008 mmHg and a solubility of 53% in water by weight. Captafol is moderately persistent in soils (Venkatramesh and Agnihothrudu, 1988).

INDUSTRIAL HYGIENE

The ACGIH and NIOSH have set the TLV and the REL, respectively, for captafol at 0.1 mg/m³ with a skin notation (NIOSH, 2009; ACGIH, 2009). The NIOSH considers captafol a possible occupational carcinogen. The OSHA has not set a PEL.

HEALTH EFFECTS

Respiratory sensitization and occupational asthma have also been associated with captafol (Royce et al., 1993).

Captafol has been reported to cause contact dermatitis (NTP, 2011; Brown, 1984). In one epidemiological study of pesticide poisonings in Japan, captafol was the most common cause of contact dermatitis, responsible for 29% of the cases (Matsushita et al., 1980).

The IARC has concluded that there is sufficient evidence of captafol's carcinogenicity in animals to classify it in Group 2A, probably carcinogenic in humans (IARC, 1991).

TARGET ORGANS

A study of subchronic administration of captafol in mice indicated that captafol is a hepatotoxin. Mice fed dietary levels of captafol over 0.3% had increased liver weights, histopathological changes, and reduced body weight gains (Tamano et al., 1991, 1993). Rats injected intraperitoneally with captafol had changes in the activities of cytochrome P-450 and NADPH-cytochrome C reductase (Dalvi and

Mutinga, 1990). Captafol produced these effects in rats at 25% of the dose required to produce a similar effect with captan. Some captafol metabolites are known to be carcinogenic, such as dichloroacetic acid, 2-chloro-2-methyl-thioethylene sulfonic acid, and transient episulfonium ion are alkylating agents like captafol (NTP, 2011). Tetrahydrophthalimide is the common metabolite of multiple metabolic pathways, which is eliminated through blood, urine, and feces across animal species (NTP, 2008, 2011). Captafol with thiol groups can lead to cytotoxicity (NTP, 2008, 2011).

As with captan, captafol is structurally similar to thalidomide and therefore a suspected teratogen. In one study, captafol was not demonstrated to be teratogenic when administered to rabbits, hamsters, and rats throughout organogenesis (Kennedy et al., 1968). In another study, captafol was found to increase malformations when given once during organogenesis (Robens, 1970).

BENOMYL

Benomyl (Benlate; methyl 1-(butylcarbamoyl)-2-benzimidazolecarbamate; CAS #17804-35-2) is a crystalline solid with a faint acrid odor. It has a solubility in water by weight of 0.0004% and a vapor pressure of <0.00001 mmHg. Benomyl is used in flora culture, on vegetables, nuts, field crops, fruit, and turf grass.

Benomyl applied to soil degrades almost completely in 10 weeks, partly because of the presence of microorganisms (Li and Nelson, 1985). Higher temperature and moisture levels speed this process. Methyl 2-benzimidazolecarbamate (MBC, or carbendazim) is the primary breakdown product of benomyl in soils and aqueous medium. It may persist in soils for 3 months to over 2 years and is responsible for benomyl's fungicidal activity.

INDUSTRIAL HYGIENE

The OSHA has set the PEL for benomyl at 15 mg/m³ total and 5 mg/m³ for the respirable fraction (NIOSH, 2009). The ACGIH has set the TLV at 1 mg/m³ (ACGIH, 2009).

Benomyl does not constitute an inhalation hazard to workers involved in landscaping applications, and respirators are not necessary. As long as the label instructions for mixing and loading, such as wearing goggles and an apron, are followed, worker exposure is well below the TLV (Leonard and Nelson, 1990).

HEALTH EFFECTS

Although benomyl contains a carbamate grouping, it does not inhibit ChE activity. Research indicates that it has a low oral toxicity in mammals. No systemic effects have been reported in humans. Contact dermatitis has been attributed to benomyl exposure (Sanitt, 1972; van Ketel, 1976; van Joost

et al., 1983). Treatment of acute poisoning, if it occurred, would be symptomatic.

Benomyl has not been found to be a human teratogen, although it has been found to produce teratogenic effects in laboratory animals. Human epidemiological studies have been reported, but none have shown a strong correlation between benomyl exposure and human birth defects (Von Burg, 1993). Spagnolo et al. (1994) studied the prevalence of anophthalmia and microphthalmia in Italy and possible associations with an occupation in agriculture. They found no association between the agricultural occupation and incidence of these conditions.

TARGET ORGANS AND MECHANISM OF ACTION

The potential teratogenicity or fetotoxicity of benomyl has been evaluated in numerous studies. Pregnant Sprague-Dawley rats treated with benomyl by gavage at 62.4 mg/kg/day from day 7 of gestation to sacrifice were reported to have an increase in the craniocerebral abnormalities (Ellis et al., 1988). Fetuses were examined on gestational days 16 and 20. The severity and incidence of abnormalities were higher in the fetuses evaluated on day 20, which suggests that benomyl may be teratogenic to animals in the later stages of gestation. Craniocerebral effects, as well as ocular effects, were also reported in fetuses of pregnant rats exposed to benomyl by Hoogenboom et al. (1991).

Methyl 2-benzimidazolecarbamate, the degradation product of benomyl, has been tested for potential fetotoxicity and embryotoxicity. Wistar rats treated with MBC late in pregnancy (days 6–15) were reported to have increased dead and resorbed fetuses at dose levels of 40 and 80 mg/kg/day (Janardhan et al., 1984). Fetal malformations were observed following a gavage dose of 63.5 mg/kg/day in rats and 100 mg/kg/day in mice (Kavlock et al., 1982). Dietary exposure was fetotoxic only at a considerably higher dose and was not teratogenic.

Another study of rats treated in the early days of pregnancy (days 1–8) found a no observed adverse effect level (NOAEL) for MBC of 400 mg/kg/day (Cummings et al., 1992, 1990). Combined, these findings suggest that MBC may exert an embryotoxic effect only late in pregnancy.

Several studies indicate that benomyl causes testicular dysfunction, specifically damage to seminiferous tubules, in laboratory rodents. In one study by Hess et al. (1991), rats were given a single oral dose of 25–800 mg/kg and examined at 2 and 70 days after treatment. Two days after exposure, investigators reported premature release of germ cells (sloughing) in rats exposed to all dosage levels (Hess and Nakai, 2000). An increase in testes weight was attributed to occluded efferent ductules. Long-term effects (at 70 days) included a dose-dependent increase in atrophy of the seminiferous tubules and decrease in testes weight. Wistar rats dosed

with benomyl at 45 mg/kg/day for 63 days by gavage were reported to have a diminished sperm production, higher incidence of decapitated sperm, and decrease in testes and epididymis weight (Linder et al., 1988). Treatment with benomyl did not affect the sperm motility or reproductive performance.

Benomyl reportedly reduced total sperm counts and caused testicular damage in Sprague-Dawley rats treated with 400 mg/kg/day for 10 days (Carter and Laskey, 1982). In another experiment, benomyl was administered by gavage and dietary routes to pregnant rats on gestational days 7–16 and by gavage to mice on gestational days 7–17. Further research suggests that male rats exposed before puberty were less sensitive to the effects of benomyl than those exposed during or after puberty (Carter et al., 1984).

Olfactory epithelial lesions have been reported in rats exposed to benomyl by inhalation (Warheit et al., 1989). However, further studies of rats fed benomyl indicate that the effect on the nasal mucosa depended on the route of exposure (Hurt et al., 1993).

In chickens, also, benomyl toxicity was found to depend on the route of administration (Terse et al., 1993). Critical enzyme levels, including cytochrome P-450, cytochrome b5, and NADPH-cytochrome C reductase were significantly affected in chickens receiving one dose (100 mg/kg) of benomyl intraperitoneally. Chickens fed benomyl at 4000 ppm for 15 days did not have any significant variation in enzyme levels. Therefore benomyl is not expected to have adverse effects on wild birds.

In rats, the hepatotoxic effects of benomyl were evident at oral doses as low as 165 mg/kg (Igbedioh and Akinyele, 1992).

There is no substantial evidence to indicate that benomyl has significant mutagenic potential.

OTHER FUNGICIDES

PENTACHLOROPHENOL

Pentachlorophenol (symbol PCP; penta; CAS #87-86-5) is a colorless to white crystalline solid with a benzene-like odor. It has a vapor pressure of 0.0001 mmHg at 25 °C (77 °F) and a solubility in water by weight of 0.001%. It is used primarily as a wood preservative, mainly to prevent fungal decay but also to protect lumber from insects. It also has been used in adhesives and textiles, as a preemergence and nonselective contact herbicide, and to control the snail host of schistosomiasis.

It is persistent in the environment and may be found in surface water close to points of application and along rights-of-way (Wan, 1992). Although PCP does bioconcentrate in individual organisms, biomagnification in food chains has not been reported, most likely because PCP is rapidly metabolized.

INDUSTRIAL HYGIENE

Workers at smaller wood preservative plants are generally at a greatest risk for PCP exposure (Wood et al., 1983). Both leather and rubber gloves may become saturated with PCP (Colosio et al., 1993a). Nitrile rubber, polyvinyl chloride, or neoprene gloves are recommended (Sulkowski et al., 1984).

The NIOSH, OSHA, and the ACGIH have set the REL, PEL, and TLV, respectively, for PCP at 5 mg/m³ with a skin notation (NIOSH, 2009; ACGIH, 2009). Pentachlorophenol is considered IDLH at 2.5 mg/m³. The ACGIH intends to add the A3 carcinogen classification to indicate that PCP is an animal carcinogen.

ACUTE EFFECTS

Acute intoxication typically occurs as a consequence of an occupational exposure during manufacture or application and by intentional ingestion (Guitart et al., 1990). Poisonings have also been reported in a neonate nursery from contaminated laundry (Armstrong et al., 1969; Robson et al., 1969). Victims of acute poisoning experience a hypermetabolic state that results from the derangement of aerobic metabolism. Symptoms of this state include weakness, changes in respiration and blood pressure, hyperpyrexia, metabolic acidosis, cardiac arrest, tachycardia, bronchitis, and tachypnea (Haley, 1977; Gray et al., 1985). Intravascular hemolysis has been reported from exposure to wood cleaners containing PCP wood cleaners (Hassan et al., 1985). Dermal

exposures to concentrations of PCP over 10% generally cause irritation and dermatitis. An exposure to PCP or its salts may also cause chloracne (Sehgal and Ghorpade, 1982; O'Malley et al., 1990). Aplastic anemia has been associated with acute poisoning (Rugman and Cosstick, 1990). Pentachlorophenol has been shown to be immunotoxic in mice (Chen et al., 2013). Survivors of intoxication may suffer from ocular damage, such as corneal opacity and inflammation of the conjunctivae. Severe exposure uncoupling of oxidative phosphorylation has been reported (Proudfoot, 2003). Acute toxic doses can range from 27 to 350 mg/kg (Black 2012).

CHRONIC EFFECTS

Pentachlorophenol has been suspected of causing cancer and abnormalities of the lymphoid system (Cooper and Jones, 2008). However, a study of workers exposed to PCP found little evidence of any significant damage to functional immune responses (Colosio et al., 1993b).

An increase in the incidence of soft tissue sarcoma and of non-Hodgkin's lymphoma in Finland has been attributed to a PCP-contaminated water supply (Lampi et al., 1992). Subjects in this study were exposed to drinking water levels of 70–140 µg/l. Clusters of Hodgkin's disease have also been associated with exposure to PCP among woodworkers (Greene et al., 1978).

Case reports have attributed aplastic anemia and leukemia to PCP (Roberts, 1983; Roberts, 1990). In one study, people exposed to PCP for over 6 months showed a decrease in lymphocyte responsiveness *in vitro* (Daniel et al., 1995). A slight increase in lymphomas was also reported among sawmill workers in Finland (Jäppinen et al., 1989). None of these reports have been confirmed. In a study of Hawaiian workers exposed to PCP and other wood preservatives for an average of 6½ years, no increase in any type of morbidity was found (Gilbert et al., 1990).

The IARC has classified PCP in Group 2B, meaning that it is considered an animal carcinogen but that there is insufficient evidence to consider it a human carcinogen (IARC, 1991). Pentachlorophenol can cause hepatocarcinogenicity (Kanno et al., 2013; Shan et al., 2013). Some pentachlorophenol metabolites have been shown to generate DNA single-strand breaks (Dahlhaus et al., 1996).

Exposure may also occur in sawmill workers and residents living in log homes treated with a wood protectant that contains PCP (Jorens and Schepen, 1993).

A study of workers in Germany reported the effects of PCP on nerve conduction velocity (Triebig et al., 1987). Workers exposed to PCP for an average of 16 years at low levels (0.3 to 180 µg/l) had no observable deficit in nerve conduction velocity.

TREATMENT

The primary treatment for PCP poisoning involves measures that promote heat loss, such as lukewarm baths, that reduce anxiety, and that replace lost fluids and electrolytes. Emesis may be induced in cases of ingestion if the patient is not at risk of coma or convulsions. Activated charcoal may also be administered. Significant symptoms are unlikely in patients with urinary levels below 36 ppm.

METABOLISM

Uhl et al. (1986) studied the pharmacokinetics of PCP in human volunteers. They determined the half-life in humans to be approximately 20 days, with about 3 months required to reach a steady state. More than 96% of PCP administered was determined to be bound to serum. Pentachlorophenol was excreted unchanged and as its glucuronide. The blood may act as a reservoir for PCP and is partly responsible for its relatively long half-life. At normal urinary pH (5–6), PCP is filtered and reabsorbed at a high rate by the kidney tubules. Oral administration of sodium bicarbonate increased the rate of excretion (Uhl et al., 1986).

The biological half-life of PCP in rodents is relatively short. It is somewhat longer in monkeys (Braun and Sauerhoff, 1976).

TARGET ORGANS

Acute systemic poisonings induced by PCP are the result of the uncoupling of oxidative phosphorylation reactions in the mitochondria. Even at low concentrations PCP has been shown to inhibit rat liver mitochondrial respiration *in vitro* (Shannon et al., 1991). This mitochondrial toxicity disrupts aerobic metabolism and precipitates the acute effects associated with PCP-induced poisoning.

It is readily absorbed through the skin, lungs, and gastrointestinal tract. It may reduce kidney function by impairing tubular function and reducing the glomerular filtration rate (Begley et al., 1977). One study on cattle suggested that the toxic effects of PCP were attributable to contaminants (McConnell et al., 1980).

Pathological examination of victims of acute poisoning has revealed centrilobular congestion in the liver and fat droplets in the myocardial fibers and proximal renal tubular epithelial cells (Gray et al., 1985). Focal swelling of myelin sheaths and cerebral edema were evident in the hemispheric white matter. Mitochondria in all organs were swollen, but this could be a result of postmortem change.

Pentachlorophenol-induced DNA damage was compared to tetrachlorohydroquinone-induced DNA damage in Chinese

hamster ovary cells, and PCP was found to be less potent (Ehrlich, 1990).

Immunotoxicity in the form of depressed humoral immune response was reported in mice exposed to technical grade PCP (Kerkvliet et al., 1982). No effect was found in mice exposed to analytical grade PCP further emphasizing the role of contaminants in PCP-induced toxicity.

BIOMONITORING

The ACGIH has advised that the Biological Exposure Index (BEI) for PCP should be 2 mg/g of creatinine measured in the urine at the end of shift or, if a blood sample is used, 70% of the individual's baseline ChE activity in red cells (ACGIH, 2009).

Colosio et al. (1993a) demonstrated that urinary concentrations correlate closely with plasma concentrations after a few days of exposure. Urinary biomonitoring should be performed in the morning before the work shift begins (Barbieri et al., 1995).

During periods of no exposure, plasma levels of PCP drop more sharply in the first 20 days than the urine levels (Begley et al., 1977).

NON-ANTICOAGULANTS

ZINC PHOSPHIDE

Target organ(s): Central nervous system, cardiovascular system

Occupational exposure limits (phosphine):

NIOSH REL: TWA 0.4 mg/m³

OSHA PEL: 0.4 mg/m³

IDLH: 50 ppm

Reference values:

Oral RfD 0.0001 mg/kg/day

Inhalation RfC for phosphine gas is 3×10^{-4} mg/m³

Risk/safety phrases: Signal words for rodenticides containing zinc phosphide range from “Caution” to “Danger” depending upon the specific formulation

BACKGROUND AND USES

Zinc phosphide was first registered for use as a rodenticide in 1947 by the U.S. Department of Agriculture. It was subsequently registered by the U.S. Environmental Protection Agency in 1982, and underwent reregistration in 1998 (US EPA, 1998a,1998b). Formulations containing zinc phosphide can be found in agricultural and general (consumer-use) settings. These formulations include powders, dusts, granules, and bait pellets. Zinc phosphide is used to control rats and house mice, voles, ground squirrels, prairie dogs, and pocket gophers. Most end-use products contain 2% zinc phosphide.

PHYSICAL AND CHEMICAL PROPERTIES

The chemical name for zinc phosphide (CAS # 1314-84-7) is trizinc diphosphide. It has the empirical formula PzZn₃ and a molecular weight of 258.09. It is a gray-black crystalline powder with a faint garlic odor. The melting point is above 420 °C. The toxicity of zinc phosphide is a result of phosphine gas. Zinc phosphide is converted to phosphine gas in the presence of moisture and acidic conditions in the stomach. The chemical name for phosphine is, and it has the empirical formula. The molecular weight of phosphine is 34. It is a gas that may have a garlic or rotting fish odor. The vapor pressure of phosphine is 2.93×10^4 mmHg at 25 °C. Humans can begin to detect phosphine at concentrations of 2 ppm, but adverse effects and toxicity have been reported to occur at lower concentrations.

MAMMALIAN TOXICOLOGY

Acute Effects

As a rodenticide, the acute toxic effects of zinc phosphide require ingestion to produce phosphine gas. Incidents of fatalities to nontarget species, including birds and other wildlife, have been reported in association with zinc phosphide ingestion (Bildfell et al., 2013). The intentional ingestion of zinc phosphide rodenticides is a common cause of suicide in certain countries (Shyam et al., 2002). The phosphine gas that is liberated presents inhalation risks to bystanders, and some case reports have described transient symptoms among medical personnel providing care to patients who have ingested zinc phosphide (Stephenson, 2002).

Phosphine gas is toxic to all of the major organ systems. Early effects include gastrointestinal symptoms of nausea, vomiting, epigastric pain, and dyspnea. Cardiovascular effects are prominent and characterized by severe hypotension and impaired myocardial contractility leading to shock and central nervous system depression. Pulmonary edema is a common clinical finding, and severe metabolic acidosis has been reported in human poisonings (Proudfoot, 2009).

Zinc phosphide is highly toxic from oral and inhalation exposure. The oral LD₅₀ in rats ranges from 12 to 56 mg/kg (Krishnakumari et al., 1980). It is considered low in toxicity from dermal exposure, with an LD₅₀ >2000 mg/kg. The 4-h inhalation LC₅₀ of phosphine gas is 11 ppm (approximately 0.015 mg/l) in rats (US EPA, 1998b).

Chronic Effects

In a 90-day subchronic toxicity study in rats, zinc phosphide was administered by gavage at doses of 0.1, 1.0, or 3.0 mg/kg/day. At higher doses, salivation, lower body temperature, and hydronephrosis were observed. The NOAEL was established at 0.1 mg/kg/day. The inhalation reference concentration (RfC) for phosphine is 3×10^{-4} mg/m³.

Mechanism of Action(s)

Several toxicodynamic mechanisms have been described for phosphine. Mitochondrial effects have been consistently reported, including inhibitory effects on cytochrome c oxidase (Chefurka et al., 1976). More recent experimental toxicology studies in animals have demonstrated inhibitory effects on other mitochondrial enzyme complexes, as well as the generation of oxidative stress synergistically leading to tissue injury and physiological dysfunction (Anand et al., 2012).

Chemical Pathology

Pathological findings in cases of animal intoxication from zinc phosphide include corrosive gastroenteritis with hemorrhage, pulmonary edema, and evidence of venous congestion and capillary damage in the cardiovascular system (Gray et al., 2011). In cases of severe and fatal phosphine poisoning in humans, pathological findings in humans include hepatic congestion, centrilobular necrosis, and acute pancreatitis (Saleki et al., 2007; Sarma and Narula, 1996).

SOURCES OF EXPOSURE

Zinc phosphide has indoor and outdoor uses as a rodenticide. Food uses include grapes, rangeland grasses, and regional uses on artichokes and sugar beets. There are also nonfood uses, including agricultural areas, in and around homes, on golf courses, and in orchards.

INDUSTRIAL HYGIENE

Occupational and industrial hygiene guidelines and limits for zinc phosphide are based on phosphine gas. The NIOSH REL for phosphine is 0.4 mg/m³ as a time-weighted average (TWA). The OSHA PEL is 0.4 mg/m³, and the IDLH is 50 ppm.

MEDICAL MANAGEMENT

The management of zinc phosphide poisoning is based on symptomatic and aggressive supportive care. Gastric lavage is discouraged, as this may result in increased production of phosphine gas. There is some evidence supporting the use of a single dose of activated charcoal to reduce the oral bioavailability. Aggressive administration of intravenous fluids and pressors may be necessary for hemodynamic instability. There are some reports of improved outcomes with the intravenous administration of magnesium; however, this

has not been validated in well-designed clinical studies (Proudfoot, 2009).

RODENTICIDES

DANIEL L. SUDAKIN

FIRST-GENERATION ANTICOAGULANT RODENTICIDES (WARFARIN, CHLOROPHACINONE, DIPHACINONE)

Target organ(s): Liver (coagulopathy)

Occupational exposure limits:

Warfarin: NIOSH REL: TWA 0.1 mg/m³; OSHA PEL: TWA 0.1 mg/m³; IDLH: 100 mg/m³

Chlorophacinone: No occupational exposure limits have been established by OSHA, NIOSH, or ACGIH

Diphacinone: No occupational exposure limits have been established by OSHA, NIOSH, or ACGIH

Reference values: (list RfDs/RfCs, TDIs, Tis, MRLs, etc.)

Warfarin: Oral RFD 3×10^{-4} mg/kg/day

Chlorophacinone: No RfDs/RfCs, TDIs, Tis, MRLs have been established

Diphacinone: No RfDs/RfCs, TDIs, Tis, MRLs have been established

Risk/safety phrases: Technical grade warfarin, chlorophacinone, and diphacinone carry the signal word "Danger." Products containing low concentrations and read-to-use formulations carry the signal word "Caution."

BACKGROUND AND USES

Warfarin was the first anticoagulant rodenticide, and was registered for use by the US Environmental Protection Agency US EPA in 1952. The toxic effects of warfarin

were originally discovered in moldy sweet clover, when cattle became sick and developed hemorrhagic effects after repeated ingestion (Link, 1959). Diphacinone was first registered for use as a rodenticide in 1960, and chlorophacinone was first registered in 1971 (United States Environmental Protection Agency, 1998).

All of the first-generation anticoagulant rodenticides share a common effect of antagonizing vitamin K, resulting in prolongation of the bleeding time and hemorrhage. The first-generation anticoagulants are sometimes referred to as "multiple-dose" because, in contrast to second-generation anticoagulants, repeated doses are usually required to result in coagulopathy.

There have been significant changes in the regulation of rodenticides as a result of recent risk assessments by the US EPA (United States Environmental Protection Agency, 1998). First-generation anticoagulants are currently registered for use in "consumer size" rodenticide products with bait stations containing less than or equal to 1 pound of bait. Target pests for these registered uses include mice and rats. They are also registered for rodent control applications outdoors, including agricultural and underground uses for moles and pocket gophers.

PHYSICAL AND CHEMICAL PROPERTIES

The chemical name for warfarin (CAS # 81-81-2) is 3(alpha-acetonylbenzyl)-4-hydroxycoumarin. It has the empirical formula of C₁₉H₁₆O₄, and a molecular weight of 308.32.

It is tasteless, odorless, and colorless, with a melting point of 15–161 °C. Warfarin is a racemic mixture of R- and S-warfarin enantiomers. Studies in rodents and humans

have reported that S-warfarin is more potent in producing coagulopathy (Breckenridge et al., 1974; Breckenridge and Orme, 1972).

Chlorophacinone (CAS # 3691-35-8) is a 1,3-indandione with the chemical name 2-[4-(chlorophenyl)phenylacetyl]-1H-indene-1,3(2H)-dione. It has the empirical formula C₂₃H₁₅ClO₃, and a molecular weight of 364.8. It is a yellow, crystalline solid with a melting point of 140 °C.

Diphacinone (CAS # 82-66-6) is also a 1,3-indandione with the chemical name 2(Diphenylacetyl)indan-1,3-dione. It has the empirical formula C₂₃H₁₆O₃, and a molecular weight of 340.4. It is a yellow crystalline powder with a melting point of 145 °C. It degrades rapidly in aqueous environments from sun exposure.

MAMMALIAN TOXICOLOGY

Acute Effects

There is a characteristic delay of 24–72 h between the ingestion of a first-generation anticoagulant and the onset of bleeding. Generalized hematoma formation, pallor, and weakness are common manifestations in acute intoxication. Fatal outcomes often result from bleeding in the central nervous system. While most cases of intoxication from first-generation anticoagulants result from repeated ingestion, some animal toxicology studies have reported that significant absorption of technical grade formulations can occur from inhalation and dermal pathways.

The oral LD₅₀ of chlorophacinone in rats is 6.26 mg/kg. The dermal LD₅₀ in rabbits is 0.329 mg/kg, and the inhalation LC₅₀ in rats range from 7 to 12 µg/l (United States Environmental Protection Agency, 1998). Chlorophacinone is not considered a dermal sensitizer or eye or skin irritant.

The oral LD₅₀ of diphacinone in rats is 2.4 mg/kg. The dermal LD₅₀ in male rabbits is 3.6 mg/kg. The inhalation LC₅₀ in rats is less than 0.6 µg/l. Diphacinone is not considered a dermal sensitizer, but slight skin irritation and moderate eye irritation have been reported (United States Environmental Protection Agency, 1998).

As warfarin has a long history of pharmaceutical use in humans, much is known about its toxicokinetics and acute effects. Warfarin has high oral bioavailability, and peak serum concentrations are observed approximately 3 h after ingestion (Sutcliffe et al., 1987). The half-life of warfarin in humans is approximately 35 h, and on average it takes several days of oral administration to achieve a steady-state anticoagulant effect. Genetic factors may influence individual susceptibility to the effects of warfarin, as polymorphisms have been found to exist in the CYP2C9 gene that metabolizes S-warfarin (Krynetskiy and McDonnell, 2007).

In adults, the typical starting dose to achieve anticoagulation is 5 mg/day, with subsequent doses based on nomograms,

computer programs, and in some cases, pharmacogenetic data (Gage et al., 2008). Resistance to the anticoagulant effects of warfarin has been described in humans, and can occur from several factors including drug interactions and pharmacokinetic effects among individuals with ultrarapid metabolism (Osibbowale et al., 2009).

Chronic Effects

In a chronic toxicity study in Sprague-Dawley rats receiving chlorophacinone by gavage, no mortality or signs of toxicity were observed at a dose of 5 µg/kg/day for 77 days. The US EPA considers this dose as a no-observed-adverse-effect-level (NOAEL), with a lowest observable effect level (for coagulopathy) of 10 µg/kg/day (United States Environmental Protection Agency, 1998).

In a study of repeated oral exposure to diphacinone over a 14-day period, the no observed adverse effect level is 0.040 mg/kg/day, and the lowest observable adverse effect level is 0.085 mg/kg/day (United States Environmental Protection Agency, 1998).

Teratogenic effects have been described, in association with the pharmaceutical use of warfarin during pregnancy. A fetal warfarin syndrome, characterized by nasal hypoplasia, limb deformities, and respiratory distress, has been described in association with the use of warfarin between 6 and 12 weeks of gestation. Other developmental anomalies, including mental retardation, microcephaly, and blindness, have been reported in association with chronic exposure to warfarin during the second and third trimesters (Holzgreve et al., 1976).

Some investigators have suggested a possible oncogenic effect of prolonged warfarin therapy, based upon a small case series (Krauss, 1982). This hypothesis was not confirmed in an epidemiological cohort study (Annegers and Zacharski, 1980).

Mechanism of Action(s)

Warfarin, chlorophacinone, and diphacinone exert their anticoagulant activity through the inhibition of vitamin K-dependent carboxylation of clotting factors II, VII, IX, and X, as well as the anticoagulant proteins C and S. Specifically, these first-generation anticoagulants inhibit the enzyme K₁ 2,-epoxide reductase complex, subunit 1 (VKORC1) (Park, 1988). Inhibition of VKORC1 prevents the conversion of vitamin K epoxide to the biologically active vitamin K hydroquinone, which carboxylates and activates these clotting factors. After exposure to warfarin, the activity of clotting factors with shorter half-lives (including factor VII) is inhibited within 12–24 h. The full anticoagulant effect is not observed until 5–7 days after initial exposure because of the longer half-lives of clotting factors X and II.

Chemical Pathology

Pathological findings at autopsy in animals poisoned by first-generation anticoagulants include pallor of the muscles and viscera, and generalized hemorrhage. Necrosis of the skin has been described in association with human exposure to warfarin as a pharmaceutical anticoagulant, in an individual with acquired protein C deficiency (Parsi et al., 2003).

SOURCES OF EXPOSURE

First-generation anticoagulants can be encountered in “consumer size” rodenticide products containing less than 1 pound of solid bait. Current EPA regulations prohibit their formulation in loose bait forms for consumer products. For agricultural applications and pesticide applicators, first-generation anticoagulants products must contain at least 4 pounds of solid bait.

INDUSTRIAL HYGIENE

Occupational exposure limits and guidelines have been established for warfarin. The National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit (REL) is a time-weighted average (TWA) of 0.1 mg/m³. The OSHA permissible exposure limit (PEL) is 0.1 mg/m³. The Immediately Dangerous to Life and Health (IDLH) for warfarin is 100 mg/m³.

Occupational exposure guidelines and limits have not been established for chlorophacinone or diphacinone.

MEDICAL MANAGEMENT

The medical management for first-generation anticoagulants depends upon the circumstances surrounding exposure. Accidental ingestion of small amounts of first-generation anticoagulants like warfarin typically present a very low risk of coagulopathy in adults and children (Katona and Wason, 1989). Intentional ingestion of these rodenticides can result in delayed onset of bleeding. For individuals presenting within several hours of intentional ingestion, a single dose of activated charcoal should be considered for gastric decontamination. The clinical laboratory assessment of individuals at risk of coagulopathy from first-generation anticoagulants should include a prothrombin time (PT-INR) at 48 h after the time of ingestion (Smolinske et al., 1989). A careful physical examination should be conducted to assess for evidence of bruising and bleeding. Life threatening hemorrhage should be managed with the infusion of fresh frozen plasma, which is rich in active vitamin K-dependent coagulation factors and will temporarily reverse coagulopathy in most patients (Cruickshank et al., 2001).

The specific antidote for coagulopathy resulting from exposure to first-generation anticoagulants is vitamin K₁. It is effective orally and via intravenous or intramuscular administration. Repeated, large doses of vitamin K (up to or greater than 60 mg/day) may be required in some cases. The health care provider should seek consultation from a Regional Poison Control Center for additional advice and treatment recommendations.

SECOND-GENERATION ANTICOAGULANT RODENTICIDES (BRODIFACOUM, BROMADIOLONE, DIFENACOUM, DIFETHIALONE)

Target organ(s): Liver (coagulopathy)

Occupational exposure limits:

Brodifacoum: No occupational exposure limits have been established by OSHA, NIOSH, or ACGIH

Bromadiolone: No occupational exposure limits have been established by OSHA, NIOSH, or ACGIH

Difenacoum: No occupational exposure limits have been established by OSHA, NIOSH, or ACGIH

Difethialone: No occupational exposure limits have been established by OSHA, NIOSH, or ACGIH

Reference values: No reference values (RfDs/RfCs, TDIs, TIs, MRLs) have been established for second-generation anticoagulants

Risk/safety phrases: End-use pesticide formulations of second-generation anticoagulants generally carry the signal word “Caution”

BACKGROUND AND USES

The second-generation anticoagulant rodenticides were developed after the emergence of resistance to first-generation anticoagulants and were observed in certain rodent species. The second-generation anticoagulants can be distinguished from the first-generation rodenticides by their higher degree of toxicological potency, and the ability to cause lethal effects from a single ingestion. Lethal effects on nontarget species, including birds and other wildlife, have been frequently reported in association with second-generation anticoagulant rodenticides (Sánchez-Barbudo et al., 2012).

Brodifacoum was first registered for use in 1979 by the US EPA. It is a rodent control agent for use against rats and mice. It is formulated as a bait in pellet formulations, in mouse bait

ready-to-use packets, and paraffin blocks. End-use products contain 0.005% brodifacoum.

Bromadiolone was first registered for use in 1980 by the US EPA. It is a rodent control agent for mice and rats in buildings, inside transport vehicles, and in sewers. It is formulated as a meal bait, in pellet formulations, in mouse bait ready-to-use packets, and paraffin blocks. End-use products contain 0.005% bromadiolone.

Difenacoum was first registered by the US EPA in 1975. It is formulated as concentrate containing 1 g/kg, and as a ready-to-use bait containing 50 mg difenacoum per kg of bait.

Difethialone was first registered for use by the US EPA in 1995. It is formulated as ready-to-use whole grain cereals and oat grain baits containing 0.0025% difethialone.

At the current time, the U.S. EPA is in the process of banning the sale of certain consumer use products containing second-generation anticoagulant rodenticides. In addition, the EPA has recently prohibited the sale of consumer products containing brodifacoum, difethialone, and difenacoum because of their toxicity to wildlife. The US EPA website should be accessed for current information about the regulatory status of products containing second-generation rodenticides.

PHYSICAL AND CHEMICAL PROPERTIES

The chemical name for brodifacoum (CAS # 56073-10-0) is 3-[3-(4'-bromo[1,1'biphenyl]-4-yl)-1,2,3,4-tetrahydro-1-naphthalenyl]-4-hydroxy-2H-1-benzopyran-2-one. It has the empirical formula C₃₂H₂₃BrO₃, and a molecular weight of 523.4. It is an odorless powder with a melting point of 228–232 °C.

The chemical name for bromadiolone is 3-[3-(4'-bromo[1,1'biphenyl]-4-yl)-3-hydroxy-1-phenylpropyl]-4-hydroxy-2H-1-benzopyran-2-one. It has the empirical formula C₃₀H₂₃BrO₄, and a molecular weight of 527.4. It is a yellowish powdered mixture of two diastereoisomers, with a melting point of 200–210 °C.

The chemical name for difenacoum is 3-[3-(1,1'biphenyl)-4-yl]-1,2,3,4-tetrahydro-1-naphthalenyl]-4-hydroxy-2H-1-benzopyran-2-one. It has the empirical formula C₃₁H₂₄O₃, and a molecular weight of 444.5. It is a white powder with a melting point of 215–219 °C.

The chemical name for difethialone is 3-[3-(4'-bromo[1,1'biphenyl]-4-yl)-1,2,3,4-tetrahydro-1-naphthalenyl]-4-hydroxy-2H-1-[benzothiopyran-2-one]. It has the empirical formula C₃₁H₂₃BrO₂S, and a molecular weight of 539.5. It is a whitish powder with a melting point of 233–236 °C.

MAMMALIAN TOXICOLOGY

Acute Effects

The acute toxicological effects of the second-generation anticoagulants are similar to those observed from the

first-generation anticoagulants. The distinctions include a higher degree of potency, and a much longer duration of effects for the second-generation anticoagulants. These distinctions arise from the higher degree of lipid solubility, and ability to concentrate within the target organ tissue of the liver (Lund, 1981). Comparative studies in target species have demonstrated the ability of second-generation anticoagulants to produce coagulopathy with a single ingestion of brodifacoum (0.005% active ingredient).

There is a characteristic delay of 24–72 h between the ingestion of a second-generation anticoagulant and the onset of bleeding. Generalized hematoma formation, pallor, and weakness, are common manifestations in acute intoxication. Fatal outcomes often result from bleeding in the central nervous system. Most cases of intoxication by second-generation anticoagulants result from ingestion pathways of exposure; however, a case report described significant coagulopathy resulting from smoking marijuana that had been mixed with brodifacoum (La Rosa et al., 1997). Another case report has described coagulopathy from dermal exposure to a concentrated liquid preparation of 0.106% diphacinone in a professional applicator (Spiller et al., 2003).

The oral LD₅₀ of technical brodifacoum in male rats is 0.418 mg/kg. The dermal LD₅₀ in female rabbits is 3.16 mg/kg, and the inhalation LC₅₀ in rats ranges from 3.05 to 4.86 µg/l (United States Environmental Protection Agency, 1998). Brodifacoum is not considered as a dermal sensitizer, and some minor transient eye and skin irritation have been reported.

The oral LD₅₀ of technical bromadiolone in rats is 0.56–0.84 mg/kg. The dermal LD₅₀ in rabbits is 1.71 mg/kg. The inhalation LC₅₀ in rats is <0.43 µg/l. Bromadiolone is not a dermal sensitizer, and minimal eye and dermal irritation have been reported (United States Environmental Protection Agency, 1998). The oral LD₅₀ of difenacoum in rats is 1.8 mg/kg in male rats, and 50 mg/kg in female guinea pigs. The dermal LD₅₀ is 50 mg/kg in rats and 1000 mg/kg in rabbits (Pelfrene, 2001).

The oral LD₅₀ of difethialone in rats is 0.56 mg/kg in male rats, 1.29 mg/kg for mice, and 2–3 mg/kg for pigs. The dermal LD₅₀ is 5.3 mg/kg in rats. The inhalation LC₅₀ in rats is between 5 and 19.3 mg/m³ in rats exposed for 4 h. Difethialone is not considered a skin sensitizer (Pelfrene, 2001).

Chronic Effects

In a 90-day study of orally administered bromadiolone in beagle dogs, the low observed effect level (LOEL) for subchronic toxicity (coagulopathy) was 15 µg/kg, and the NOEL was 10 µg/kg (United States Environmental Protection Agency, 1998).

Mechanism of Action(s)

The second-generation anticoagulant rodenticides exert their anticoagulant activity through the inhibition of vitamin K-dependent carboxylation of clotting factors II, VII, IX, and X, as well as the anticoagulant proteins C and S. Specifically, they inhibit the enzyme K₁ 2,-epoxide reductase complex, subunit 1 (VKORC1) (Park, 1988 #14612). Inhibition of VKORC1 prevents the conversion of vitamin K epoxide to the biologically active vitamin K hydroquinone, which carboxylates and activates these clotting factors. The higher degree of potency of the second-generation anticoagulants may partly reflect their ability to saturate hepatic detoxification enzymes at very low concentrations, as demonstrated by zero-order elimination kinetics following overexposure (Bruno et al., 2000).

After exposure to second-generation anticoagulants, the activity of clotting factors with shorter half-lives (including factor VII) is inhibited within 12–24 h. The full anticoagulant effect is not observed until 5–7 days after initial exposure because of the longer half-lives of clotting factors X and II.

Chemical Pathology

Pathological findings at autopsy in animals and humans poisoned by first-generation anticoagulants include pallor of the muscles and viscera, and generalized hemorrhage.

SOURCES OF EXPOSURE

At the current time in the United States, second generation rodenticides may be found in bait stations for consumer-use products. The US EPA has recently announced plans to cancel these uses. Second-generation anticoagulants are also currently approved for use in bait products for agricultural and professional applicator uses in indoor and outdoor settings.

INDUSTRIAL HYGIENE

Occupational exposure guidelines and limits have not been established for second-generation anticoagulant rodenticides.

MEDICAL MANAGEMENT

As a result of the high incidence of accidental human exposures to long-acting anticoagulant rodenticides, most commonly in the pediatric population, evidence-based

consensus guidelines have been established for the out-of-hospital management of ingestions (Caravati et al., 2007). Most accidental pediatric ingestions result in small doses that do not result in coagulopathy. Consultation with a Regional Poison Control Center is recommended for the triage and medical management of all exposures to second-generation anticoagulants.

Intentional ingestion of these rodenticides can result in delayed onset of bleeding. For individuals presenting within several hours of intentional ingestion, a single dose of activated charcoal should be considered for gastric decontamination. The clinical laboratory assessment of individuals at risk of coagulopathy from first-generation anticoagulants should include a prothrombin time (PT-INR) at 48 h after the time of ingestion (Smolinske et al., 1989). A careful physical examination should be conducted to assess for evidence of bruising and bleeding. Life threatening hemorrhage should be managed with the infusion of fresh frozen plasma, which is rich in active vitamin K-dependent coagulation factors and will temporarily reverse coagulopathy in most patients (Cruickshank et al., 2001).

The specific antidote for coagulopathy resulting from exposure to first-generation anticoagulants is vitamin K₁. It is effective orally and via intravenous or intramuscular administration. Repeated, large doses of vitamin K₁ (up to or >60 mg/day) may be required in some cases. In contrast to first-generation anticoagulants, the duration of coagulopathy from second-generation anticoagulants can last from weeks to months (Jones et al., 1984; Spahr et al., 2007). Careful monitoring of coagulation status and high doses of vitamin K₁ are required until the coagulopathy resolves.

NON-ANTICOAGULANTS

BROMETHALIN

Target organ(s): Central nervous system

Occupational exposure limits: No occupational exposure guidelines limits have been established by OSHA, NIOSH, or ACGIH.

Reference values: No reference values (RfDs/RfCs, TDIs, TIs, MRLs) have been established for second-generation anticoagulants

Risk/safety phrases: End-use pesticide formulations containing bromethalin generally carry the signal word “Caution”

BACKGROUND AND USES

Bromethalin is an uncoupler of oxidative phosphorylation, and available in the United States since 1985 as a rodenticide. It is registered for use in and around buildings, inside transport vehicles, and in sewers to control rats and mice. It is a single-dose poison, formulated in blocks, baits, or pellets. All registered products contain 0.01% bromethalin, with the exception of one formulation containing 0.005% active ingredient.

PHYSICAL AND CHEMICAL PROPERTIES

The chemical name for bromethalin (CAS # 63333-35-7) is N-Methyl-2,4-dinitro-N(2,4,5-tribromophenyl)-6(trifluoromethyl)benzenamine. It has the empirical formula $\text{Cl}_3\text{H}_7\text{Br}_3\text{F}_3\text{N}_3\text{O}$, and a molecular weight of 577.93. It is white crystal with a melting point of 148–154 °C.

MAMMALIAN TOXICOLOGY

Acute Effects

The acute toxic effects target the central nervous system, and differences in toxic syndromes susceptibility have been observed in different animal species. A convulsant syndrome, characterized by tremors, seizures, CNS, and hyperthermia, has been described at higher doses within 4–18 h after ingestion. A paralytic syndrome has also been described, with a slower onset of toxicity ranging from 1 to 7 days, and consisting of ataxia, CNS depression, weakness, and progression to paralysis. Other acute effects that have been reported in animals include anorexia, positional nystagmus, muscle tremors, and abnormal pupillary light reflexes. (DeClementi and Sobczak, 2012).

The oral LD₅₀ of technical bromethalin in rats is 9.1–10.7 mg/kg. The dermal LD₅₀ in rabbits is 2000 mg/kg, and the inhalation LC₅₀ in rats is 0.24 mg/l. In an acute neurotoxicity study conducted in rats receiving bromethalin in mineral oil via gavage, the NOEL was >3 mg/kg. Bromethalin is not considered a skin sensitizer or skin irritant, but slight eye irritation has been reported (United States Environmental Protection Agency).

Chronic Effects

In a 13 week study of subchronic bromethalin toxicity in rats, the NOEL is 25 µg/kg/day, and the LOEL is 125 µg/kg/day, based upon findings of leukoencephalopathy in the central nervous system (United States Environmental Protection Agency, 1998).

Mechanism of Action(s)

Bromethalin is a neurotoxin that uncouples oxidative phosphorylation, leading to decreased production of ATP and failure of the sodium–potassium ATPase. Bromethalin has high oral bioavailability, and peak levels in plasma are observed within 4 h. Its immediate metabolite, desmethyl bromethalin, has higher neurotoxic potency than the parent compound (Van Lier and Cherry, 1988).

Chemical Pathology

Pathological findings at autopsy or necropsy include generalized spongy degeneration and edema of the white matter,

spinal cord, and optic nerve (Van Lier and Cherry, 1988; DeClementi and Sobczak, 2012).

SOURCES OF EXPOSURE

At the current time in the United States, bromethalin can be found in consumer-use bait products, as well as rodenticide products for agricultural and professional applicator use.

INDUSTRIAL HYGIENE

Occupational exposure guidelines and limits have not been established for bromethalin.

MEDICAL MANAGEMENT

Relatively few case reports of human poisoning from bromethalin have been published, and no evidence-based guidelines exist for the medical management of intoxication. Symptomatic and supportive management are recommended, including monitoring for adverse effects in the central nervous system and aggressive treatment with benzodiazepines if seizures develop. The potential for delayed onset of serious neurological complications should be considered.

NON-ANTICOAGULANTS

CHOLECALCIFEROL

Target organ(s): Kidneys, bones

Occupational exposure limits: No occupational exposure guidelines limits have been established by OSHA, NIOSH, or ACGIH

Reference values: A tolerable upper limit of 50 µg vitamin D/day for adults has been suggested by authorities in North American and the European Union

Risk/safety phrases: End-use pesticide formulations containing cholecalciferol generally carry the signal word "Caution" or "Warning"

BACKGROUND AND USES

Cholecalciferol (vitamin D-3) was first registered in the United States for use as a multiple-dose rodenticide in 1984. It is currently registered for consumer-use products, and it also has agricultural and professional applicator uses in and around buildings, and inside transport vehicles. It is typically formulated for use in bait formulations. There is typically a delay of several days between ingestion and the onset of toxic and lethal effects in target species.

PHYSICAL AND CHEMICAL PROPERTIES

The chemical name for cholecalciferol (CAS # 67-97-0) is 9,10-secocholesta-5,7,10(10)-trien-3-betaol. It has the empirical formula C₂₇H₄₄O and a molecular weight of 384.62. It has a melting point of 84–86 °C.

MAMMALIAN TOXICOLOGY

Acute Effects

Rats and mice are more susceptible to the effects of cholecalciferol than humans, and to date, cases of serious human toxicity from exposure to this rodenticide have not been reported. The metabolites of cholecalciferol cause acute toxicity by increasing serum calcium and phosphorus. The metabolites increase intestinal absorption of calcium, and stimulate mobilization of calcium and phosphorus from bones into the plasma. The effects of these electrolyte imbalances result in renal injury from tissue mineralization in the kidneys, and other signs and symptoms associated with severe hypercalcemia, including vomiting, polyuria, and polydipsia. The acute effects of cholecalciferol intoxication generally occur within 12–36 h after ingestion (DeClementi and Sobczak, 2012).

The acute oral LD₅₀ of cholecalciferol in rats is 43.6 mg/kg. In dogs, the oral LD₅₀ is 88 mg/kg. Some authors have reported fatal outcomes from ingestions of 10–20 mg/kg in rats at 9.1–10.7 mg/kg (Pelfrene, 2001).

Chronic Effects

In a 4-month study of daily doses ranging from 100 to 4000 IU cholecalciferol/kg of feed in swine, atherosclerotic

lesions were observed in a dose-dependent fashion (Toda et al., 1985).

Mechanism of Action(s)

Cholecalciferol is metabolized in the liver to 25-hydroxycholecalciferol. This metabolite is subsequently metabolized by the kidney into the active metabolite 1,25-dihydroxycholecalciferol, which is responsible for the intestinal absorption of calcium and mobilization from bone tissues (Morrow, 2001). This produces hypercalcemia, osteomalacia, and calcification of tissues in the kidneys, cardiovascular system, stomach, and lungs. Death usually occurs in 2–5 days.

Chemical Pathology

Pathological findings in cases of cholecalciferol poisoning in animals include soft tissue mineralization within the kidneys, heart, GI tract, skeletal muscles, and connective tissues. Within the lungs, alveolar septal thickening has been observed, with mineralization and hemorrhage (DeClementi and Sobczak, 2012).

SOURCES OF EXPOSURE

At the current time in the United States, cholecalciferol can be found in consumer-use bait products, as well as rodenticide products for agricultural and professional applicator use. Cholecalciferol also has human uses in vitamins and dietary supplements, as the natural form of vitamin D.

INDUSTRIAL HYGIENE

Occupational exposure guidelines and limits have not been established for cholecalciferol.

MEDICAL MANAGEMENT

No reports of human poisoning from the use of cholecalciferol as a rodenticide have been published, and no evidence-based guidelines exist for the medical management of intoxication.

Veterinary treatment of acute toxicity consists of preventing and treating the hypercalcemia by aggressive hydration, the administration of loop diuretics, and glucocorticoids. In more serious intoxications, medications that inhibit bone resorption such as pamidronate have been utilized. Careful

monitoring of serum calcium, phosphorus, BUN, and creatinine are warranted in the veterinary management of intoxication (Morrow, 2001).

SECTION VII

DUSTS AND FIBERS

SECTION EDITOR: RAYMOND D. HARBISON

INTRODUCTION

DAVID R. JOHNSON

Dusts are dispersed solid airborne particles, capable of temporary suspension in a gaseous medium, and often produced by the breakup of larger organic or inorganic materials. Dusts are frequently generated in occupational environments and are often complex mixtures of a variety of substances and contaminants. Workers are exposed to these dusts principally by inhalation but also by direct contact with skin or conjunctiva.

Once the dust is inhaled, characteristics of particles in the dust determine where and how much of the particle is deposited in the respiratory tract. Such particulate characteristics include size, shape, diameter, aerodynamic equivalent, surface area, density, electrostatic charge and hygroscopicity (Gross, 1981; Timbrell, 1965; Brain and Valberg, 1979; Beckett, 2000; Maxim et al., 2006). Based on such characteristics, dust particles are deposited in the nose, mouth, throat, trachea, bronchi, and alveoli or promptly exhaled.

Host characteristics also affect particle deposition. Such host characteristics include physiological and anatomical factors of the respiratory system, such as breathing patterns and airway geometry (Beckett, 2000). The location and amount of deposition of various respirable particles in the respiratory tract has been subjected to considerable experimental study in humans, and statistical analysis has allowed probability calculations of the location and quantity of particle deposition (Yu, Diu, Soong, 1981; Chen, 2003; Heyder, 2004; Straum and Hofmann, 2009; Sturm, 2011).

Once deposited in the respiratory tract, factors that influence the ability of dust particles to cause disease include particle fibrogenicity, antigenicity, toxicity, propensity to combine with lung tissues, penetrability, durability, solubility, acidity, and alkalinity. Host factors influencing the particle's ability to cause disease include the individual's

respiratory tract clearing mechanisms such as ciliary action and macrophage function. Host susceptibility is influenced by the individual's health status, immunologic status, nutritional status, age, and personal habits such as smoking, medications, drug use, and alcohol use.

Typical examples of dust-induced disease include dermatitis, rhinitis, conjunctivitis, urticaria, bronchitis, bronchoconstrictive disease (asthma), pneumoconiosis, hypersensitivity pneumonitis (extrinsic allergic alveolitis), interstitial lung disease, emphysema, granulomatous disease, and cancer. The greater the intensity and duration of exposure to dust, the greater is the risk of developing an acute or chronic disease.

Pneumoconioses refers to mineral dust-induced lung disease characterized by the permanent deposition of particulate matter in the lung, which may cause tissue reactions. This term is derived from the Latin *pneumono* (lung) and *cono* (dust) and has a terminal ending that denotes reaction to dust in the lung. A group of cases associated with the inhalation of a single or predominant etiological dust is referred to as pneumoconiosis. Coal workers pneumoconiosis, silicosis, asbestosis, baritosis, and siderosis are examples of pneumoconioses. Asbestos and silica are well-known examples of dusts that have fibrogenic properties. Asbestosis has been clearly associated with progression to cancer, including mesothelioma and bronchogenic carcinoma. If the dust elicits no inflammatory reaction in the lung, it is referred to as a benign pneumoconiosis, such as stannosis arising in tin mining. In benign pneumoconiosis, there may be striking radiologic findings with no significant pulmonary pathology. Many dusty operations involve an exposure to a mixture of dusts that leads to chronic lung illness. The term *mixed dust pneumoconioses* is best used for this category and often

involves silica mixed with other types of dusts. Some authors use a diagnostic label to identify the dust in terms of the offending agents, for example, anthracosilicosis for the disease of underground coal miners inhaling both coal and silica.

Man-made mineral fibers, also called man-made vitreous fibers (MMVF), are amorphous silicates that include fibrous glass, mineral wool, refractory ceramic fibers, and alkaline earth silicate wool. They can generate irritating dusts if not handled properly; however, no consistent epidemiological findings have found them to be fibrogenic or carcinogenic to humans. They have been associated with respiratory irritation. Fiberglass dermatitis is one of the most common forms of irritant occupational dermatitis.

Organic dusts are composed of particulates of plants, animal, and/or microorganisms and often include complex mixtures of substances. Exposure occurs in a wide range of occupations and is commonly associated with bronchoconstrictive disease, asthma, and hypersensitivity pneumonitis. rhinitis, conjunctivitis, and bronchitis are also common. Mechanisms are often not clearly delineated and may involve immunological, pharmacological or genetic mechanisms, as well as airway and neurogenic inflammation (Mapp et al., 1994). A few wood dusts have been associated with nasal cancer.

Traditionally, the focus has been on occupational lung disease caused by an exposure to mineral dusts such as asbestos, silica, and coal. However, the incidence of diseases caused by mineral dusts has declined in postindustrial countries, and asthma has emerged as the principal occupational lung disease with new substances capable of inducing asthma being introduced into the workplace every year (Beckett, 2000).

Governmental regulations vary from one country to another in setting standards for acceptable dust exposure in industry. Different companies within the same industry may voluntarily implement various levels of industrial hygiene measures resulting in different levels of dust exposure and therefore different prevalence rates of disease. Environmental conditions may also vary within the same facility. The composition of dusts are often complex and will vary considerably in various settings. With all of these variables at play, and with often limited information about the exact amount of dust capable of causing disease, linking a respiratory disease to occupational exposures can be quite challenging.

Ongoing research using a variety of modern investigative tools, including bronchoalveolar lavage, gallium-67 scanning,

bioassays, diagnostic imaging, and air monitoring technology have improved our understanding of the associations and mechanisms of lung disease; however, much more research is needed. Increasingly, sophisticated instrumentation, international use of recommended safe levels of exposure, improved engineering of industrial processes, medical monitoring, and personal protective equipment are rapidly contributing to the prevention of the debilitating cases of occupational lung diseases that were seen in the past.

Medical management of dust-induced respiratory disease should always involve efforts to identify the offending agent with elimination or minimization of exposure to that agent. Preventing exposure from the outset is best.

BENIGN DUSTS (NUISANCE DUSTS)

HUMAIRAT H. RAHMAN AND RAYMOND D. HARBISON

BACKGROUND

Tiny solid particles formed by disintegration processes such as crushing, grinding, polishing, sanding, or impact constitute nuisance dusts. This dust may cause non-fibrogenic pneumoconiosis. When inhaled in excessive amounts chest X-rays may present with a radio opaque appearance. Nuisance dust or inert dust contains <1% quartz. Nuisance dust may produce little adverse effects on the lungs over long periods of time because of its low silica content but excessive concentrations due to intense short-term exposure may deposit in eyes, ears, and nasal passages. This may lead to decreased visibility and can cause injury to the skin or mucus membranes by chemical or mechanical action. This may also result in damage by overwhelming the lymphatic drainage, by obstructing the anatomy of terminal bronchioles to cause infarction, necrosis, bronchiectasis, and atelectasis. Nuisance dust can be classified in three categories depending upon size. These categories are respirable dust, inhalable dust, or total dust. Nuisance dust particle size is generally measured in micrometers. Occupational Safety and Health Administration (OSHA) has categorized nuisance dust or benign dust as either inorganic or organic, with <1% of quartz, and dust that does not contain asbestos, as particulates not otherwise regulated.

BARIUM

BACKGROUND

Barium is an earth metal that is alkaline in nature. Elemental barium is a silver-white metal and constitutes nearly 0.05%

of the earth's crust. Barium sulfate and barium carbonate are the two most common forms of barium. Barium compounds have a wide variety of uses in industry, including brick, ceramic, rubber, glass, and painting industries. It is used in the manufacture of paper electrodes, in fireworks, and as contrast medium in diagnostic X-ray studies. Oil and gas industries use barium as a lubricant for mud drilling.

PHYSICAL AND CHEMICAL PROPERTIES

Insoluble barium sulfate is an odorless powder compound, yellowish or white in color. It is solid and noncombustible in nature. The molecular weight, specific gravity, and boiling point of barium sulfate are 233.4, 4.25–4.5, and 2912 °F, respectively.

EXPOSURE ROUTES AND MAMMALIAN TOXICOLOGY

Workers can be exposed to barium sulfate from withering of mineral and rock and from processes such as welding (Dare et al., 1984). Exposure to barium sulfate can occur through inhalation and skin and/or eye contact.

Inhalation of barium sulfate dust may cause irritation of nose, eyes, and throat. Barium-containing dust after long and intense exposure may form bilateral lung infiltrates. This harmless condition results in a benign pneumoconiosis known as baritosis. Various case reports and studies have reported baritosis in barium-exposed workers. Baritosis is characterized by dense, circumscribed nodules profusely disseminated throughout the lung fields, though available

human data suggest that baritosis is without clinical significance with limited symptoms or disability. Exposure to barium sulfate may produce non-collagenous type of pneumoconiosis that generally disappears when exposure ceases. Chronic exposure to barium sulfate may lead to bronchial irritation.

INDUSTRIAL HYGIENE

The current OSHA's permissible exposure limit (PEL) is 15 mg/m³ of air (total dust) and 5 mg/m³ respirable fraction 8-h time-weighted average (TWA) concentration. The National Institute for Occupational Safety and Health (NIOSH) has established a recommended exposure limit (REL) of 10 mg/m³ of air (total dust) and 5 mg/m³ respirable fraction 8-h TWA concentration. The American Conference of Industrial Hygienists's (ACGIH) threshold limit value (TLV) for barium sulfate is 10 mg/m³ for total dust, containing no asbestos and <1% silica.

TIN

BACKGROUND

Tin is found in powder form and is white or pale-grey in color. Tin oxide is the most common compound of tin. Tin mining has been ongoing for 3000 years (Cierny and Weisgerber, 2003). Tin oxide is brownish-black powder. Tin oxide is insoluble in water with a specific gravity and molecular weight of 6.3 and 134.7, respectively.

EXPOSURE ROUTES AND MAMMALIAN TOXICOLOGY

Exposure to tin oxide can occur due to inhalation of tin oxide dust or fumes in a work place. Exposure to tin oxide can cause irritation of eyes and skin. Inhalation of dust or fumes may lead to deposition in the lungs. This may lead to stannosis, a benign pneumoconiosis (Sluis-Cremer et al., 1989). Grinding, briquet making, smelting, and casting of tin, as well as handling of tin oxide in industry may cause stannosis (Karkhanis and Joshi, 2013). Occupational stannosis in non-mining industries may occur when molten tin is poured into heated iron hollow ware or when articles are dipped by hand into molten tin to coat them. Inhalation of tin oxide dust or fumes may cause difficulty in breathing or may result in decreased pulmonary function. The chest X-ray may show dense, bilateral infiltrates but without any tissue reaction to deposition of dust. This condition results in

non-fibrotic pneumoconiosis. Laboratory tests showed that tin oxide engulfed by macrophages is present in alveolar space, intralobular hilar nodes, and the perivascular lymphatic system. Pathologically, cut surface of lung may contain 1–3 mm of tin oxide particles that are grayish-black in color and are spongy to touch (Yilmaz et al., 2009).

INDUSTRIAL HYGIENE

The current OSHA PEL is 15 mg/m³ of air (total dust). The NIOSH has established a REL of 2 mg/m³ TWA. The ACGIH TLV for tin oxide is 2 mg/m³ for total dust.

IRON

BACKGROUND

The oxide form of iron, iron oxide, is a major source of iron dust or fumes. The main use of iron oxide is in the steel industry where processes such as welding and silver finishing results in the production of iron oxide dust or fumes. Iron oxide is reddish-brown in color and solid in nature. Molecular weight, specific gravity, and melting point of iron oxide are 159.7, 5.25, and 2664 °F, respectively.

EXPOSURE ROUTES AND MAMMALIAN TOXICOLOGY

Inhalation is the major route of exposure to iron oxide fume or dust. A study on human volunteers who were exposed to iron oxide for 30 min at a standard concentration of nearly 13 mg/m³ showed no significant reduction in lung function, permeability of alveolar epithelium, or diffusing capacity of lung (Lay et al., 2001). Human volunteers presenting with subclinical inflammation due to acute deposition of intra-pulmonary ferric oxide showed resolution of symptoms after 96 h (Lay et al., 1998). Exposure to iron oxide fume or dust may lead to siderosis in workers. Siderosis is also known as arc welder pneumoconiosis or welder siderosis (Kleinfeld et al., 1969). In 1936, siderosis was first described in welder workers exposed to iron oxide (Doherty et al., 2004; Doig and Laughlin, 1936). Siderosis is considered as a benign condition because it is not associated with fibrosis or abnormal pulmonary function tests (Chong et al., 2006). When iron is mixed with certain amounts of silica, it can cause silico-siderosis. Silico-siderosis is a pathological condition and requires medical monitoring (Billings and Howard, 1993). Workers with siderosis can reverse symptoms after they are removed from the exposure area, by elimination of iron dust from lungs in a few years (Kim et al., 2001).

In a study of 25 workers exposed to iron oxide, eight workers presented reticulo nodular patterns on chest X-ray (Harding et al., 1958). In another study the lung function tests of 16 welders were abnormal with chest X-ray demonstrating siderosis (Stanescu et al., 1967). The welders complained of dyspnea though their spirogram was normal. After removal from exposure, iron dust is gradually eliminated from lungs resulting in partial or complete disappearance of radiographic appearance of lung opacities.

INDUSTRIAL HYGIENE

The current OSHA PEL is 10 mg/m³ of air. The NIOSH has established a REL of 5 mg/m³ of air. The ACGIH TLV-TWA for iron oxide dust and fume is 5 mg/m³.

PERLITE

BACKGROUND

Expanded perlite is an amorphous material consisting of fused sodium potassium aluminum silicate. Perlite is volcanic rock and needs to be heated up to 1000 °C to form expanded perlite. Expanded perlite is used as a conditioner for soil, packing material, construction insulator for floors, walls, and as a filter aid in agriculture processes. Perlite is categorized as one of the nuisance or benign dust that does not cause pneumoconiosis (Sampatakakis et al., 2013; Du et al., 2010).

EXPOSURE ROUTES AND MAMMALIAN TOXICOLOGY

Inhalation, skin, and/or eye contact are the common routes of exposure to expanded perlite. Exposure to perlite dust may lead to irritation of eyes, skin, or upper respiratory tract. A study in Taiwan of 24 workers exposed to expanded perlite due to an accidental explosion resulted in irritation of the respiratory tract within 24–48 h. The follow-up study showed that three subjects developed reactive airway dysfunction syndrome (Du et al., 2010). However a follow-up of perlite workers for 23 years showed no decreased pulmonary function tests (Cooper and Sargent, 1986).

INDUSTRIAL HYGIENE

The current OSHA PEL for expanded perlite is 15 mg/m³ of air (total dust) and 5 mg/m³ respirable fraction as 8-h TWA

concentration. The NIOSH has established a REL of 10 mg/m³ of air (total dust) and 5 mg/m³.

CARBON BLACK

BACKGROUND

Carbon Black is a spherical form of pure carbon particles and is produced by the incomplete combustion or thermal decomposition of liquid or gaseous hydrocarbons. Carbon black is used in rubber, plastic, paper, fiber, and the electrical industry. It is also used as a reinforcing agent and as a pigment in the printing and paint industry.

PHYSICAL AND CHEMICAL PROPERTIES

Carbon black contains nearly 95% of pure carbon along with 4–5% of nitrogen, hydrogen, sulfur, and oxygen. Carbon black is a combustible, odorless solid particle and is black in color. It is a strong oxidizer, insoluble in water with molecular weight of 12 and specific gravity of 1.8–2.1 (Brockmann et al., 1998).

EXPOSURE ROUTES AND MAMMALIAN TOXICOLOGY

The common routes of exposures to carbon black are inhalation, ingestion, or dermal contact. Accidental exposure to carbon black can cause difficulty in breathing, eye, and dermal irritation. Carbon black inhalation can cause respiratory symptoms such as cough, phlegm, and chest pain. Dermal exposure can cause skin irritation. In a study of 125 Nigerian workers exposed to carbon black abnormal pulmonary symptoms, including cough with phlegm were observed though the X-ray findings were normal (Oleru et al., 1983). Chronic exposure to carbon black may result in abnormal pulmonary function and myocardial dystrophy. However, a study of 913 workers exposed to carbon black demonstrated no pulmonary function effects on spirometry (Robertson et al., 1988). In one retrospective cohort study, no significant increase in cardiac abnormality and mortality due to cardiac disease was observed in workers employed in carbon black plants. Three studies of female rats exposed to carbon black found significant increase of malignant lung tumors, though there is inadequate and inconsistent evidence to assign carcinogenicity to humans (Brockmann et al., 1998).

A study was conducted on 3027 workers that were exposed to carbon black in the United States and Europe and evaluated using pulmonary function tests, chest X-ray,

and questionnaires to examine respiratory health. Among the group only six cases showed benign pneumoconiosis among those who had nearly 10 years of carbon black exposure. In addition, this study observed decreased pulmonary function in the cases that had a history of smoking (Crosbie, 1986).

INDUSTRIAL HYGIENE

The current OSHA PEL for carbon black is 3.5 mg/m³ of air. The NIOSH has established a REL of 3.5 mg/m³. The ACGIH TLV-TWA for carbon black is 3.5 mg/m³.

MANAGEMENT OF NUISANCE DUSTS

Exposure scenarios need to be identified to evaluate and keep exposures below acceptable levels. Other measures like wet operations and appropriate ventilation can be employed. Adequate housekeeping needs to be maintained to remove nuisance dust and reduce exposure levels. Irrigation of eyes and cleaning of skin with soap and water is advisable along with respiratory support to anyone who is exposed to excessive amounts. Contact with eyes and skin should also be prevented by using appropriate personal protective equipment. Ensure fresh air by removing workers from the exposure source as well as use first aid procedures if required. For management of pneumoconiosis, further follow-up may be needed.

If excessive absorption occurs from inhalational exposure, further management is necessary to rule out other causes of complaints. Laboratory investigation of blood chemistry, respiratory function tests, and chest X-ray may be used. Workers complaining of respiratory symptoms who were exposed to benign dust for long periods should be followed up to rule out any pathological conditions. Regular monitoring and follow-up of excessively exposed individuals may be necessary for further management.

FIBROGENIC DUSTS

CHARLES BARTON

ASBESTOS

First aid: Remove the patient from exposure. If on the body, wash the contaminated body part with copious amounts of soap and water. If the eyes are exposed, immediately irrigate the affected eye thoroughly with water or 0.9% saline. Provide treatment for any symptoms that may arise.

Target organ(s): Respiratory system, eyes

Occupational exposure limits: OSHA PEL—0.1 fiber/cm³ TWA; NIOSH REL—0.1 fiber/cm³ for fibers >5 µm; ACGIH TLV—0.1 fiber/cm³ TWA (respirable fibers)

Reference values: EPA MCL—7 million fibers per liter of water (MFL)

Hazard/precautionary phrases: H350 may cause cancer; H372 causes damage to organs through prolonged or repeated exposure

BACKGROUND AND USES

The term asbestos (CAS # 1332-21-4) refers to a group of six naturally occurring fibrous minerals that have been widely used in commercial products and are divided into two groups, serpentine and amphibole. Chrysotile (white asbestos; CAS #12001-29-5) is the only member of the serpentine group; amosite (brown asbestos; CAS #12172-73-5), crocidolite (blue asbestos; CAS #12001-28-4), anthophyllite (CAS #17068-78-9), actinolite (CAS #13768-00-8), and tremolite (CAS #14567-73-8) comprise the amphibole group. Amphiboles are thin, straight fibers; whereas, serpentine

(chrysotile) fibers are curly or coiled. All forms of asbestos are composed of silicate (SiO_4) groups and are essentially chemically inert.

It should be noted that serpentine and amphibole minerals also occur in nonfibrous or nonasbestiform forms. These nonfibrous minerals, which are not asbestos, are much more common and widespread than the asbestiform varieties. Non-asbestiform forms are considered to have less bioreactivity and cytotoxicity than asbestiform fibers. Moreover, they are generally considered to be nonpathogenic (Mossman, 2008).

Once highly prized for its flame-retardant properties and use in countless commercial products, asbestos has become a global concern with significant economic consequences (Sly et al., 2010). Until the 1970s, asbestos was widely used in the construction, shipbuilding, and automotive industries, among others. For example, asbestos was formerly used in the following items: boilers and heating vessels; cement pipes; clutch, brake, and transmission components; conduits for electrical wiring; corrosive chemical containers; electric motor components; heat-protective pads; laboratory furniture; paper products; pipe covering; roofing products; sealants and coatings; insulation products; and textiles (including curtains). These materials remain in many buildings, ships, and automobiles built before 1975 (Seidman and Selikoff, 1990).

Asbestos was widely used commercially until the 1970s, when health concerns led to some uses being banned and some voluntary phase outs (Seidman and Selikoff, 1990). Mining and milling of the raw material and production of asbestos has declined since the early 1970s, but asbestos is still used in some construction materials. Some asbestos-containing products, such as amphibole-contaminated vermiculite insulation, remain in many homes in the United

States. Asbestos fibers are released into the air and dust when asbestos-containing materials are loose, crumbling, or disturbed.

Today, most asbestos used in the United States is imported. Commercial-grade asbestos is made up of fiber bundles. These bundles, in turn, are composed of extremely long and thin fibers, often with splayed ends, which can easily be separated from one another. Asbestos is still used in brake pads, automobile clutches, roofing materials, vinyl tile, imported cement pipe, and corrugated sheeting (American Thoracic Society, 2004).

In the United States some past estimates of lung cancer attributable to asbestos exposure have been reported (Churg, 1983). The estimate of 5000—10,000 cases annually has not been verified. Similar estimates have come from other countries. In Norway, asbestos has been estimated to account for about two-thirds of work-related lung cancer (Langård, 1994). In the former East Germany, asbestos has been estimated from a 1988 analysis to be responsible for the majority of occupationally induced cancer (Sturm et al., 1994). Recently, the trend in worldwide asbestos use has shifted from established industrialized nations to developing nations (Delgermaa et al., 2011; Levy and Seplow, 1992). There is concern among occupational medicine practitioners that asbestos-related diseases are being “exported” to nations that may not have sufficient industrial hygiene experience or regulatory power to prevent them.

The majority of health effects associated with asbestos are of occupational origin. In addition to being at risk of exposure from the commercial uses of asbestos, people in some areas of the world are at risk because of geological deposits of asbestos near the surface that release asbestos if disturbed. For example, there have been reports of asbestos and lung cancer in areas such as Turkey where there are large mineral deposits of tremolite asbestos (Metintas et al., 2012).

PHYSICAL AND CHEMICAL PROPERTIES

The asbestos minerals are not classified on a mineralogical basis, but rather on a commercial basis because of their unique properties. Therefore, the asbestos variety commercially known as crocidolite is referred to in the mineralogical literature as riebeckite. The asbestos variety called amosite is known mineralogically as grunerite. All other asbestos types are referred to by their proper mineral names. However, all asbestos fibers represent a form of silica fibers. Representative chemical formulas include chrysotile $Mg_3Si_2O_5(OH)_4$ (CAS 12001-29-5) and crocidolite $[NaFe_3^{2+}Fe_2^{3+}Si_8O_{22}(OH)_2]_n$ (CAS 12001-28-4).

Asbestos fibers are basically chemically inert, or nearly so. They do not evaporate, dissolve, burn, or undergo significant reactions with most chemicals. In acid and neutral

aqueous media, magnesium is lost from the outer brucite layer of chrysotile. Amphibole fibers are more resistant to acid attack and all varieties of asbestos are resistant to attack by alkalis (Chissick, 1985; WHO, 1998).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Once in the environment, fibers are mainly transported and distributed via air and water. Airborne mineral fibers are stable and may travel significant distances from the site of origin. Asbestos fibers will not volatilize or degrade, although they may be resuspended to the air by vehicular traffic over unpaved soil surfaces containing asbestos or through mining and milling operations. The importance of the transport of asbestos from the surface of water is presently undetermined. Asbestos will not volatilize or degrade in water. Asbestos released to the air will eventually settle out by gravitational settling and dry deposition.

Mineral fibers are relatively stable and tend to persist under typical environmental conditions. However, asbestos fibers may undergo chemical alteration as well as changes in dimension. The comparative solubility of selected mineral fibers has been studied and a general trend determined: chrysotile > amosite > actinolite > crocidolite > anthophyllite > tremolite (NAS, 1977). Because of their high adsorptive properties, it is thought that some mineral fibers may adsorb and carry various organic agents present in the environment.

As a naturally occurring substance, asbestos can be present in surface and ground water. Because asbestos fibers in water do not evaporate into air or break down in water, small fibers and fiber-containing particles may be carried long distances by water currents before settling to the bottom; larger fibers and particles tend to settle more quickly.

Asbestos does not tend to adsorb to solids normally found in natural water systems, but some materials (trace metals and organic compounds) have an affinity for asbestos minerals. The fibers are not able to move down through soil to ground water.

Asbestos is not affected by photolytic processes and is considered to be non-biodegradable by aquatic organisms. Asbestos fibers are not broken down to other compounds in the environment and, therefore, can remain in the environment for decades or longer.

There are no data regarding the bioaccumulation of asbestos in aquatic organisms.

MAMMALIAN TOXICOLOGY

Acute Effects

There are no clinically significant acute or intermediate effects associated with exposure to asbestos.

Significant exposure to any type of asbestos will increase the risk of lung cancer, mesothelioma and nonmalignant lung and pleural disorders, including asbestosis, pleural plaques, pleural thickening, and pleural effusions. Chronic laryngitis has also been associated with asbestos exposure (Kambic et al., 1989; Parnes, 1990). This effect is likely due to the irritant properties of asbestos and the mucociliary clearance of large fibers from the upper airways.

Chronic Effects

Asbestosis Asbestosis, also called white lung, is a lung disease that is caused by the prolonged inhalation of asbestos fibers. A type of pneumoconiosis, it is found primarily among workers whose occupations involved asbestos. Asbestos fibers that have been inhaled remain in the lungs for years and eventually cause excessive scarring and fibrosis, resulting in a stiffening of the lungs that continues long after exposure ceases.

Asbestosis is defined as diffuse pulmonary fibrosis caused by the inhalation of excessive amounts of asbestos fibers (Roggli et al., 2010). Although the finding of asbestosis may be associated with pleural abnormalities, these alone do not constitute asbestosis. The only clinical symptom commonly associated with asbestosis is dyspnea (Selikoff et al., 1965). Clubbing of the fingers may also occur, but this is a relatively late finding in the progression of asbestosis (McGavin and Hughes, 1998).

The pulmonary effect of asbestosis is primarily the reduction of lung volumes detected by reduced inspiratory capacity and vital capacity. Large airway function, represented by the forced expiratory volume (FEV1)/forced vital capacity (FVC) ratio is relatively unaffected (Murphy, 1987).

Cancer Chrysotile asbestos is the most common form of asbestos still produced and used. In 1992 chrysotile asbestos accounted for 99% of U.S. asbestos consumption (Pigg, 1994). Chrysotile was formerly thought to be a relatively safe form of asbestos compared to the amphibole forms (Craighead and Mossman, 1982). It was believed that because chrysotile is a curled fiber and more soluble, it would be deposited in the upper airways and effectively cleared before exerting a carcinogenic effect. The mesotheliomas associated with occupational exposure to chrysotile were attributed by some researchers to relatively low concentrations of tremolite fibers also present (Huncharek, 1994). Stayner et al. (1996) found that chrysotile may be a less potent inducer of mesotheliomas than amphiboles, but they could not determine a lower lung cancer risk. Also, the amount of time a fiber must stay in the lung to contribute to lung cancer or mesothelioma has been investigated (Barrett, 1994). Because workers are generally exposed to a mixture of fibers, it is prudent to treat chrysotile with the same level of concern as the amphibole forms of asbestos despite the fact

that evidence has not conclusively demonstrated that chrysotile is an independent cause of cancer in humans.

The mechanism of asbestos carcinogenesis is far from clear and is likely to be complex, depending on fiber dimensions, surface properties, and physical durability (Hei et al., 2006). The induction of reactive oxygen and nitrogen species upon phagocytosis of asbestos fibers plays an important role in fiber genotoxicity. The beta ig-H3, a secreted protein induced by the transforming growth factor-beta and essential for cell adhesion, is down regulated in asbestos-induced tumorigenic human bronchial epithelial cells. Ectopic expression of the beta ig-H3 gene abrogates the tumorigenic phenotype and suggests that the gene plays a causal role in fiber carcinogenesis.

Lung Cancer An association between asbesto-silicosis and lung cancer was suggested as early as the mid-1930s (Lynch and Smith, 1935). Doll (1955) examined the association between asbestos and lung cancer in British workers exposed before the first asbestos dust control efforts in 1931. He found asbestos workers in dusty environments had about 10 times the risk of developing lung cancer compared with the general population. A Canadian cohort study of asbestos cement plant workers also reported a significant excess of lung cancer (Finkelstein, 1983).

Hammond et al. (1979) studied the lung cancer incidence among 12,051 asbestos insulation workers with at least 20 years of work experience. Non-smoking asbestos workers had five times the risk of dying of lung cancer as non-smoking controls. Asbestos workers who smoked had a five times greater risk of dying of lung cancer than smoking controls. Analysis of the data suggested a multiplicative rather than additive relationship between smoking and asbestos exposure. Those exposed to both had a mortality ratio of 53 compared with non-smoking, non-asbestos control workers. Similar results were reported by Meurman et al. (1974) for anthophyllite miners and millers in Finland.

A Danish study assessed the standardized incidence ratio (SIR) of different types of lung cancer in asbestos cement workers (Raffn et al., 1996). They reported an SIR of 2.6 for adenocarcinoma, 1.7 for squamous cell carcinoma, and 1.5 for anaplastic carcinoma. Also, researchers noted that the risk for different histological types of lung cancer was similar during the first 25 years after the first exposure. After 25 years, the risk of adenocarcinoma increases.

The question of whether lung cancer can be attributed to asbestos exposure in the absence of asbestosis remains controversial (Hessel et al., 2005). This area continues to generate differences of opinion. The scientific question of whether or not asbestos-related lung cancer in man arises only in the presence of pulmonary fibrosis may be unanswerable epidemiologically. Microscopic evidence of fibrosis is a great deal more sensitive in detecting asbestosis than chest radiography (CR) or even high resolution

computed tomography (HRCT). Even HRCT scans may fail to detect fibrosis evident on microscopic examination, and fibrosis may have causes other than asbestos.

Mesothelioma Mesothelioma is a relatively rare cancer of the thin membranes that line the chest and abdomen. Although rare, mesothelioma is the most common form of cancer associated with asbestos exposure. Its incidence is anticipated to increase over the next decade in both Europe and the developing nations (Remon et al., 2012). Malignant mesotheliomas were first reported by Wagner et al. (1960) in crocidolite miners of North Western Cape Province, South Africa. Epidemiological and pathological studies have repeatedly shown a strong association between mesothelioma and high levels of asbestos exposure. Because mesothelioma is a rare form of cancer, this diagnosis typically leads the physician to search for possible sources of asbestos exposure even though there does exist a background rate of non-asbestos induced mesothelioma.

This disease is characterized clinically by chest pain and pleural effusion, and CR reveals irregular pleural thickening or pleural densities. Severe pleuritic pain, breathlessness, cough, weight loss, and fatigue follow. Peritoneal mesotheliomas produce dull pain followed by swelling and weight loss. Progression is rapid, with average survival time from onset of symptoms of about 6 months for pleural tumors and 13–14 months for peritoneal tumors (Becklake, 1976). Mesothelioma may spread to all serosal tissues, including pleura, pericardium, diaphragm, peritoneum, and tunica vaginalis testis (Watanabe et al., 1994). Tumors typically have an epithelial form, but may also have sarcomatous and microcystic patterns. Immunostaining for procollagen type 1 may distinguish mesothelioma from adenocarcinoma. Hyponatremia is common among mesothelioma victims, and its treatment may improve the comfort of these patients (Perks et al., 1979).

Because of its latent period and the occupational nature of some mesotheliomas, it is typically a disease of middle age. However, there is one report of pathologically confirmed asbestos-related mesothelioma in a 17-year-old boy (Andrion et al., 1994). The asbestos exposure was presumably due to cosmetic talc contaminated with asbestos.

Mechanism of Action(s)

The presence of asbestos fibers in the lungs sets off a variety of responses leading to inflammation and cell/tissue damage, which can lead to disease. The mechanisms by which asbestos causes disease are not fully understood. Currently, there are three hypotheses to account for asbestos's pathogenicity: (1) direct interaction with cellular macromolecules, (2) generation of reactive oxygen species, and (3) other cell-mediated mechanisms (especially inflammation). Asbestos is genotoxic and carcinogenic.

Because of their surface charge, asbestos fibers can bind to cellular macromolecules, such as proteins. This binding is believed to induce changes in macromolecular conformation, thereby affecting function. Also, long asbestos fibers can interfere physically with the mitotic spindle and cause chromosomal damage, especially deletions (NAS, 2006).

The physical-chemical attributes of mineral fibers are important in determining the type of toxicity observed. The three main determinants of asbestos toxicity are fiber size, durability, and iron content. Fibrosis results from a sequence of events following lung injury, which includes inflammatory cell migration, edema, cellular proliferation, and accumulation of collagen. Fibers do migrate to the pleural space, and it has been hypothesized that a similar cascade of inflammatory events may contribute to fibrotic lesions in the visceral pleura. Thickening of the visceral pleura is more often localized to lobes of the lung with pronounced parenchymal changes, and it has also been hypothesized that the inflammatory and fibrogenic processes within the lung parenchyma in response to asbestos fibers may influence the fibrogenic process in the visceral pleura.

Asbestos fibers are elaborators of active oxygen species, whether by reactions involving iron on the surface of the fiber, or by attempted phagocytosis of fibers by cell types resident in the lung. The link between production of active oxygen species and the pathogenesis of asbestos-mediated disease has been highlighted by the use of antioxidant scavengers that inhibit the cytotoxic effects of asbestos *in vitro* and *in vivo*. The use of antioxidant enzymes ameliorates the induction of certain genes necessary for cell proliferation, such as ornithine decarboxylase, implicating oxidants as causative factors in some abnormal cell replicative events (Quinlan et al., 1994).

Cytogenetic and molecular studies of asbestos-related cancers indicate that inactivation or loss of multiple tumor suppressor genes occurs during lung cancer development. Aneuploidy and other chromosomal changes induced by asbestos fibers may also be involved in genetic alterations. Furthermore, asbestos fibers may influence the carcinogenic process by inducing cell proliferation, free radicals, or other promotional mechanisms. Therefore, asbestos fibers may act at multiple stages of the carcinogenic process by both genetic and epigenetic mechanisms. Their biopersistence also remains important in fiber carcinogenicity (Barrett, 1994).

Pathological changes resulting from the inhalation of asbestos fibers and dust vary with the quantity and kind of material. Benign pleural plaques first described in Finland by Meurman (1966) in parietal pleura are located at the sites of greatest respiratory movement. These plaques consist of collagenous connective tissue with secondary calcification. Such plaques may occur in the absence of lung fibrosis even though asbestos bodies are found in the lung.

Smoking combined with asbestos exposure has a synergistic effect on the incidence of lung cancer and asbestosis

(Hammond et al., 1979). The strength of this effect varies depending on the type, intensity, and duration of the exposure. It is generally thought to be a multiplicative effect, more than additive (Vainio and Boffetta, 1994).

SOURCES OF EXPOSURE

Occupational

In the United States, an estimated 27 million workers were exposed to aerosolized asbestos fibers between 1940 and 1979 (Nicholson et al. 1982). Secondary exposure occurred when people who did not work directly with asbestos were nevertheless exposed to fibers as a result of sharing workspace where others handled asbestos. For example, electricians who worked in shipyards were exposed because asbestos was being used to coat the ships' pipes and hulls (Pan et al., 2005).

Currently, the people most heavily exposed to asbestos in the United States are those in construction trades. This population includes an estimated 1.3 million construction workers as well as workers in building and equipment maintenance (American Thoracic Society, 2004). Because most asbestos was used in construction, and two-thirds of asbestos produced is still used in this trade, risk to these workers can be considerable if the hazard is not recognized and the Occupational Safety and Health Administration (OSHA) standards are not enforced.

The risk of exposure to asbestos is highest for people who mine and export asbestos or those who work with it in manufacturing. The risk of developing cancer is potentially highest in these groups. Today, strict government regulations and improved work practices have decreased the risk of asbestos exposure for workers.

During renovations and repairs to older buildings, construction workers, other trade workers and building maintenance workers may be exposed to high concentrations of asbestos fibers. Most tradespeople working in construction, maintenance, or the renovation of older buildings are trained in the proper handling of asbestos-containing materials and should be particularly careful when handling these materials.

Environmental

Asbestos is ubiquitous in the environment, albeit in small quantities. Small levels of asbestos fibers occur in the soil, air and water, from natural and artificial sources. Asbestos can be released into the environment from the natural erosion of asbestos-bearing rock or when asbestos-containing products are damaged or worn down.

In the past, because of a lack of proper industrial hygiene, asbestos workers went home covered in asbestos dust. This brought about a tendency for workers' families and other

household contacts to be exposed via inhalation of asbestos dust from workers' skin, hair, and clothing, and during laundering of contaminated work clothes. A mortality study of 878 household contacts of asbestos workers revealed that 4 out of 115 total deaths were from pleural mesothelioma and that the rate of deaths from all types of cancer was doubled (Joubert et al., 1991). In addition, asbestos was released into the air and soil around facilities such as refineries, power plants, factories handling asbestos, shipyards, steel mills, vermiculite mines, and building demolitions. People living around these facilities were also exposed to asbestos.

Today, the risk of environmental exposure to asbestos is considered to be very low.

Asbestos was used widely in building materials such as insulation and floor and ceiling tiles. However, asbestos used in these products is very dense and does not release significant amounts of fibers unless the products are cut, damaged, or disturbed.

There is some concern about vermiculite insulation, which may contain small amounts of amphibole asbestos. However, there is currently no evidence of a health risk if the insulation is sealed behind wallboards and floorboards, isolated in an attic or kept from exposure and from being disturbed.

Some home attic insulation and many other home and building materials produced before 1975 contain asbestos. People who live in homes with these materials are at risk of exposure if the materials are loose, crumbling, or disturbed by household activities or renovations. On the other hand, asbestos contained in intact solid material poses a negligible risk of exposure.

There are many ways that people can also be exposed to asbestos through hobbies and recreational activities that entail contact with materials containing asbestos; some examples are activities such as home renovation, auto repair, and urban spelunking (exploring abandoned buildings). In places where naturally occurring asbestos is close to the earth's surface, activities such as gardening and dirt biking can cause exposures if asbestos-bearing rock is disturbed.

INDUSTRIAL HYGIENE

Historically, a number of industries have been sources of occupational exposure to asbestos, including textiles, shipyards, construction, oil refineries, railroads, insulation installation, and pipefitting.

Determinations of employee exposure should be made from breathing zone air samples that are representative of the 8-h time-weighted average (TWA) and 30 min short-term exposures of each employee. Exposure monitoring samples should be analyzed by phase contrast microscopy (PCM) for OSHA purposes. Phase contrast microscopy methods accurately assess fiber exposure levels, but PCM cannot differentiate between asbestos and non-asbestos fibers. The

transmission electron microscopy (TEM) methods may be used to identify asbestos fibers specifically. Exposures should be evaluated with standard total dust sampling techniques for comparison to the OSHA permissible exposure limits (PEL). Controlling the exposure to asbestos can be done through engineering controls, administrative actions, and personal protective equipment (PPE). Engineering controls include such things as isolating the source and using ventilation systems. Administrative actions include limiting the workers exposure time and providing showers. PPE include wearing the proper respiratory protection and clothing.

The National Institute for Occupational Safety and Health (NIOSH) recommends that exposure to all asbestos fibers <5 µm to be reduced to the lowest feasible level. The OSHA and NIOSH have set the PEL and the recommended exposure limit (REL) for all airborne asbestos fibers >5 µm at 0.1 fiber/cm³. The OSHA has set an additional 30 min ceiling at 1 fiber/cm³. The American Conference of Governmental Industrial Hygienists (ACGIH) has set the threshold limit value (TLV) at 0.1 fiber/cm³.

The National Toxicology Program (NTP) has classified asbestos as a known human carcinogen. The International Agency for Research on Cancer (IARC) has classified asbestos as a Group 1 carcinogen (carcinogenic to humans).

RISK ASSESSMENTS

The California Environmental Protection Agency (CalEPA) has established an oral slope factor of 0.000190 mg/kg per day. The U.S. Environmental Protection Agency (USEPA) has established an inhalation unit risk of 0.23 fibers/ml of air. An inhalation cancer risk of 1 in 10,000 is associated with a concentration of 0.0004 fibers/ml of air.

In accordance with the United Nations Globally Harmonized System of Classification and Labelling of Chemicals (GHS), asbestos is classified as a Category 1A Carcinogen (known to have carcinogenic potential for humans, based largely on human evidence) and specific target organ toxicity-repeated or prolonged exposure (STOT-RE) Category 1. Category 1 is assigned for STOT-RE because it has produced significant toxicity in humans, or that, on the basis of evidence from studies in experimental animals can be presumed to have the potential to produce significant toxicity in humans following repeated or prolonged exposure.

Studies concerning natural asbestos in the environment show that the exposure that begins at birth does not seem to affect the duration of the latency period, but the studies do not show whether early exposure increases susceptibility; they do not suggest that susceptibility differs according to sex. Solid evidence shows an increased risk of mesothelioma among people whose exposure comes from a paraoccupational or domestic source. The risk of mesothelioma

associated with exposure as result of living near an industrial asbestos source (mines, mills, asbestos processing plants) is clearly confirmed. No solid epidemiological data currently justify any judgment about the health effects associated with passive exposure in buildings containing asbestos. Most of the studies on nonoccupational sources reported mainly amphibole exposure, and it is unclear if environmental exposure to chrysotile may also cause cancer.

SILICA

First aid: No specific first aid is necessary since the adverse health effects associated with exposure to crystalline silica (quartz) result from chronic exposures. If there is a gross inhalation of crystalline silica (quartz), remove the person immediately to fresh air, give artificial respiration as needed, seek medical attention as needed. If on the body, wash the contaminated body part with copious amounts of soap and water. If the eyes are exposed, immediately irrigate the affected eye thoroughly with water or 0.9% saline. Provide treatment for any symptoms that may arise.

Target organ(s): Respiratory system, eyes

Occupational exposure limits: OSHA PEL—10/(% SiO₂⁺²) (respirable) or 30/(% SiO₂⁺²) (total) TWA; NIOSH

REL—0.05 mg/m³ TWA; ACGIH TLV—0.025 mg/m³ TWA (respirable)

Hazard/precautionary phrases: H315 causes skin irritation; H319 causes serious eye irritation; H335 may cause respiratory irritation; H372 causes damage to organs through prolonged or repeated exposure

BACKGROUND AND USES

Pulmonary disease attributable to silica (silicon dioxide, quartz, SiO₂) exposure has been recorded since the mid sixteenth century. Since that time, reports of mineral dust diseases of the chest have come from all areas where mining is operational. Silica is abundant in the earth, has fibrogenic properties, and is unique in acting synergistically with acid-fast bacillary infections. Silica should not be confused with silicates, which are based on SiO₄ units. Industrially important silica-containing materials are quartzite, sandstone, flint, tripoli, and diatomaceous earth. Cristobalite and tridymite silica are considered more potent inducers of silicosis than quartz.

At least 1.7 million U.S. workers are exposed to respirable crystalline silica in a variety of industries and occupations, including construction, sandblasting, and mining. Silicosis, an irreversible but preventable disease, is the illness most closely associated with occupational exposure to the material, which is also known as silica dust. Occupational exposures to respirable crystalline silica are associated with the development of silicosis, lung cancer, pulmonary tuberculosis, and airways diseases. These exposures may also be related to the development of autoimmune disorders, chronic renal disease, and other adverse health effects.

Crystalline silica is commonly found and used in industries such as electronics; foundry; ceramics, clay, pottery, stone and glass; construction; agriculture; maritime; railroad (setting and laying track); slate and flint quarrying and flint crushing; use and manufacture of abrasives; manufacture of soaps and detergents; and mining.

Perhaps the most familiar use of quartz sand is as an abrasive blasting agent to remove surface coatings prior to repainting or treating. The NIOSH estimates that there are more than one million American workers who are at risk of developing silicosis. Of these workers, 100,000 are employed as sandblasters (NIOSH, 1992).

PHYSICAL AND CHEMICAL PROPERTIES

Silica is a group IV metal oxide, which has good abrasion resistance, electrical insulation, and high thermal stability. It is practically insoluble in water or acids. However, it will dissolve in hydrogen fluoride (HF), forming silicon tetrafluoride.

Crystalline silica has a molecular weight of 60.09. The transparent crystals are odorless and tasteless. It has a melting point of 1710°C, and is not corrosive.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Silica-bearing deposits are found to some degree in every land mass and stratum from every era and period of geological time. Silica deposits are almost uniformly quartz or derived from quartz, formed by metamorphism, sedimentation or through igneous activity. The majority of deposits mined for silica sand consist of free quartz, quartzites, and quartzose sedimentary deposits, such as sandstone.

Silicon is the second most abundant chemical element, after oxygen, in the earth's crust accounting for 28.15% of its mass. Silicate minerals (such as plagioclase, alkali feldspars, pyroxenes, amphiboles, micas and clays, excluding silica) comprise together 80% by volume of the earth's crust, while quartz, by far the most common form of silica in nature, comprises 12% by volume of the crust.

Being refractory to weathering, quartz can be carried for long distances by eolian transport (pertains to the activity of the winds). For example, one study noted that Asian dust can be transported within five days from the Gobi desert in China to the mountain ranges between British Columbia and California, a distance >8000 km (Husar et al., 1998). The mean diameter of this material was between 2 and 3 µm and was dominated by the single minerals quartz, K-feldspar and plagioclase. An important dust fall on northern Scandinavia originated from western North Africa, and hence, particles were transported for at least 7000 km before their final destination. Mineralogically, these particles were dominated by small round quartz grains of a mean diameter of 2.7 µm (Franzén et al., 1994). Finally, microscopic analyses of particulate matter collected during six long-range transport events led researchers to conclude that large quartz grains (>62.5 µm) can be transported over great distances, up to 10,000 km, to oceanic and terrestrial locations (Middleton et al., 2001).

Silica does not bioaccumulate.

ECOTOXICOLOGY

No data were found with regards to the toxicity of quartz and cristobalite to aquatic organisms. The effects of respirable crystalline silica on terrestrial mammals and birds have been noted. Development of silicosis in terrestrial organisms is mainly dependent on the quantity of particulate exposure and size of the silicon dioxide crystals.

Acute Effects

Exposure to the toxic mineral dust silica produces an acute inflammatory response in the lungs of both humans and laboratory animals. The aryl hydrocarbon receptor (AhR) may regulate silica-induced inflammation, but not fibrosis (Beamer et al., 2012).

Intense crystalline silica exposure has resulted in outbreaks of acute silicosis referred to medically as silico-proteinosis or alveolar lipoproteinosis-like silicosis. Initially, crystalline silica particles produce an alveolitis that is characterized by sustained increases in the total number of alveolar cells, including macrophages, lymphocytes, and neutrophils. The alveolitis has been found to progress to the characteristic nodular fibrosis of simple silicosis. A rapid increase in the rate of synthesis and deposition of lung collagen has also been seen with the inhalation of crystalline silica particles. The collagen formed is unique to silica-induced lung disease and biochemically different from normal lung collagen (Olishfski, 1988).

Chronic Effects

Inhalation of crystalline silica-containing dusts has been associated with silicosis, chronic obstructive pulmonary disease, bronchitis, collagen vascular diseases, chronic granulomatous infections such as tuberculosis, and lung cancer. In general, aerosols of particulates can be deposited in the lungs. This can produce rapid or slow local tissue damage, eventual disease or physical plugging. Dust containing crystalline silica can cause formation of fibrosis (scar tissue) in the lungs (Markowitz and Rosner, 1995).

Animal studies have confirmed human experience that a lung dusted with silica is extremely vulnerable to infection by tubercle bacilli (Gardner and Dworski, 1922). In areas where tuberculosis is endemic, death rates among workers concurrently exposed to silica are much higher. The risk of a patient with silicosis developing tuberculosis is higher (2.8–39-fold higher, depending on the severity of silicosis) than that found in non-exposed controls (Milovanović et al., 2011).

Scleroderma (progressive systemic sclerosis) and arthritis have been reported to be associated with silica exposure. Steenland and Goldsmith (1995) suggested a link between silica exposure and autoimmune effects.

Silicosis Silicosis is a diffuse interstitial fibronodular lung disease, caused by the inhalation of crystalline silica in the forms of quartz (the most frequently found), cristobalite, trydimite, stishovite, and coesite (Santos et al., 2010). Silicosis is believed to be the oldest form of pneumoconiosis. The term was first used by Visconti in 1870, but the disease had already been seen in ancient Egyptian and Greek mummies. Hippocrates also described observing breathing difficulties in metal miners and the condition was also seen in

the sixteenth century in miners in Bohemia and in eighteenth century stonecutters.

Silicosis is the leading cause of disability among occupational respiratory diseases, classified as the sixth most frequently occurring occupational respiratory disease by the European Occupational Disease Statistics (EODS). This pathology is rarely seen before the age of 50 years old and is more commonly found in males, due to the nature of the profession exercised.

Gradually increasing dyspnea and nonproductive cough, often thought by the patient to be due to smoking habits or to age, are the usual initial complaints. Well-studied groups of workers exposed to silica have established the fact that some of them, who have no symptoms, will show densities in the lungs on routine chest X-ray.

In the usual case of silicosis and in the absence of infection, there is a slow deterioration of capacity for physical effort. If respiratory infection occurs, dyspnea and cough are often increased and become established at more severe levels after the infection has subsided. Vague chest tightness and clinically obvious pleuritis occur in some cases. Hemoptysis is unusual unless acid-fast infection complicates the silicosis. Asthmatic bronchitis characterized by wheezing and difficulty in expiring air often occurs.

Chronic bronchitis, as a result of the direct effect of finely divided silica dust, is a consequence that is hard to establish, but emphysema is a common complication of silicosis. Smoking habits, bacterial infection, and aging are all factors that can affect normal upper respiratory tract defenses or by themselves may act as complicating etiological factors. In addition, many jobs with silica exposure may involve the inhalation of irritant chemicals, such as oxides of nitrogen from blasting fumes or welding. Underground mining in hot, damp atmospheres and operations near furnaces create other modifying or aggravating influences acting on respiratory function.

Silicosis results in an increased risk of cor pulmonale (Murray et al., 1993).

Carcinogenicity Exposure of workers to respirable crystalline silica is associated with elevated rates of lung cancer (NTP, 2011). The link between human lung cancer and exposure to respirable crystalline silica has been shown to be strongest in studies of quarry and granite workers and workers involved in ceramic, pottery, refractory brick, and diatomaceous earth industries. Human cancer risks are associated with exposure to respirable quartz and cristobalite but not to amorphous silica. The overall relative risk is approximately 1.3–1.5, with higher risks found in groups with greater exposure or longer time since first exposure. Silicosis, a marker for exposure to silica dust, is associated with elevated lung cancer rates, with relative risks of 2.0–4.0. Elevated risks have been seen in studies that accounted for smoking or asbestos exposure, and confounding by co-exposure is unlikely to explain these results (IARC, 1997).

In rats, exposure to various forms of respirable crystalline silica by inhalation or intratracheal instillation consistently caused lung cancer (adenocarcinoma or squamous-cell carcinoma). Single intrapleural or intraperitoneal injections of various forms of respirable crystalline silica also caused lymphoma in rats (IARC, 1997). Silica may increase lung cancer rates through a synergistic or promoting effect rather than direct carcinogenicity (Agius, 1992).

The IARC classifies silica as a Type 1 known human carcinogen. The NTP also lists respirable crystalline silica as a known human carcinogen.

Renal Toxicity Nephrotoxicity is associated with silica exposure (Ghahramani, 2010). Exposure to silica has been associated with tubulointerstitial disease, immune-mediated multisystem disease, chronic kidney disease, and end-stage renal disease. A rare syndrome of painful, nodular skin lesions has been described in dialysis patients with excessive levels of silicon. Balkan endemic nephropathy is postulated to be due to chronic intoxication with drinking water polluted by silicates released during soil erosion. The mechanism of silica nephrotoxicity is thought to be through direct physical action, as well as silica-induced autoimmune diseases such as scleroderma and systemic lupus erythematosus.

Chemical Pathology

Inhalation of respirable silica dusts leads to deposition in distal airways. Silica can produce reactive oxygen species either directly on freshly cleaved particle surfaces or indirectly through its effect on the phagocytic cells. Scavenger receptors, especially the macrophage receptor with collagenous structure expressed in alveolar macrophages, seem to have a role in the recognition and uptake of silica (Pollard and Kono, 2013).

Phagocytosis of crystalline silica in the lung causes lysosomal damage, activating the NALP3 inflammasome and triggering the inflammatory cascade with subsequent fibrosis. Impairment of lung function increases with disease progression, even after the patient is no longer exposed.

Pathological varieties of silicosis include simple (nodular) silicosis, progressive massive fibrosis, silicoproteinosis, and diffuse interstitial fibrosis. Gross pathological examination of the lung identifies discrete hard nodules, usually with upper-lobe predominance (Leung et al., 2012). Hilar and peribronchial lymph nodes are frequently enlarged.

Mechanism of Action(s)

Respirable crystalline silica deposited in the lungs causes epithelial injury and macrophage activation, leading to inflammatory responses and proliferation of the epithelial and interstitial cells (NTP, 2011). In humans, respirable crystalline silica persists in the lungs, culminating in

the development of chronic silicosis, emphysema, obstructive airway disease, and lymph-node fibrosis. Respirable crystalline silica stimulates (1) release of cytokines and growth factors from macrophages and epithelial cells, (2) release of reactive oxygen and nitrogen intermediates, and (3) oxidative stress in the lungs. All of these pathways contribute to lung disease. Marked and persistent inflammation, specifically inflammatory-cell-derived oxidants, may provide a mechanism by which respirable crystalline silica exposure can result in genetic damage in the lung parenchyma.

SOURCES OF EXPOSURE

Occupational

Respirable quartz levels exceeding 0.1 mg/m³ are most frequently found in metal, nonmetal, and coal mines and mills, granite quarrying and processing, crushed-stone and related industries, foundries, the ceramics industry, construction, and sandblasting operations (IARC, 1997). Potential exposure was highest for sculptors and carvers, stencil cutters, polishers, and sandblasters; for these occupations, the silica content of respirable dust ranged from 4.8% to 12.2%. Concentrations of respirable crystalline silica ranged from 0.01 to 0.20 mg/m³ in clay-pipe factories and from 0 to 0.18 mg/m³ in a plant producing ceramic electronic equipment parts.

Environmental

Crystalline silica is an abundant and commonly found natural material. Human exposure to respirable crystalline silica, primarily quartz dust, occurs mainly in industrial and occupational settings. Nonoccupational exposure to respirable crystalline silica results from natural processes and anthropogenic sources; silica is a common air contaminant. Residents near quarries and sand and gravel operations potentially are exposed to respirable crystalline silica. A major source of cristobalite and tridymite in the United States is volcanic rock. Local conditions, especially in deserts and areas around recent volcanic eruptions and mine dumps, can give rise to silica-containing dust.

Consumers may be exposed to respirable crystalline silica from abrasives, sand paper, detergent, grouts, and concrete (IARC, 1997). Crystalline silica may also be an unintentional contaminant; for example, diatomaceous earth, used as a filler in reconstituted tobacco sheets, may be converted to cristobalite as it passes through the burning tip of tobacco products (IARC, 1987).

INDUSTRIAL HYGIENE

Industrial hygiene assessments should be conducted to include silica dust monitoring, hazard analysis and providing

the results to exposed workers and their supervisors. Results of these assessments should include (1) recommendation of engineering and administrative controls to reduce silica dust exposure; (2) recommendation of appropriate and suitable respirators and other PPE for the job; (3) offering hands-on practical training and quantitative fit tests for respirator use; and (4) if feasible, recommending non-silica material for abrasive blasting operations.

Engineering controls may include attaching a dust control system to power tools; using a wet spray method if feasible to suppress dust during sand blasting, jack hammering or other construction activities; and when feasible, using a local exhaust ventilation system to remove dust from the work area.

A half or full-face air-purifying respirators with the appropriate filters must be used if concentrations of silica are at or above the PEL. Safety glasses or goggles should also be worn.

The NIOSH has approved four methods for determining silica in dust samples, namely, colorimetry, X-ray powder diffraction, and two infrared spectroscopy methods (NIOSH, 2010).

TALC

First aid: If on the body, wash the contaminated body part with copious amounts of soap and water. If the eyes are exposed, immediately irrigate the affected eye thoroughly with water or 0.9% saline. Provide treatment for any symptoms that may arise.

Target organ(s): Respiratory system, eyes

Occupational exposure limits: NIOSH REL: TWA 2 mg/m³; ACGIH TLV: TWA 2 mg/m³; OSHA PEL: TWA 20 mppcf (80 mg/m³/%SiO₂)

Reference values:

Hazard/precautionary phrases: H319 causes serious eye irritation; H332 harmful if inhaled; H372 causes damage to organs through prolonged or repeated exposure

BACKGROUND AND USES

Talc (hydrous magnesium silicate; steatite talc; CAS #14807-96-6) is an odorless white powder. It is insoluble in water and has a vapor pressure of approximately 0 mmHg. Talc is chemically similar to anthophyllite, chrysotile, and tremolite forms of asbestos, as they are all hydrated magnesium silicates. It is commonly found in combination with asbestos, quartz, and other minerals. Two forms occur in mineral deposits, namely, nonfibrous (platy or non-asbestiform) and fibrous (tremolite). Talc is used in the manufacture of ceramics, paints, paper, roofing materials, plastics, cosmetics, and rubber.

Talc is produced by open pit or underground mining of talc rocks and processed by crushing, drying, and milling. Geological formation of talc rock results from the alteration of magnesia- and silica-rich ultramafic rocks under a range of temperatures and pressures.

Domestic talc production in 2012 was estimated to be 623,000 tons valued at \$22 million. Three companies operated six talc-producing mines in three states in 2011. Montana was the leading producer state, followed by Texas and Vermont. Sales of talc were estimated to be 572,000 tons valued at \$90 million. Talc produced and sold in the United States was used for ceramics, 26%; paint and paper, 20% each; plastics and roofing, 9% each; cosmetics, 4%; rubber, 3%; and other, 9% (USGS, 2013).

According to the Hazardous Substances Data Bank (HSDB) record for talc, (NLM, 2013), the compound is typically used as: (1) an additive to clay in ceramic manufacture and paper coatings, for roofing materials; (2) a carrier and diluent for insecticides; filler and pigment for paints and elastomers; additive in manufacture of refractories; (3) in ceramics; cosmetics and pharmaceuticals; filler in rubber, paints, putty, plaster, oilcloth; abherent; slate pencils and crayons; (4) in dusting powder, either alone or with starch or boric acid, for medicinal and toilet preparations; excipient and filler for pills, tablets and for dusting tablet molds; clarifying liquids by filtration; (5) as pigment in paints, varnishes, rubber; filler for paper, rubber, soap; in fireproof and cold-water paints for wood, metal, and stone; lubricating molds and machinery; glove and shoe powder; electric and heat insulator; and (6) in veterinaries as topically on vulva fold pyoderma of dogs as protectant.

PHYSICAL AND CHEMICAL PROPERTIES

Talc as a pure chemical compound is defined as hydrous magnesium silicate, $Mg_3Si_4O_{10}(OH)_2$ and consists of a brucite sheet containing magnesium ions sandwiched between two silica sheets, which are held together by relatively weak forces. Talc as a pure mineral is composed of 63.5% SiO_2 , 31.7% MgO , and 4.8% H_2O . A variety of

elements such as nickel and iron may be included in the talc particle lattice but are so bound within the particle that they are not free to exert any biological action. As talc dusts are obtained from different sources, the amount and specific form of talc, as well as the amount and nature of mineral contaminants, will be different for each dust.

Talc can be tabular, granular, fibrous, or platy but it is usually crystalline, flexible, and soft. It is commonly whitish to light green but it can be yellowish to reddish, the reddish color being associated with small amounts of iron bound within the talc particle.

Talc has a greasy feel and luster. It is insoluble in water, cold acids, and alkalies and has a density of 2.7–2.8 and a melting point of 900–1000 °C.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Talc is commonly found in the environment. It shows no bioaccumulation potential.

Talc is not expected to undergo chemical transformation when released into the environment. Its refractory nature precludes the effects of melting/boiling point, solubility, vapor pressure, octanol/water partition coefficient, etc., on its transport. Terrestrial and fluvial transport processes affecting talc are not well characterized.

ECOTOXICOLOGY

Talc is not expected to have an ecotoxicologic effect or to be harmful to aquatic life. The 96 h LC50 in *Danio rerio* (zebrafish) is >100 g/l (semi-static).

MAMMALIAN TOXICOLOGY

Acute Effects

While ingestion or topical application of talc produces a benign effect, the substance acts as an irritant when it is inhaled. As an immediate consequence, it dries the tracheo-bronchial tree mucous membranes and impairs ciliary function, inhibiting the clearing of particulate matter within the airway. Talc inhalation can produce various signs and symptoms, including sneezing, coughing, dyspnea (transient or chronic), respiratory distress/failure, and death. Conditions such as diffuse pulmonary infiltrates, acute lung injury, bronchiolar obstruction, bronchiolitis, pneumonitis, or pneumonia caused by a secondary bacterial infection can develop. Any of these conditions can lead to severe respiratory compromise, such as acute respiratory distress syndrome (Lawson, 2012).

Chronic Effects

The greatest cause of pulmonary disease resulting from talc occurs in workers engaged in mining and milling so-called tremolite talc. The four distinct forms of pulmonary disease resulting from chronic exposure to talc have been defined (Marchiori et al., 2010). Three of them (talcosilicosis, talcoasbestosis, and pure talcosis) are associated with inhalation and differ in the composition of the inhaled substance. The fourth form, a result of intravenous administration of talc, is seen in drug users who inject medications intended for oral use. Presentation of patients with talc granulomatosis can range from asymptomatic to fulminant disease. Symptomatic patients typically present with nonspecific complaints, including progressive exertional dyspnea, and cough. Late complications include chronic respiratory failure, emphysema, pulmonary arterial hypertension, and cor pulmonale.

Dyspnea on effort and cough are presenting symptoms in talc pneumoconiosis. As pathological changes progress, cyanosis, clubbing, and increasing dyspnea are the usual complaints. Diminished breath sounds, diffuse rales, and limitation of chest expansion have also been noted (Kleinfeld et al., 1963). Tuberculosis, emphysema, and right heart disease are complications of pulmonary talcosis.

Postmortem studies show talc causes a nonspecific pulmonary fibrosis of the lung (Seeler et al., 1959). In addition, foreign body granulomas containing talc fibers are found in the lung, pleura, diaphragm, pericardium, and gastric wall. These findings were once attributed to the silica content of talc. However, X-ray diffraction studies of affected lungs have demonstrated the presence of <0.1% of free silica.

Wild (2006) reviewed the epidemiological evidence between lung cancer risk and talc not containing asbestos. No increased lung cancer mortality was observed among talc millers despite their high exposure experience. In populations in which talc was associated with other potential carcinogens, some lung cancer excesses were observed.

Lung damage has developed in rats exposed repeatedly, by inhalation, to talc. No fetal effects were seen in rabbits, rats, mice, or hamsters treated orally during pregnancy. In rats given oral doses, there was no evidence of activity in assays for chromosomal damage or dominant lethal mutations. Talc did not cause chromosomal damage in human cells treated in culture and it was not mutagenic to yeast or to bacteria in Ames tests (Bibra, 1991).

No conclusive evidence of pure talc-induced carcinogenicity has been demonstrated in workers (IARC, 2010). However, talc containing asbestos may be carcinogenic. The collective data from animal, cellular studies, and epidemiological studies do not support a causal relationship between industrial-grade talc and mesothelioma (Price, 2010). Data do not support the hypothesis that use of talc in the perineal area is associated with an increased risk of endometrial cancer (Neill et al., 2012).

A number of observational studies (largely case control) suggest an association between use of talc powders on the female perineum and increased risk of ovarian cancer. However, the weak statistical associations observed in a number of epidemiological studies do not support a causal association (Huncharek and Muscat, 2011).

Based on the lack of data from human studies and on limited data in lab animal studies, the IARC classifies talc not containing asbestos as “not classifiable as to carcinogenicity in humans.”

Chemical Pathology

The characteristic histopathologic feature in talc pneumoconiosis is the striking appearance of birefringent, needle-shaped particles of talc seen within the giant cells and in the areas of pulmonary fibrosis with the use of polarized light. Computed tomography can play an important role in the diagnosis of pulmonary talcosis, since suggestive patterns may be observed. The presence of these patterns in drug abusers or in patients with an occupational history of exposure to talc is highly suggestive of pulmonary talcosis.

Mechanism of Action(s)

Different mechanisms are probably operative in the effects of talc on the lung and pleura, depending on the route of exposure.

Talcosilicosis and talcoasbestosis are probably due to concomitant exposure of talc with crystalline silica and asbestos, respectively. The previous sections discuss the mechanisms by which these produce disease.

Talc deposition in the lungs typically causes granulomatous inflammation characterized by formation of foreign body granulomas of varying degree within a fibrotic stroma (Scheel et al., 2012). These granulomas are typically composed of free or intracellular birefringent deposits accompanied by multinucleated giant cells. They may also appear ill defined with only few surrounding histiocytes. Distribution of these lesions is variable and they may develop intra- and perivasculär as well as in the interstitium.

SOURCES OF EXPOSURE

Occupational

Exposure to talc dust occurs during its mining, crushing, separating, bagging, and loading and in various industries that use talc.

Environmental

Talc is found in small amounts in metamorphic mafic and ultramafic rocks and in carbonates. These metamorphic rocks

crop out in mountain belts such as the Alps, the Appalachians, and the Himalayas and in ancient continental shields such as the Canadian shield in New York and Canada.

Talc may also be in the environment from consumer products that contain talc.

INDUSTRIAL HYGIENE

The ACGIH and NIOSH have set the TLV and REL, respectively, for respirable talc containing no asbestos and <1% quartz at 15 million particles per cubic foot (mppcf) of air (mppcf; 2 mg/m³). OSHA has set the PEL at 20 mppcf (~3 mg/m³). The exposure limits for asbestos or silica should be used for any talc containing asbestos or silica.

According to the European Chemicals Agency (ECHA) (ECHA, 2013) Registered Substances Database, a derived no effect level (DNEL) for long-term exposure to talc via inhalation is 72 mg/m³ for the general population and 245 mg/m³ for workers. The DNEL for long-term dermal exposure is 83 mg/kg bw/day for the general population and 139 mg/kg bw/day for workers. The DNEL for the general population for long-term exposure via the oral route of administration is 8.3 mg/kg bw/day.

MIXED DUSTS

CHARLES BARTON

COAL

First aid: Remove the patient from exposure to fresh air. If the eyes are exposed, immediately irrigate the affected eye thoroughly with water or 0.9% saline. Provide treatment for any symptoms that may arise.

Target organ(s): Respiratory system, eyes.

Occupational exposure limits: OSHA PEL—TWA 2.4 mg/m³ [respirable, <5% SiO₂] or TWA (10 mg/m³)/(%SiO₂ + 2) [respirable, >5% SiO₂]; NIOSH REL for occupations other than mining—TWA 1 mg/m³ [measured according to MSHA method (CPSU)] or TWA 0.9 mg/m³ [measured according to ISO/CEN/ACGIH criteria]; ACGIH TLV—TWA 2 mg/m³ if <5% SiO₂ or 0.1 mg/m³ if 5% or greater SiO₂.

Hazard/precautionary phrases: H₂O₅ may mass explode in fire; H₃T₂ causes damage to organs through prolonged or repeated exposure.

BACKGROUND AND USES

Coal is a generic term for a heterogeneous, carbonaceous rock of varying composition and characteristics. It is mined in over 70 different countries around the world, and utilized in many more for electricity generation, heating, steel making, and chemical processes. It varies in type from the soft and friable lignite to the hard and brittle anthracite. The term "rank," which reflects the percentage carbon content, is used for its classification. Coal typically contains variable but substantial amounts of mineral matter, of which quartz is an important component.

Throughout history, coal has been a useful resource for human exploitation. It is primarily burned as a fossil fuel to produce electricity and heat. Coal forms when dead plant matter decomposes into peat, which in turn is converted into lignite, and then anthracite. Coal is the largest source of energy for the generation of electricity worldwide, as well as one of the largest worldwide anthropogenic sources of carbon dioxide release.

Coal dust is a fine powdered form of coal, which is created by the crushing, grinding, or pulverizing of coal. Because of the brittle nature of coal, coal dust can be created during mining, transportation, or by mechanically handling coal.

A number of occupational factors influence the symptoms and signs of chest disease in addition to the individual coal miner's medical history or the health of the community where he or she lives. Because coal mining may occur near ground level in open pits, at varying depths underground, or far under the sea, a variety of risks may be encountered. Differences in the particle size distribution and the quantity of dust inhaled by the worker vary depending on the method of mining being used. Deep mines are hard to ventilate, and this problem may involve exposure not only to dust but also to irritating chemicals arising from blasting charges and to dangerous levels of carbon monoxide and methane.

Coal occurs in ore, varying in content of the fibrogenic dust silica (quartz). Silica in the form of sand may also be applied to underground tracks with compressed air to provide traction for heavily laden cars, a practice leading to a serious risk of silicosis, especially to motormen. Rock dust used to prevent explosions may create a dust hazard.

Coal dust suspended in air is explosive because coal dust has far more surface area per unit weight than lumps of coal and is more susceptible to spontaneous combustion. Some of

the worst mining accidents in history have been caused by coal dust explosions, such as the disaster at Senghenydd in South Wales in 1913 in which 439 miners died, the 1906 Courrières mine disaster in Northern France which killed 1099 miners, the 1962 Luisenthal Mine disaster in Germany, which claimed 299 lives, and the explosion at Benxihu Colliery, China, which killed 1549 in 1942.

PHYSICAL AND CHEMICAL PROPERTIES

Coal mine dust is a complex and heterogeneous mixture containing more than 50 different elements and their oxides. The mineral content varies with the particle size of the dust and with the coal seam.

Coal comes in four main types or ranks: lignite or brown coal, bituminous coal or black coal, anthracite, and graphite. Each type of coal has a certain set of physical parameters which are mostly controlled by moisture, volatile content, and carbon content. Coal is composed primarily of carbon along with variable quantities of other elements, chiefly hydrogen, sulfur, oxygen, and nitrogen. Relative density of the coal depends on the rank of the coal and degree of mineral impurity. The physical properties of coal dust vary depending on the specific type of coal.

ENVIRONMENTAL FATE AND BIOACCUMULATION

It is unknown whether and to what extent toxic heavy metals (arsenic, cadmium, barium, chromium, selenium, lead, mercury) from coal dust leach into water. Coal dust may negatively affect vegetation by reducing growth, reducing reproduction, and causing leaf lesions and partial defoliation (Farmer, 1993). Fluoride and sulfur compounds are also contained in coal dust, and their fate and effects on the environment are unknown.

There are no data regarding the bioaccumulation of coal dust in aquatic organisms.

ECOTOXICOLOGY

Coal and coal dust have the potential to affect marine and estuarine organisms and habitats through abrasion, smothering, alteration of sediment texture and stability, reduced availability of light, and clogging of respiratory and feeding organs (Ahrens and Morrisey, 2005). It is likely that significant coal and coal dust from transfer activity and cargo spills will become deposited in the marine/estuarine environment (Johnson and Bustin, 2006).

Ahrens and Morrisey (2005) reported that particles of coal in suspension in the water column reduced the

amount and possibly the spectral quality of light reaching the sea bed. Moreover, deposition of coal dust on plants decreased photosynthesis, and killed eggs of fish and invertebrates by smothering them. Species richness and biomass were also found to decline with the change of sediment composition.

MAMMALIAN TOXICOLOGY

Acute Effects

Coal dust exposure can induce an acute alveolar and interstitial inflammation. There is a two-step inflammatory response to acute coal-dust exposure. In an acute phase, there is lymphocyte infiltration and some neutrophil recruitment followed by a chronic phase of macrophage predominance (Pinho et al., 2004).

Chronic Effects

Chronic inhalation of coal dust can cause several lung disorders, including simple coal workers pneumoconiosis (CWP), progressive massive fibrosis (PMF), chronic bronchitis, lung function loss, and emphysema.

Studies have shown some decreased pulmonary function even at permissible exposure limits (PELs) adopted after 1970. Henneberger and Attfield (1996) followed a cohort of 1915 male coal miners for 13–19 years. They noted annual declines in forced vital capacity (FVC) of 0.10 ml/year per mg/m³/year of cumulative coal dust exposure, and a decrease in forced expiratory volume in 1 s (FEV1) of 0.07 ml/year per mg/m³/year. Seixas et al. (1993) reported decreased FEV1 and FVC in a cohort of 977 workers. Decreases were primarily seen in workers over 25 years of age. Decreases were observed in smokers, nonsmokers, and former smokers, but the largest decreases were in former smokers. Lewis et al. (1996) reported slightly reduced pulmonary function independent of smoking in British coal miners without pneumoconiosis.

Coal Workers' Pneumoconiosis Coal workers' pneumoconiosis may be simple or complicated. Simple CWP is defined as having coal macules (discolored tissue) in the lungs <2 cm in diameter, and complicated CWP is defined as having coal macules >2 cm in diameter. Simple CWP is not associated with any clinical signs or symptoms.

There may be an increase in alveolar–arterial diffusion in simple pneumoconiosis as well as evidence of emphysema undetected by X-ray. These findings mean that X-ray pneumoconiosis categories 0 and 1 of the International Classification may be associated with disabling disease. These facts require the attention of U.S. physicians because the 1969 Federal Coal Mine Health and Safety Act awards benefits on

the basis of chest X-ray abnormalities. There is a confusing and serious defect in the law inasmuch as disabling disease of coal workers can occur, as shown by lung function studies and pathological findings, without demonstrable radiographic abnormalities.

Anthracite coal is a more potent inducer of CWP than bituminous coal.

Gastrointestinal Effects It has been suggested that coal particles concentrated in the lung are eliminated by the ciliary cleaning function and then swallowed with saliva, thus reaching the stomach (Ames, 1982). The combustion of coal releases PAHs, including benzo[a]pyrene, a known carcinogen. Hence, it is postulated that dust particles, essentially inhalable, are swallowed and thereby exert a carcinogenic effect upon the stomach.

Inhaled coal dust is swallowed and introduced in the acidic environment of the stomach, where it may interact with nitrosating agents, such as nitrite. Swaen et al. (1995) studied the association between coal dust exposure, pneumoconiosis, and mortality from gastric cancer in a cohort of 3790 miners. Workers employed underground for at least 30 years had a standard mortality ratio for gastric cancer of 154. The increased risk of gastric cancer roughly correlated with years spent underground. Risk of gastric cancer was not elevated in workers with severe pneumoconiosis. The authors proposed that the pulmonary clearance system is so impaired in this group of workers that inhaled coal dust does not reach the digestive tract.

CHEMICAL PATHOLOGY

Depending on the quantity of dust in the lungs, chest radiographs may reveal bilateral, widely disseminated shadows described as linear or nodular opacities. The accumulation of coal dust both inside and adjacent to the respiratory bronchioles may cause distortion of the normal anatomy and may lead to focal emphysema. Infection and dust further destroy the bronchioles leading into the alveoli to produce what is now called centrilobular emphysema or centriacinar emphysema. Depending on the quantity inhaled, coal dust may be distributed throughout the lungs and the lesions of centrilobular emphysema can result in disabling disease. Distortions thus produced lead to shadows on X-ray variously described as confluent, complicated, or characteristic of PMF.

Busch et al. (1981) exposed Wistar rats to bituminous coal dust. They developed lesions similar to simple CWP as described in human subjects. Comparable lesions observed were macules (focal, coal-laden macrophage accumulations associated with increased interstitial reticulin and collagen, with emphysema involving alveoli within the macule), which were of increased size, altered shape, and increased density

in animals experiencing chronic exposures. More advanced lesion types, i.e., micronodule, macronodule, silicotic nodule, Caplan's lesion, and infective granuloma, were not observed in the experimental animals. Focal bronchiolization occurred in animals receiving at least 20-months' exposure. Usually, this pathologic change is not described as a component of CWP.

MODE OF ACTION(S)

The development and progression of CWP occurs with four basic mechanisms: (a) direct cytotoxicity of coal dust or silica; (b) activation of oxidant production by pulmonary phagocytes; (c) activation of mediator release from alveolar macrophages and epithelial cells, which leads to recruitment of polymorphonuclear leukocytes (PMNs) and macrophages, resulting in the production of proinflammatory cytokines and reactive species and in further lung injury and scarring; and (d) secretion of growth factors from alveolar macrophages and epithelial cells, stimulating fibroblast proliferation and eventual scarring (Castranova and Vallyathan, 2000).

Coal particles penetrate the lower respiratory tract and are taken up by the lung macrophages if they are $<5\text{ }\mu\text{m}$ in diameter. In contrast to silica, coal does not harm the macrophages that engulf the dust throughout the lungs. During a bacterial infection the coal-laden macrophage may "dump" the coal particles in the involved lung area, a process that may account for conglomerate lesions visible on X-ray. Inhaled coal containing $<2\%$ silica is held in a reticulin network without causing a fibrotic reaction.

Inhaled coal dust particles can be important sources of reactive oxygen species (ROS) in the lung, and may be significantly involved in the damage of lung target cells as well as important macromolecules, including alpha-1-antitrypsin and DNA. *In vitro* and *in vivo* studies with coal dusts showed the upregulation of important leukocyte recruiting factors, such as leukotriene B3, platelet derived growth factor, monocyte chemotactic protein-1, tumor necrosis factor-alpha, and the neutrophil adhesion factor intercellular adhesion molecule-1. Coal dust particles can stimulate the macrophage production of various factors with potential capacity to modulate lung cells and extracellular matrix.

Miners who have an abnormally high dust-stimulated release of TNF- α have an increased risk of developing CWP (Lee et al., 2010).

In vitro studies indicate strong mechanistic links between iron content in coal and ROS, which play a major role in the inflammatory response associated with CWP (McCunney et al., 2009). The ROS can inactivate alpha-1-antitrypsin. This mechanism may also play an important role in the development of coal workers' emphysema.

SOURCES OF EXPOSURE

Occupational

The major exposures to coal dust occur during mining and processing of coal. In these operations the exposure includes dusts generated not only from the coal but also from adjacent rock strata and other sources. These may increase the quartz component of the airborne dust to about 10% of the total mixed dust, or to even greater levels if significant rock cutting is being undertaken.

Dust levels in underground mines vary considerably according to location within the mine. In general, workers at the coalface receive the highest exposures, while those working progressively further away experience lower exposures. In addition, those employed in locations receiving intake (clean) air are exposed to lower dust levels than those who have to breathe returning air, which has passed the coalface. Most surface workers at underground mines experience lower dust exposures than their colleagues underground. However, some jobs, such as tipple and coal cleaning, involve dust exposures equivalent to some underground occupations.

Although dust levels in surface mines are generally lower than those at underground mines, some jobs put workers at risk for silica exposure and silicosis.

Environmental

Other than in mining, exposure to coal dust can also occur during bulk coal transfer and at sites where coal is used. These sites include power stations, steel and coke works, and plants where coal is refined to produce chemicals or liquid fuels. The domestic use of coal for heating is another potential source of exposure to coal dust. However, information on these other exposures to coal dust is limited.

INDUSTRIAL HYGIENE

Twentieth-century medical reports of lung damage first appeared in all coal mining countries at about the same time, between 1928 and 1936. After World War II, considerable effort was spent on studying and controlling diseases of coal miners, an activity continuing today. Economic interests, strengthening of unions, health legislation, and the action of citizen groups, including miners and their families, have played a part in forcing control of coal-mining diseases. Efforts culminated in the United States with the passage of the Federal Coal Mine Health and Safety Act of 1969, which created the Mine Safety and Health Administration (MSHA). From this point on, regulations regarding coal dust exposure have been promulgated by MSHA.

Although this plan has improved conditions greatly through engineering controls and routine air measurements, coal dust-related health effects have not been abolished completely.

The most common route for coal dust exposure is through inhalation. Dermal absorption and ingestion patterns are negligible. Poor ventilation and drilling procedures are the major determinants of exposure. The cost effectiveness and optimum control measures are generally site specific for mining operations. The depth and angle of the tunnel, number of workers, and drilling procedures vary among mines and will affect dust levels and engineering procedures. Individual control measures should be evaluated and implemented as the requirements indicate.

The general plan for coal dust exposure controls is a multilayered approach, including engineering and administrative controls. Ventilation is the most important step to reducing airborne concentrations of coal dust. Directional fan systems can be used to drive sources of coal dust away from machine operators. Increased automation has allowed for higher concentrations in areas where no workers are expected. MSHA requires periodic sampling of mines to monitor the concentrations. Damp conditions help keep air concentrations of coal dust low. Sprayers and water jets associated with the drilling procedure are used to keep dust settled.

Respirators are also necessary to protect worker's health. Simple paper masks are not effective in limiting exposure and should not be used. The proper respirator should be chosen to maximize protection and minimize breathing interference. A common administrative control for reducing exposure to coal dusts is to reduce the amount of time a worker spends in high coal dust areas.

The current Occupational Safety and Health Administration (OSHA) PEL for the respirable fraction of coal dust (<5%silica) is 2.4 mg/m³ time-weighted average (TWA) concentration. The National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit (REL) for coal dust in industries other than mining is TWA 1 mg/m³ [measured according to MSHA method (CPSU)] or TWA 0.9 mg/m³ [measured according to ISO/CEN/ACGIH criteria]. The American Conference of Governmental Industrial Hygienists (ACGIH) has assigned the respirable fraction of coal dust containing <5% crystalline silica a threshold limit value (TLV) of 2 mg/m³ as a TWA for a normal 8-h workday and a 40-h workweek, or 0.1 mg/m³ if 5% or greater SiO₂. The ACGIH limit is based on the risk of pneumoconiosis.

The National Fire Protection Association (NFPA) has not assigned a flammability rating to coal dust. Other sources rate coal dust as a fire hazard and consider the airborne dust an explosion hazard when these substances are exposed to heat or open flame.

RISK ASSESSMENTS

Although current mining procedures and regulations have reduced occupational exposures and cases of CWP, chronic exposure to low levels of coal dust is still capable of causing an adverse health effect. Attfield and Morring (1992) reported a 9% theoretical risk of a worker developing CWP with a working lifetime exposure to 2 mg/m^3 for coal dust. Considering the large number of mining employees in the west and central regions of the United States, there will still be many reported cases of occupational respiratory effects in the future.

The risk of CWP pneumoconiosis increases with duration of exposure, dust concentrations, and hardness of coal (Attfield and Seixas, 1995).

According to International Agency for Research on Cancer (IARC), coal dust cannot be classified as to its carcinogenicity to humans due to inadequate evidence in humans and in experimental animals.

GRAPHITE

First aid: Remove the patient from exposure to fresh air. If the eyes are exposed, immediately irrigate the affected eye thoroughly with water or 0.9% saline. Provide treatment for any symptoms that may arise.

Target organ(s): Respiratory system, cardiovascular system.

Occupational exposure limits: OSHA PEL—TWA 15 mg/m^3 (total) TWA 5 mg/m^3 (respirable); NIOSH REL— 2.5 mg/m^3 TWA (respirable); ACGIH TLV— 2 mg/m^3 TWA (respirable); IDLH— 1250 mg/m^3 .

Hazard/precautionary phrases: H319—causes serious eye irritation; H335—may cause respiratory irritation.

BACKGROUND AND USES

Graphite is a soft, crystalline form of carbon that occurs naturally and can also be produced artificially. Graphite (black lead, plumbago, mineral carbon; CAS 7782-42-5) is one of two forms of natural carbon, the other being diamond. It is an odorless solid with a steel gray to black appearance and a greasy feeling. Granite and other metamorphosed rock contain graphite and when it is mined, free silica becomes airborne. Synthetic graphite (CAS 7440-44-0) has a well-developed crystalline structure. Graphite is used in foundries; in the electrical industry; in lead pencils; in the manufacture of carbon black and electrodes; in the rubber industry; and in heat exchangers, pumps, and valves. For certain nuclear reactor operations, the graphite must be pure (i.e., free of naturally occurring traces of other metals and silica).

Natural graphite may be classified as crystalline or microcrystalline (sometimes referred to as amorphous), and

contains various impurities, such as silica (quartz). The content of free silica in natural graphite varies considerably, and can be as high as 11% or more. Synthetic graphite is almost pure crystalline carbon. The quartz content of synthetic graphite is <1%. Graphite is extremely resistant to heat and chemicals, and is therefore used in metallurgy, in foundries, in the chemical industry, etc. Natural graphite is used in the production of steel and cast iron and (in powdered form) in casting sand. Natural graphite was once widely used in the production of fireproof materials for blast furnaces, crucibles, solder ladles, etc., but it has now been largely replaced by synthetic graphite. Natural graphite is also used in brushes for motors and generators. Carbon electrodes used in steel production, electrochemical processes etc., and components for atomic reactors (neutron moderators) are made with synthetic graphite. Both synthetic graphite and high purity natural graphite are used in lubricants. Pencils contain natural graphite in microcrystalline form.

PHYSICAL AND CHEMICAL PROPERTIES

Graphite exists as a black or gray crystalline mass and occurs naturally in lump, amorphous, and flake forms. It is found in most parts of the world and is usually found with impurities such as quartz, mica, iron oxide, and granite. The crystalline silica content of natural graphite can range from 2 to 25%. Synthetic graphite contains <1% silica, if any.

Graphite is one of the softest minerals known and, on rare occasions, is found in hexagonal crystal form. It is insoluble in water and has a vapor pressure of 0 mm Hg. Graphite has a molecular weight of 12.01 g/mole, a melting point of 3650 °C, a density of 2.09–2.23 g/cm³, and a specific gravity of 2.25 (water = 1).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Graphite is insoluble in water and, therefore, would not be expected to be transported in surface of ground water. Although it may be ingested by bottom feeders, it is not expected to accumulate in aquatic organisms. No volatilization is expected to occur under natural conditions. Graphite could be present in air as particulate matter which has a settling time of days.

ECOTOXICOLOGY

The LC₅₀ is >100 mg/l in *Daphnia magna* (water flea) and *Oncorhynchus mykiss* (rainbow trout).

MAMMALIAN TOXICOLOGY

Acute Effects

Acute health effects from graphite exposure have not been reported.

Chronic Effects

Pneumoconiosis may occur among graphite workers. The amount of graphite inhaled and the quantity of free silica determine the clinical and pathological determinants. Pneumoconiosis has been reported from graphite dust exposure in mining, milling, and grinding; in carbon electrode manufacturing; and in pure carbon production from carbon and soot dust (Hanoa, 1983). Case reports have demonstrated that high level exposure to graphite or other relatively pure forms of carbon dust produce chest X-ray and pathological effects like those caused by coal with low silica content. Because varying amounts of fibrogenic silica dust are inhaled with graphite in all but a few work exposures, the clinical picture may be more or less like silicosis. Iron dust may also be inhaled with graphite to produce a modified dust effect.

CHEMICAL PATHOLOGY

The earliest changes that appear in X-rays may be the disappearance of normal vascular markings, with the appearance later of pinpoint and macronodular densities in all lung fields. Small nodular hyperattenuating areas (ill-defined or well defined, corresponding to macular lesions along the walls of bronchioles and nodules, respectively) are most often observed in CT scans of people with graphite pneumoconiosis (Akira, 1995). Interlobular septal thickening and large hyperattenuating areas are sometimes observed.

MODE OF ACTION(S)

Pure graphite is inert (Pendergrass et al., 1968). However, graphite dust containing silica is fibrogenic. Fibrosis associated with graphite exposure is possibly due to concomitant silica exposure (Hanoa, 1983).

SOURCES OF EXPOSURE

Occupational

Occupational exposure to graphite may occur in mining and in other industries that employ the substance. A variety of occupations use graphite, due to its many uses. These uses include for “lead” pencils, refractory crucibles, stove polish, as pigment, lubricant, graphite cement, for matches and

explosives, commutator brushes, anodes, arc-lamp carbons, electroplating, polishing compounds, rust and needle-paper, coating for cathode ray tubes, and as moderator in nuclear piles.

In the production of dry cells and storage cells, graphite powder is mixed with the active mass to increase the electrical conductivity. The conductivity of natural graphite powder is also used in plastics (against static charge buildup), explosives (against ignition by friction), and conductive lacquers.

Environmental

Although graphite occurs naturally, exposure to graphite is expected to be primarily occupational.

INDUSTRIAL HYGIENE

Industrial hygiene assessments should be conducted to include dust monitoring, hazard analysis, and providing the results to exposed workers and their supervisors.

Engineering controls may include: attaching a dust control system to power tools; using a wet spray method if feasible to suppress dust during sand blasting, jack hammering, or other construction activities; and when feasible, using a local exhaust ventilation system to remove dust from the work area.

A half or full-face air-purifying respirators with the appropriate filters must be used if concentrations of silica are at or above the PEL. Safety glasses or goggles should also be worn.

RISK ASSESSMENTS

The degree of risk from graphite exposure is correlated to the silica concentration. A large concentration of silica would pose more risk than dust containing a small concentration. Steenland and Brown (1995) calculated the risk of silicosis from exposure to silica based on a cohort of gold miners. They calculated that a worker exposed to the OSHA PEL [10/(% SiO₂ + 2) (respirable) or 30/(% SiO₂ + 2) (total) TWA for 45 years would have a theoretical 35–47% chance of developing silicosis.

MISCELLANEOUS MIXED DUSTS

CLAYS

Clays are natural fine-grained materials found in the earth, with particle sizes not exceeding 4 µm in diameter. They are formed by sedimentation, hydrothermal action, or weathering. The mineral components of clay materials are crystalline hydrous aluminum silicates. A large variety of clays are found in nature, and many have specific applications in industry.

Brick clays are used for building, and fireclay is used where resistance to high temperature is required. Kaolin (china clay; CAS 1332-58-7) is a gray powder used in the manufacture of porcelain, as a textile dressing, and as a filler in paper; it is also a well-known ingredient in certain medications. The main constituent of kaolin is aluminum silicate. Before purification, kaolin clay may contain some quartz and mica from the granite rock in which it occurs and is formed. This clay has been widely studied for its health effects. Attapulgite (CAS 12174-11-7) is a gray to yellow fibrous aluminum–silica complex with similar characteristics to kaolin. It is used as a colloidal substance in pharmaceuticals such as antidiarrheal medications, pesticides, and other products. Shales are related to clays because they are impure silicates of aluminum and are mined to extract mineral oils.

The primary route of exposure to clay dusts is inhalation. Free silica may be inhaled in some operations in which clay is the chief dust and there is little control of dust levels. Because of mechanization of some industries and especially the replacement of the older wet process for preparing kaolin, large amounts of dust may reach the lungs. Control measures for clay dusts have steadily improved since they were determined to be a health hazard years ago. The actual mining of clays is not usually considered hazardous because the clay is wet. Personal protection from inhalation exposures is important in those areas of the clay process responsible for expected high concentrations, generally the milling and bagging of fine clay particles.

NIOSH has set a REL for kaolin particles at 10 mg/m³ for total exposure and 5 mg/m³ for respiratory exposure. The OSHA has established a PEL similar to NIOSH for respiratory exposures, but a less stringent 15 mg/m³ for total exposure. The ACGIH has set a TLV–TWA for kaolin at

2 mg/m³. Kaolin is not considered classifiable as to its carcinogenicity.

Worker exposure to clays may be hazardous because there are a few reports of pneumoconiosis and other effects after chronic exposure. A study of a large population of workers in kaolin production indicated some radiographic opacity changes associated with clay dust exposures, but no overt health effects were reported (Rundle et al., 1993). Cases of mixed dust pneumoconiosis may occur, with the fibrogenic behavior of silica dominating the clinical and pathological findings. The ensuing simple or complicated pneumoconiosis occurring similarly in coal workers may end fatally because of massive fibrosis and may be associated in some cases with pulmonary tuberculosis.

Workers exposed to attapulgite clay do not demonstrate the health effects of those exposed to kaolin. Waxweiler et al. (1988) reported no significant excesses for any cause of mortality in exposed miners. Some hemolysis was observed when this clay was incubated with human red blood cells. However, this is not a great concern because this compound will most likely not enter the bloodstream during occupational exposures (Perderiset et al., 1989). The substance is not classifiable as to its carcinogenicity.

FULLER'S EARTH

Fuller's earth is a variable material that will decolorize mineral and vegetable oils. Its name is derived from an old process of cleaning raw wool by kneading it in water to which earths have been added to absorb dirt and oil, a practice known as "fulling." Fuller's earth is frequently a clay composed of an aluminum silicate (usually montmorillonite) and traces of quartz. It is also used as a filter material, in soaps and pigments, in oil-drilling muds, as an insecticide carrier, and as a paper filler. Bilateral chest X-ray changes in workers exposed over a period of years to fuller's earth demonstrate fine punctate mottling with some coalescence (McNally and Trostler, 1941). There may be scattered pneumoconiosis without the pathological changes of silicosis (Campbell and Gloyne, 1942). The pathological examination of the

lung tissues may show an interstitial collection of dust-laden macrophages associated with mild fibrosis.

GRANITE

Granite is an igneous rock composed primarily of quartz and feldspar, with an admixture of mica and granules of other minerals. The chest disease of granite workers appears to be silicosis. When workers are exposed to granite dust with low silica levels, there are no differences in pulmonary function tests (Graham et al., 1994). After chronic silica exposures, the severity of disease can be measured by both lung function studies and chest radiographs. It is possible to measure diminution in lung function as long as 13.5 years before chest X-ray abnormalities appear in granite quarry workers exposed to silica.

MICA

Mica occurs in nature in several forms (muscovite, phlogopite, and others) and is composed of potassium-aluminum silicate. This mineral, which occurs in flat sheets, is used for stove and lantern windows, paper and paint manufacture, and in insulators and dielectrics in the electric and electronic industries. There are reports of pneumoconiosis as a result of heavy exposure to mica over a period of 5 years or more. Complaints of dyspnea and cough have been described with changes in the lungs, especially the mid-zones, visible by chest X-ray.

The NIOSH has set the REL for mica containing <1% quartz at 3 mg/m³. The OSHA has set the PEL at 20 million particles per cubic foot of air. The ACGIH has set the TLV at 3 mg/m³.

Landas and Schwartz (1991) reported the case of a worker who had a long history of extensive exposure to mica. He presented 30 years later with a chronic nonproductive cough

and progressive shortness of breath. Pulmonary function testing revealed restrictive lung changes and a 50% reduction in diffusion capacity. A computed tomography scan showed diffuse interstitial fibrosis. Bronchoalveolar lavage revealed abundant rectangular flaking crystals. Energy-dispersive spectroscopy and electron diffraction studies confirmed the material to have the features of mica.

A controversy in the literature exists as to whether mica induces pneumoconiosis. An extensive review of the experimental and epidemiological papers, and case studies involving mica exposure up to 1985, reported only a few descriptions of pneumoconiosis due to pure mica exposure in humans and inadequate data on the potential for collagen deposition in experimental animals (Skulberg et al., 1985). Other reviews concluded that mica has a relatively low fibrogenic potential (Jones et al., 1994). However, several case reports presented with careful pathological and mineralogical analysis leave little doubt that mica with low quartz content can be associated with the development of disabling forms of pneumoconiosis (Davies and Cotton, 1983; Landas and Schwartz, 1991; Zinman et al., 2002). Furthermore, there is clear evidence that exposure to fine sericite particles is associated with the development of functional and radiological changes in workers inducing mixed dust lesions, which are distinct histologically from silicosis (Algranti et al., 2005).

SLATE

Slate is a metamorphic, fine-grained rock derived from sedimentary deposits. Its components include silica, aluminum

silicates, and small amounts of chlorite, hematite, magnetite, and various carbonates. The flaky crystal structure is, in part, from mica and other constituents of slate, including quartz and other minerals.

There are a number of reports of pneumoconiosis in workers who handle slate, as well as in those who mine and quarry it. The mining and processing of slate may result in concurrent exposure to silica and silicosis. Dust control measures have been successfully implemented in many areas to reduce silica and slate dust exposure.

Oldham et al. (1986) conducted a mortality study of 725 men exposed exclusively to slate dust between 1975 and 1981. There was a high prevalence of pneumoconiosis, particularly among smokers. However, this ailment did not significantly contribute to mortality. Smokers in the cohort had a 76% greater risk of mortality than nonsmokers compared with a 50% greater mortality for smokers in the control group. Mortality associated with slate dust exposure was 0.25% for nonsmokers and 26% for smokers.

Reports vary from descriptions of slight X-ray changes to severe dust disease, inhalation of varying percentages of free silica explains this difference because the amount of such free silica is said to vary from 7% to as much as 35%.

REFERENCE

CALCIUM DUSTS

This category includes lime, limestone, gypsum, marble, and cement, which is a complex compound of lime. Many dusts of calcium are soluble in lung tissue and thus cannot cause pneumoconiosis. Most series of cases reported for workers with heavy or long exposures to calcium dusts describe ill-defined or no chest X-ray changes. Workers disabled as a result of exposure to calcium dusts are considered to suffer damage because of the silica content of such dust.

Because cement varies in composition, the literature on its effects on the lungs is confusing. Cement is described as 62% calcium oxide (CaO) and 22% silicon dioxide (SiO_2), but the amount of silica may be reduced to 6.5% in some processes and only 1% in finished cement. Although there are scattered case reports of pneumoconiosis diagnosed by X-ray or at necropsy, surveys of cement workers suggest that cement remains a relatively harmless dust. Animal studies have supported the view that cement dust is biologically harmless. Without proper engineering controls and

personal protection, however, cement remains irritating and causes dermatitis, rhinitis, and pharyngitis.

Vestbo and Rasmussen (1990) and Vestbo et al. (1991); in their two studies of 546 cement factory workers, concluded that long-term exposure to cement dust did not lead to higher morbidity from severe respiratory disease and did not increase the risk of lung cancer. However, Zeleke et al. (2011) concluded that there is a higher prevalence in lung function reduction and chronic respiratory symptoms among workers in the cement industry due to high cement dust exposure.

SYNTHETIC VITREOUS FIBERS

THOMAS TRUNCAL AND YEHIA Y. HAMMAD

Target organ(s): Skin, eye, respiratory

Occupational exposure limits:

OSHA:

Regulated in *General Industry* as inert or nuisance dust:

Respirable fraction: 5 mg/m³

Total dust: 15 mg/m³

Shipyard: Fibrous glass

Respirable fraction: 5 mg/m³

Total dust: 15 mg/m³

Shipyard: Mineral wool

Respirable dust: 5 mg/m³

Total dust: 15 mg/m³

NIOSH: Fibrous glass dust:

Total dust: 5 mg/m³

Fibers with diameter equal or <3.5 µm, and length ≥10 µm:
3 f/cc

RCF: REP 0.5 f/cc with action level of 0.25 f/cc

ACGIH: Synthetic vitreous fibers

Continuous filament glass fibers: 1 f/cc* A4

Continuous filament glass fibers: 5/mg/m³** A4

Glass wool fibers: 1 f/cc* A3

Rock wool fibers: 1 f/cc* A3

Slag wool fibers: 1 f/cc* A3

Special purpose glass fibers: 1 f/cc* A3

Refractory ceramic fibers: 0.2 f/cc* A2

MRLs: A minimal risk level (MRL) of 0.03 WHO fibers/cc has been derived for chronic-duration inhalation exposure to refractory ceramic fibers

Risk/safety phrases: [list information for classification and labeling]

Post warning labels and signs (in English and the predominant language of workers who do not read English, or verbal) describing the health risks associated with RCF at entrances to work areas and inside work areas where airborne concentrations of RCF may exceed the REL

Depending on work practices and the airborne concentrations of RCF's state on the signs the need to wear protective clothing and the appropriate respiratory protection for RCF exposures above the REL

BACKGROUND AND USES

Man-made mineral fibers as the name suggests do not occur in nature. It is a generic name for a group of silica-based inorganic fibers manufactured from varying concentrations of rock, slag, glass, clay, and processed inorganic oxides. Other names include man-made vitreous fibers (MMVF), vitreous fibers,

*Fibers longer than 5 µm; diameter <3 µm; aspect ratio >5 : 1 as determined by the membrane filter method at 400–450× magnification (4-mm objective) phase contrast illumination.

**Measured as inhalable particle

A2: Suspected human carcinogen

A3: Confirmed animal carcinogen

A4: Not classifiable as a human carcinogen

manufactured vitreous fibers, synthetic vitreous fibers, glass wool (GW), continuous glass filament, special purpose glass fiber, or mineral wool. Depending on the process, MMVF are produced as a mass of tangled, discontinuous fibers of varying length and diameters or as filaments, which are continuous fibers of intermediate length with diameters that are more uniform and typically thicker than wool (IARC, 2002). Their noncrystalline or amorphous molecular structure facilitates early removal from the lung parenchyma, which differentiates them from crystalline forms of fibers.

In an effort to reflect the changes in industry as well as consider the variability in toxicity and the potential for causing cancer among the groups of MMVF, the World Health Organization (WHO) updated and expanded the classification of man-made mineral fibers into two main

categories: filaments that include continuous glass filament and wools that include glass (insulation and special purpose), rock (stone), slag, refractory ceramic fibers (RCF), and other unspecified fibers, including high temperature (HT), high alumina, low silica, or alkaline earth silicate (AES) wools. The term whisker is used for thin inorganic fibers in crystalline form, which are placed in a different category. Examples include potassium titanate, potassium octatitanate, and silicon carbide, which unlike amorphous inorganic forms of MMVF have definite fibrogenic potential in lung tissue. In addition to the inorganic form, man-made fibers also occur in the organic form. These include natural polymers, most commonly viscose made from cellulose, or synthetic polymers, which include acrylic, polyester, polyurethane, and nylon (Figure 94.1).

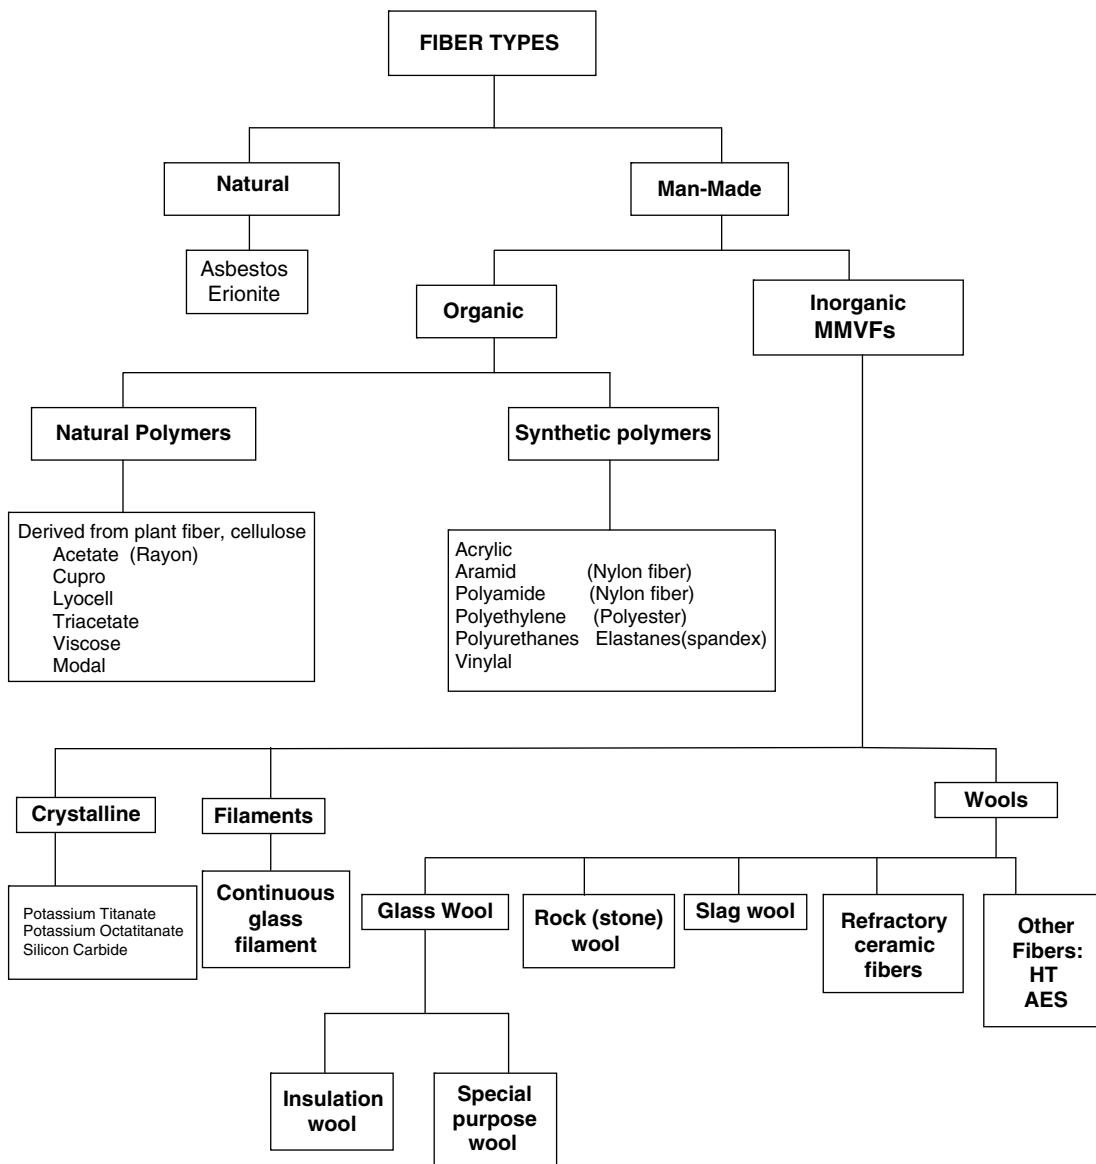

FIGURE 94.1 Classification of man-made fibers.

Historically, organic fibers have not been associated with occupational lung disorders until recently when a cluster of unexplained interstitial lung disease cases developed in the nylon flocking industry (Kern et al., 1998). In 2002, the WHO estimated that over 9 million tons of MMVF were produced annually in over 100 factories around the world. Primary applications include thermal or acoustical insulation where GW (~3 million tons, used predominately in the North America), and rock (stone) and slag wools (~3 million tons, used predominately in Europe and the rest of the world) are used in many cases as a replacement for asbestos. More recently, rock (stone) and slag wools have been replaced by high alumina, low silica wools (~1 million tons) for these applications. Special purpose glass developed for its durability is used in applications that require thermal insulation, such as the aircraft industry as well as for other purposes, including filtration media and batteries. Continuous glass fibers (~2 million tons) are used as reinforcement of plastics and textiles in the automobile, electrical, and building industries. Refractory ceramic fibers (150 thousand tons) are most often used during HT applications as insulation for furnaces and heaters (IARC, 2002). Alkaline earth silicate wools (~20,000 tons), developed in the 1980s in response over the fibrogenic and malignant potential of RCF, are a new class of fibers capable of being used as a substitute in a wide range of HT applications (Brown et al., 2012).

PHYSICAL AND CHEMICAL PROPERTIES

Man-made mineral fibers are divided based on the method of production, chemical composition, and application. Glass fibers, which include continuous filament fibers and GW,

consist mainly of silicon dioxide and varying amounts of intermediate stabilizers, including aluminum, zinc, and titanium. Other oxides acting as modifiers include lithium, potassium, calcium, magnesium derived from dolomite, or boric acid from calcium borate. Varying the concentration of stabilizers and modifiers will alter the chemical and physical properties of the fiber resulting in changes in durability, heat and water resistance, and in solubility. The average diameter of continuous glass fibers ranges from 3 to 25 µm with lengths solely dependent on the industrial process. Ordinary GW diameters range from 3 to 15 µm and special purpose GW have diameters ranging from 0.1 to 10 µm. Category "c" fibers are considered special application fibers and make up <1% of the total glass fibers produced. The ability to distinguish between several types of glass fibers depends not only on the dimensions but also on their composition (Table 94.1).

Mineral wool is a term used to describe rock (stone) and slag wools in the United States, although in Europe, GW is included in the category. Rock and slag wools are composed mainly of calcium, aluminum, or magnesium silicates (-Table 94.2). Rock wool (RW) is derived by heating igneous rocks (basaltic, diabase, or olivine), which are classified based upon their alkali–silica content. Slag wool is produced by melting and fiberizing slag (wastes) from furnace iron and other raw materials, including clay, sand, and limestone. Naturally, the chemical properties will be dependent on the content of the slag that is used. Bonded wool is produced with the addition of urea–phenolic resin and is processed into ceiling tiles or used for blown insulation or other insulation material. The manufacturing process using centrifugation produces discontinuous fibers with diameters ranging from 3.5 to 7 µm.

TABLE 94.1 Composition of Various Glass Fibers

Component	C	D	E	S	AR
SiO ₂	55–65	72–75	52–56	55–85	60–70
Al ₂ O ₃	1–5	0	12–16	10–35	0–5

C fibers (chemical glass) typically glass wool and resistant to acids.

D fibers are sold as textile yarns.

E fibers (electrical glass) resistant to water and used for electrical applications.

S glass has the highest tensile strength and stiffness.

AR glass (alkali resistant) used for strengthening cement.

TABLE 94.2 Fiber Composition by Percent Weight of Mineral Wool and Ceramic Fibers

Component	Rock Wool	Slag Wool	Kaolin	Zirconia	Aluminum Silicate and Al Silicate	High Purity AES Wool	High Alumina Low Silica

Refractory ceramic fibers sometimes called refractory fibers or ceramic fibers are characterized by their ability to withstand temperatures as high as 3000 °F and are used primarily for HT or aerospace applications. Refractory fibers consist mainly of kaolin clay, aluminum silicate with various metallic oxides (chromous, zirconia), or highly purified aluminum silicate (Table 94.2). Where HT applications are needed, fibers can contain more than 90% zirconia oxide. Ceramic fibers are unique in that they occur initially as amorphous structures but when heated the alumina–silica matrix changes to mullite, forming an aluminosilicate crystalline compound (Naval Environmental Health Center, 1997; IARC, 2002). As temperatures approach 1100 °C, excess silica is crystallized in a process known as devitrification to form crystabelite, which is considered to be carcinogenic to humans. Fibers containing higher concentrations of aluminum or zirconium oxides are able to retain their chemical structure and physical characteristics even when exposed to HTs. The average diameter of RCF ranges from 1 to 5 µm (Naval Environmental Health Center, 1997; WHO, 2000).

Alkaline earth silicate wools are produced by melting a combination of silica, calcium and magnesium oxide, alumina, titania, zirconia, and trace oxides. Commercially available in the 1990s they are primarily used in industrial equipment, fire protection, and automobile exhaust systems.

Manufacturing Process

The production of MMVF first involves liquefying raw materials, including sand, kaolin, aluminum silicate, or igneous rock, where they can be solidified and used at a later date or they can be used immediately. Continuous fibers or filaments are produced exclusively from glass, as the molten material is extruded using a set of bushings or spinnerettes. Insulation wools are constructed as molten raw

materials are extruded through small holes in a rotary or centrifugal method, producing fibers of variable diameters. When the molten glass emerges from the holes, they are stretched by a rotary or centrifugal force and cooled by air into individual fibers. The diameters of these fibers can be adjusted with great accuracy and reproducibility to 6–25 µm. Flame attenuation refers to the special purpose glass fibers that are remelted by a jet flame blast after they are stretched into individual fibers. They are typically used for extreme temperature applications such as the skin of the space shuttle.

Once the fiber is made, various binding resins, including phenol formaldehyde, are used to give structure and rigidity to the fiber. Because glass filaments are fragile, sizings are added and used as a protective coating to increase the adhesion between the fibers. These include polyvinyl silane, epoxy silane, and polyvinyl acetate chrome chloride mixtures. Other lubricating or paraffin oils can be added to decrease dust generation during production of the end product (Naval Environmental Health Center, 1997; ATSDR, 2004).

MAMMALIAN TOXICOLOGY

Acute Effects

Skin irritation is the most common health effect associated with an exposure to MMVF. Irritation is usually related to mechanical trauma from coarse fibers measuring 4–6 µm in diameter. Irritation is reduced or resolves completely with continued exposure but returns when there is a lapse or interruption in an exposure for a few days (Lockey and Ross, 1998; Stam-Westerveld et al., 1994). Less commonly, allergic contact dermatitis resulting from sensitization to epoxy resins or hardening by-products used for finishing glass fibers or reinforced plastics have been described (Minamoto et al., 2002; Nogueira et al., 2011; Jolanki et al., 1990).

Symptoms of dry cough, eye, nose, and throat irritation have also been described (Burge et al., 1995) and appear associated with dusty working conditions >1 f/cc involving removal of fiberglass materials in closed spaces without respiratory protection (ATSDR, 2004).

Chronic Effects

Reports of airflow obstruction (Hansen et al., 1999), decrements in forced expiratory volume (FEV₁) (Trethewan et al., 1995; Clausen et al., 1993) irregular opacities, and pleural plaques (Lockey et al., 2002) have been described in workers exposed to MMVF; however, no consistent evidence for increased prevalence of any of these exists.

The National Institute for Occupational Safety and Health (NIOSH) (NIOSH, 2006) concluded that an exposure to RCF may pose a carcinogenic risk based on the results of chronic animal inhalation studies. Likewise, the National Toxicology Program (NTP) concluded that inhalable glass fibers and ceramic fibers of respirable size (3 µm in diameter and length to width (aspect) ratio of 3 : 1) were reasonably anticipated to be human carcinogens based on animal studies (National Toxicology Program). Despite this, epidemiologic studies of workers exposed to MMVF have failed to reveal an increased risk of respiratory cancer or mesotheliomas. In 2009, Lipworth conducted a systemic review and meta-analysis of risk estimates of lung and head and neck (HN) cancer in epidemiologic studies of workers exposed to MMVF, specifically RW and GW and concluded:

despite a small elevation in RR of lung cancer among MMVF production workers, the lack of excess risk among end users, the absence of any dose-risk relation, the likelihood of detection bias, and the potential for residual confounding by smoking and asbestos exposure argue against a carcinogenic effect of MMVF, RW or GW at this time. Similar conclusions apply to HN cancer risk among workers exposed to MMVF

(Lipworth et al., 2009).

Marsh performed a systemic review of the literature published following the 2001 International Agency for Cancer Research (IARC) decision to downgrade insulation GW from a Group 2B to Group 3 carcinogen. Utilizing selected Bradford Hill criteria for the evaluation of epidemiologic associations, they found no statistical significant increase in the incidence of respiratory cancer in workers exposed to MMVF (Marsh et al., 2011). Similarly, as others have mentioned (SCOEL/SUM/88 March, 2012), the NTP concludes,

the data available from studies in humans inadequate to evaluate the relationship between human cancer and exposure to glass wool fibers. Although studies of occupational exposure found excess lung-cancer mortality or incidence, it is unclear that the excess lung cancer was due to exposure

specifically to glass wool fibers, because (1) no clear positive exposure-response relationships were observed (however, misclassification of exposure is a concern), and (2) the magnitudes of the risk estimates were small enough to potentially be explained by co-exposure to tobacco smoking.

The investigators further conclude that the data available from epidemiological studies are inadequate to evaluate the relationship between human cancer and exposure specifically to respirable ceramic fibers (National Toxicology Program).

Mechanism of Action(s)

Fiber toxicity is related to three essential factors that are as follows: An exposure to a sufficient *dose* of respirable fibers with the correct aerodynamic *dimensions* to allow deposition in the terminal portions of the lung (alveoli) and finally, after inhalation, *durability* of a fiber that will allow it to persist in the lung for long periods of time. In addition to the 3 Ds (dose, dimension, durability), alveolar macrophages, surface properties, the chemical composition and biopersistence of the fibers play a role in the elimination and half-life of the fiber.

Respirable fibers or dusts are defined by their ability to bypass the protection mechanisms of the upper airway and lodge on the alveolar surfaces of the lung. Lung deposition depends on the aerodynamic diameter of the fiber. Inhalable fibers, considered fibers with diameters of 3 µm or less with an aspect ratio (length/diameter ratio) >3, will be deposited in the lower airway. Fibers present particular problems because they can be of lengths >15–20 µm yet align parallel to the air current and be inhaled into the lower airway. Fiber dose is dependent on the length since long fibers are unable to be completely engulfed by the alveolar macrophages and thus cleared from the lung. Unlike asbestos fibers that tend to arrange in bundles and are split longitudinally, MMVF tend to occur as individual fibers and break transversely into shorter segments, which allows easier and earlier removal.

Once a fiber enters the lower respiratory tract, clearance is enhanced through removal by mucociliary transport or by the alveolar macrophage. Only those fibers <10 µm can be effectively phagocytized by alveolar macrophages (Oberdörster, 1997; Tran et al., 1996; SCOEL/SUM/88 March, 2012). Incomplete phagocytosis occurs with fibers >20 µm, which in turn leads to an inflammatory and fibrotic response that is associated with activation of various cell lines, including neutrophils, lymphocytes, mast cells, and fibroblasts. This stimulates the release of inflammatory mediators and chemokines (tumor necrosis factor α (TNF α), interleukin-1 α , interleukin 6 and 8, basic fibroblast growth factor, MIP-1 α , growth regulated peptide) and generates reactive oxygen and nitrogen species leading to epithelial and mesothelial cell proliferation (Ishihara, 2001; Churg et al., 2000; Driscoll, 1996; ATSDR, 2004; Morimoto et al., 1999).

Reactive oxygen species (ROS) have also been shown to induce cell injury and death by lipid peroxidation through interaction with fatty acids in the cell membrane. Alveolar macrophages isolated by bronchoalveolar lavage (BAL) and exposed to mineral and chrysotile fibers increase the production of superoxide anion and hydrogen peroxide, depleting the level of glutathione and increasing serum Ca in alveolar macrophages (Wang et al., 1999). Under more acidic conditions, the release of iron from MMVF, particularly refractory fibers, results in the production of hydroxyl free radicals in a similar way as amphibole asbestos (Brown et al., 1998). Further, the release of ROS through contact with highly durable fibers may activate signaling pathways and trigger the secretion of additional growth factors, proteases, and other proinflammatory cytokines (Nguea et al., 2008). Still other mechanisms of MMVF-induced cytotoxicity may involve the depletion of adenosine triphosphate (ATP) in the alveolar macrophage resulting in cell death (Kim et al., 2001). And finally, translocation of fibers from the lung parenchyma to the pleura may play a role in fiber-induced pleural disease (Gelzleichter et al., 1996).

The mechanism of fiber-induced genotoxicity has been investigated using various types of MMVF that have been shown to produce 8-OHdG (possibly resulting in miscoding during DNA replication) (Jaurand, 1997), induce the occurrence of micronuclei and/or polynuclei abnormalities (Hart et al., 1992), stimulate morphologic transformation (Gao et al., 1995) and squamous metaplasia (preneoplastic characteristics) (Woodworth et al., 1983). Long fibers appear to induce the production of bi/trinucleated cells (an early event in asbestos-induced cancers) through incomplete or failed cytokinesis (Jenson and Watson, 1999) and result in oxidative DNA damage, all of which are considered precursors to the initiation of the cancerogenic process (Cavallo et al., 2004).

Chemical Pathology

As discussed, the dose and dimension play a key role in a fiber's ability to produce toxic effects in the lung. Fiber durability, the ability of a fiber to remain in the lung, is dependent on the dissolution rate (solubility) of the fiber. *In vitro* estimates of dissolution rate constants at varying pH for numerous fibers have been published and summarized by Maxim et al., 2006. The chemical components of the fiber influence the rate at which they dissolve. Man-made vitreous fibers composed of calcium, magnesium, and sodium tend to have faster dissolution rates, while alumina and silica tend to decrease the rate of dissolution making them less bio-soluble, thus allowing them to persist in the lung for longer periods of time. *In vitro* evidence suggests that slag wool and RCF dissolve more rapidly at a pH of 4 (simulating the environment following phagocytosis by the macrophage) as opposed to GW, which appears to dissolve more rapidly at a pH of 7.6

(simulating the extracellular environment). Thus the dissolution of fibers may involve both the intra- and extracellular environment and is accompanied by varying degrees of compositional and physical changes to the fiber. Changes in fiber morphology or dimension may in turn alter both the physical and surface chemical properties, ultimately affecting their overall biological reactivity (Bauer et al., 1994). Much of the current research regarding newer formulations of man-made mineral fibers has centered on the development of products that break down easier and faster yet retain their industrial functions. Newer fibers tend to have higher solubility, in essence, limiting the biopersistence and health effects. Biopersistence is therefore the duration a fiber remains in the lung and is determined by the physiologic/mechanical clearance as well as the chemical properties and dissolution rate of the fiber.

SOURCES OF EXPOSURE

Occupational

The IARC concluded that the worldwide average exposure levels during production, processing, and use of these fibers is thought to be generally <0.5 respirable fiber/cm³ as an 8-h time-weighted average (TWA) (IARC, 2002). Those involved in the manufacture, installation, service, removal/repair, or use of these products are expected to be exposed to higher concentrations of the fibers.

Recently in the United States, the Health and Safety Partnership Program (HSPP), a workplace safety program for workers involved in the application of glass and mineral wool products and developed to create an occupational exposure database in the synthetic fiber industry, reported mean concentrations of 0.23–0.28 f/cc for the GW industrial sector and a mean of 0.38 f/cc for those involved in GW installation. Analysis of the mineral wool sector revealed a mean of 0.19 f/cc, with the highest levels in the manufacturing sector with a mean of 0.20 f/cc. In general, airborne concentrations of fibers measured during the production of glass and mineral wool (slag, and/or rock (stone)) are below 1 f/cc, except in areas where small diameter fibers (<1 µm) are produced (aircraft insulation, separation and filtration media) or specific products are used (blowing wool with binder) (Marchant et al., 2002).

Recently, an update to ongoing monitoring studies of an occupational exposure to RCF at plants that produce RCF and customer facilities in the United States was reported by Maxim et al. (2008), who found workers at RCF manufacturing plants to be exposed to TWA concentrations of ≤0.5 f/cc 95.8% of the time and when corrected for respirator use, 97.8% were at or below that level. The average TWA concentration of ceramic fibers adjusted for respiratory use from 2002 to 2006 was 0.28 f/cm³ (NTP, 2011).

Environmental

Exposures to airborne MMVF in both occupational and environmental settings primarily occur as the result of construction, installation, maintenance/repair, physical damage, by degradation, or as MMVF are released to the environment over time. Much of the literature reporting on airborne levels of MMVF in commercial, residential, or ambient air fails to distinguish between organic (cellulose, cotton, nylon), inorganic mineral fibers (silicates and sulfates), or MMVF. Despite these limitations, it appears that an exposure to MMVF in indoor or environmental air is 2–3 orders of magnitude less than the exposure that occurs in an occupational environment (IARC, 2002). Mean air concentrations in 79 buildings containing MMVF products (Gaudichet et al., 1989) ranged from none detectable to 0.006 f/cm^3 , in 16 schools none detectable to 0.08 f/cm^3 (Schneider, 1986), and more than 130 measurements of indoor air in various locations (office buildings, schools, laboratories, private homes) was none detectable to 0.038 f/cm^3 (IARC). In the 1990s, Carter et al. (1999) sampled residential and commercial buildings while taking 21 simultaneous samples from 19 locations using scanning electron microscopy (SEM) to distinguish among the fiber types. The indoor respirable fiber levels averaged 0.008 f/cm with a maximum of 0.029 f/cc using phase contrast optical microscopy (PCOM). Ninety seven percent of the respirable fibers identified by SEM were determined to be organic. Inorganic fiber levels measured indoors using SEM averaged $<0.0001\text{ f/cc}$. The ambient air samples revealed a mean of 0.002 f/cc by PCOM.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration (OSHA) estimates that there are more than 225,000 workers in the United States who are exposed to MMVF in manufacturing and end-use applications (OSHA, 2002). Mineral fibers are currently regulated only as a nuisance dust in general industry as OSHA has no specific permissible exposure limit (PEL) for an occupational exposure to fibrous glass. Inert or nuisance dust is regulated to 15 mg/m^3 for total dust and 5 mg/m^3 for respirable fractions. For employees involved in ship repairing, shipbuilding, shipbreaking or related employments, fibrous glass, and mineral wool (including rock or slag), the PEL is 15 mg/m^3 for total dust and 5 mg/m^3 for respirable fractions. In 1999, the OSHA partnered with various trade organizations and major manufacturers of fiberglass, slag and rock wool insulation products to institute a voluntary HSPP for fiberglass and mineral wool. The program established a voluntary PEL of 1 f/cc 8-h TWA for respirable synthetic mineral fibers (glass/rock/slag wool). The HSPP also established a database, monitored by the North American Insulation Manufacturers Association (NAIMA), of representative exposure limits for workers

involved in manufacturing and end-use applications. It was also recommended that workers wear NIOSH-certified dust respirators when the PEL is exceeded or when performing certain tasks such as blowing SVF insulation into attics and other places and when demolishing buildings.

The current guidelines from the American Conference of Governmental Industrial Hygienists (ACGIH) adopted a threshold limit value (TLV) for an 8-h TWA of 1 f/cc for continuous glass filaments with a A4 (not classifiable as a human carcinogen) rating and 1 f/cc for GW, rock and slag wools, and special purpose fibers with an A3 (confirmed animal carcinogen with unknown relevance to humans) rating. A TLV-TWA of 0.2 f/cc was adopted for RCF with an A2 (suspected human carcinogen) rating (ACGIH, 2001).

In 1977, the NIOSH established a recommended exposure limit of (REL) of 3 f/cc^3 as a TWA for glass fibers with diameters $\leq 3.5\text{ }\mu\text{m}$ and lengths $\geq 10\text{ }\mu\text{m}$ for up to 10 h/day during a 40-h workweek. The NIOSH also recommended that airborne concentrations determined as total fibrous glass be limited to a 5 mg/m^3 of air as a TWA. In an effort to minimize the risk of lung cancer and irritation of the eyes and upper respiratory tract, the NIOSH proposed a REL for RCF of 0.5 f/cm^3 of air as a TWA and an action level of 0.25 f/cm^3 (used for determining when additional actions should be taken to reduce RCF exposures) (NIOSH, 2006). They further recommended that all reasonable efforts be made to reduce exposures to $<0.2\text{ f/cm}^3$ where cancer risk estimates between 0.03/1000 and 0.47/1000 have been extrapolated from risk models (Moolgavkar et al., 1999; Maxim et al., 2003).

Exposure control and prevention is aimed at limiting exposure through a combination of engineering controls and workplace practices. Airborne concentrations can be reduced by adequate ventilation and local exhaust systems, tool selection, modifying workplace practices, and isolation of the manufacturing process to enclose airborne fibers and separate them from the workers. Personal protective equipment is geared at reducing skin, eye, and respiratory irritation and should include long sleeves, gloves, and eye protection when performing dusty activities involving MMVF. When airborne concentrations of RCF exceed the REL, the NIOSH recommends the following respiratory protection: At a minimum, use a half-mask, air-purifying respirator equipped with a 100 series particulate filter (this respirator has an assigned protection factor (APF) of 10. For a higher level of protection and for prevention of facial or eye irritation, use a full facepiece, air-purifying respirator (equipped with a 100 series filter) or any powered, air-purifying respirator equipped with a tight-fitting full facepiece. For greater respiratory protection when the work involves potentially high airborne fiber concentrations (such as removal of after-service RCF insulation such as furnace insulation), use a supplied-air respirator equipped with a full facepiece, since airborne exposure to RCFs can be high and unpredictable (NIOSH, 2006).

MEDICAL MANAGEMENT

For workers exposed to MMVF, a medical monitoring program should be established by providing a baseline medical examination within 3 months of employment. The exam should include a detailed occupational history that gathers information about past jobs, dust or fiber exposures and should include a physical exam with emphasis placed on the skin and respiratory tract, spirometry, chest X-ray, and other tests deemed necessary by the health-care provider. Suggested guidelines for the frequency of periodic examinations have been published by the NIOSH who recommend examinations every 5 years for workers exposed to RCF with fewer than 10 years since first exposure and for those with 10 years or more since first exposure, every 2 years. More frequent evaluations may be required depending on the dose, duration, and intensity of exposures, new or worsening respiratory symptoms, recurrent or chronic dermatitis, exposure to other respiratory hazards (i.e., asbestos), or changes in the job process. Programs should be monitored periodically to identify patterns where workplace practices are linked to worker health and well-being. In addition, medical monitoring programs may be useful in identifying changes needed in job processes or specific exposure conditions.

ORGANIC DUSTS

DAVID R. JOHNSON

INTRODUCTION

Organic dusts are dispersed airborne particles of animal or plant protein, bacteria, fungi, amoeba, and/or molds. The dust can often be complex mixtures of organic and inorganic substances.

SOURCES OF EXPOSURE

The respiratory system is exposed through inhalation of organic dust; then, depending on their size and shape, the component particles may deposit in the respiratory tract and interact with the mucous membranes and epithelial lining of the mouth, nose, sinuses, throat, bronchial system, and/or lungs. The skin and conjunctiva can be directly exposed to airborne particles. Organic dusts can also settle on food and be ingested, however, this is not a pathway commonly associated with organic dust-induced disease.

Exposure to organic dusts occurs in many occupations such as agriculture, veterinarian practices, laboratory workers, researchers, animal caretakers and groomers, wood-workers, food producers and processors, and other manufacturing and production operations. Exposure can also occur at home, during recreational activities, while enjoying hobbies and in other nonoccupational environments.

Thorough and skillfully performed exposure histories are needed due to the complex nature of organic dusts, variations in host characteristics and habits, and the potential for obscure exposures in various occupational and nonoccupational settings.

ASSOCIATED AGENTS AND ANTIGENS

Organic dusts can be composed of a wide variety of organic substances such as animal dander, hair, feathers, serum, urine, and feces; insect parts; microorganisms; plant fibers, leaves, grains, enzymes, and foods. These organic mixtures may contain direct irritants, toxins, endotoxins, high or low molecular weight proteins acting as antigens, and even carcinogens. Examples include: an endotoxin suspected of causing inflammation in organic dust toxic syndrome (ODTS); specific sensitizing and/or precipitating antigens being linked to cases of allergic asthma, and/or hypersensitivity pneumonitis (HP); and a few wood dusts reported to increase the risk of cancer (ACGIH, 2005, Wood Dust) (See Tables 95.1, 95.2 and 95.3).

MECHANISM OF ACTION

Due to the nature and complexity of organic dusts, current science frequently cannot firmly establish the specific putative agent, the mechanism of action, and/or the chemical pathology responsible for an associated disease. For example, a case of occupational extrinsic asthma is generally accepted to be due to IgE type I-mediated immune response; however, multiple mechanisms may be involved, including additional immunologic processes, pharmacological, or genetic mechanisms, as well as airway and neurogenic inflammation (Mapp et al., 1994). Several mechanisms may be at play at any one time. It is not clear if HP is a type III immune complex-mediated or a type IV cellular-mediated disease. The former is supported by the presence of

TABLE 95.1 Examples of Occupational Asthma Associated with Organic Dusts

Occupational Exposure	Agent
*Laboratory workers, researchers, veterinarians, agriculture/farmers, animal caretakers, meat processing, furriers (animal handler's disease)	Animal proteins (hair, dander, serum, urine, feces from rodents, rabbits, horses, dogs, cats, farm animals, etc.)
*Poultry workers, bird handlers, pigeon breeders, feather processing, caretakers, veterinarians (bird handler's disease)	Bird proteins (parakeets, pigeons, chickens ducks, etc.)
Growers, manufacturers, food industry work	Buckwheat
Oil producers, food processors, coffee bean handlers, farmers	Castor bean
*Coffee processors, coffee roasters	Coffee bean dust
*Textile workers and food processors (Byssinosis)	Cotton dust, oils, flax, hemp
*Detergent manufacturers, plastics, food processors, laboratories (detergent workers disease)	Enzymes (e.g., <i>Bacillus subtilis</i> , proteases, amylases, lipases, cellulases)
*Fishermen, food processors, shell grinders, shellfish preparation	Fish and mollusks (crabs, shrimp other shellfish)
*Bakers, millers, food processors (baker's asthma)	Flour: Wheat, rye, barley oats
*Farmers, growers, grain handlers (grain fever)	Grain dust: Wheat, barley, oats
Food processors/handlers	Garlic
Brewery workers	Hops
*Laboratory workers, researchers, breeders, farmers, sewage workers, entomologists, grain workers	Insect proteins (butterfly, cockroach, locusts, maggots, mites, moths, silkworms, weevils)
Humidifiers, office workers, woodworkers, cheese workers, <i>many potential exposures</i>	Molds
Mushroom growers/handlers	Mushrooms
Food processors	Pepper
Gardeners, landscapers, outdoor workers	Pollens
*Tea processing/manufacturing (tea maker's asthma)	Tea
Tobacco growers and processors	Tobacco
*Carpenters, timber millers, construction workers, sawmill workers, lumber production, furniture making, cabinet making, joinery, woodworkers	Wood dusts (<i>many types of wood</i>)

Those marked with an asterisk (*) are further described in the chapter. See text. Additional references include Avila and Lacey (1974), Bielory (1982), Butikofer et al. (1970), Cockcroft et al. (1983), Cormier et al. (1998), Duchaine et al. (1999), Flannigan (1987), Greene et al. (1981), Harper et al. (1970), Huuskonen et al. (1984), Ismaili et al. (2006), Johnson et al. high titers of antigen-specific precipitating serum IgG, the latter by combined cell infiltration and granuloma formation (Girard and Cormier, 2010).

Organic dust toxic syndrome is thought to be a nonallergic and noninfectious condition associated with endotoxin exposure, however, the dusts involved are complex and other mechanisms are likely to be involved. Exposure to wood dust has been associated with nasal cancer; again however, the mechanisms are not clearly delineated.

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

Inhalation of organic dusts has been associated with a wide spectrum of acute and chronic diseases of the respiratory system, including upper respiratory allergy, irritation and inflammation, bronchitis, asthma, HP, also called extrinsic allergic alveolitis (EAA), granulomatous disease, interstitial lung disease (fibrosis) and in a few cases, cancer. Skin or mucous membrane exposure, irritation, sensitization, and subsequent reactions are also reported. The clinical picture

varies depending on the status of the host, the organic dust involved, as well as the intensity and duration of exposure.

Linking clinical findings to specific organic dust exposure in the workplace can be challenging. Exposure must be well documented and temporally defined and be associated with established clinical signs and symptoms. Given this, and depending on the situation at hand, supportive diagnostic studies may include one or more of the following: a chest X-ray (CXR), pulmonary function testing (PFT), arterial blood gas (ABG) determinations, diffusing capacity (DLCO), a complete blood count (CBC), IgE antibodies, radioallergosorbent testing (RAST), enzyme-linked immunosorbent assays (ELISA), skin allergy testing (prick test, patch testing, end point titration), magnetic resonance imaging (MRI), and/or high resolution CAT scanning (HRCT). Additional testing that may be needed includes pulmonary biopsy, provocation inhalation challenge, and bronchoalveolar lavage (BAL).

As you review the discussions of specific disease syndromes in this chapter, it is helpful to have a general understanding of occupational asthma (OA), HP, and the difference between the two. The reader is also expected to

TABLE 95.2 Examples Hypersensitivity Pneumonitis Associated with Organic Dusts

Disease	Exposure	Suspected Antigens
*Animal handlers lung	e.g., farm, veterinary, caretaker, laboratory, and researcher animals	Animal hair, dander, serum and urine proteins
*Bagassosis	Moldy pressed sugar cane (bagasse)	<i>Thermoactinomyces sacchari, T vulgaris</i>
*Bird handlers disease (bird fanciers lung, bird breeder's lung, pigeon breeder's lung, poultry workers lung, etc.)	Various birds: pigeons, parrots, parakeets, chickens, turkey, ducks, lovebirds, etc.	Avian proteins, serum, feathers, droppings
*Cheese workers lung	Moldy cheese	<i>Penicillium casei or P. roqueforti</i>
*Coffee workers lung	Coffee bean dust	coffee bean dust, <i>Thermoactinomyces spp.</i>
Compost lung	Compost	<i>Aspergillus fumigatus</i>
Dry rot disease	Old houses (Europe)	<i>Merulius lacrymans</i>
*Farmer's lung	Moldy grain, hay, oats, barley, millet	<i>Thermophilic actinomycetes, Aspergillus species, Saccharopolyspora rectivirgula, (Micropolyspora faeni)</i>
Fertilizer workers lung	Dirt; contaminated fertilizer	<i>Streptomyces albus</i>
*Furrier's lung	Animal fur	Animal hair protein
Horseback riders lung	Horses	<i>Sporobolomyces spp.</i>
Malt workers lung	Moldy barley	<i>Aspergillus clavatus, Aspergillus fumigatus</i>
Maple bark strippers lung	Moldy maple bark	<i>Cryptostroma corticale</i>
Mushroom workers lung	Mushroom compost	<i>Thermophilic actinomycetes Thermoactinomycetes vulgaris, Micropolyspora faeni, Aspergillus spp</i>
Papermill workers lung	Moldy wood pulp/dust	<i>Alternaria species</i>
Paprika slicer's lung	Paprika	<i>Mucor stolanifer</i>
Peat moss workers lung	Peat moss	<i>Monocillium species and Penicillium citreonigrum</i>
Pituitary snuff-takers lung	Pituitary snuff	pituitary protein (porcine and bovine)
Sequoiosis	Redwood bark, moldy sawdust	<i>Aureobasidium pullulans, Graphium species</i>
Suberosis	Moldy cork dust	<i>Penicillium glabrum, Penicillium frequentans</i>
Summer-type hypersensitivity pneumonitis	Japanese wood houses, damp wood and mats	Trichosporon cutaneum
Thatched roof disease	Dried grass	<i>Saccharomonospora viridis</i>
Tobacco workers lung	Tobacco dust; fungal spores	<i>Aspergillus species</i>
Wheat weevils disease (Miller's lung)	Infested grain/wheat flour	<i>Sitophilus granaries</i>
Wine-growers lung	Moldy grapes	<i>Botrytis cinerea mold</i>
Wood pulp workers lung	Wood pulp, dusts	<i>Alternaria, Penicillium</i>

Those marked with an asterisk (*) are further described in the chapter. See text. Additional references include ACGIH (2005), Anonymous (1986), Johnson et al. (1981), Mapp et al. (1994), Sigsgaard and Schluesssen (2004), and Zenz (n.d.).

have a prior understanding of occupational rhinitis, conjunctivitis, bronchitis, and dermatitis.

Occupational asthma: Organic dusts have been associated with occupational and nonoccupational asthma; which can be irritant or allergic. Symptoms include dyspnea, wheezing, cough, and mucous production, and usually occur immediately after exposure to an inciting agent but can be delayed for hours or days. Pulmonary

function testing typically shows an obstructive pattern but can be normal between episodes. Pulmonary function testing done pre and post bronchodilator administration can help to measure airway hyperresponsiveness. Chest X-rays are usually normal; evidence of air trapping might be seen during an acute episode. Serial peak expiratory flow rates (PEFR) performed during a work-shift may be helpful in determining the work relatedness of asthma. Various allergy tests

TABLE 95.3 Examples of Cancer Associated with Organic (Wood) Dusts

Wood Dust Exposure*	Occupation	Cancer Classification
Oak, beech	Woodworkers, carpenters, processors, lumber mills	A1—confirmed human carcinogen
Birch, mahogany, teak, walnut	Woodworkers, carpenters, processors, lumber mills	A2—suspected human carcinogen
All other wood dusts	Woodworkers, carpenters, processors, lumber mills	A4—not classifiable as a human carcinogen

Those marked with an asterisk (*) are further described in the chapter. See text. Additional references include ACGIH (2005).

may help to establish allergic asthma and an associated antigen. Sigsgaard et al. described the following steps in the clinical evaluation of OA: (1) confirm a diagnosis of asthma, (2) determine a temporospatial relationship of exposure to symptoms and lung function, (3) determine if the disease at hand is an IgE- or a non-IgE-mediated disease, and (4) perform a specific or nonspecific challenge test. Challenge tests are important in order to distinguish a causal relationship from nonspecific hyper-responsiveness in persons with pre-existing asthma. In these situations, removing the patient from exposure with subsequent challenge tests might be the only way to find the answer (Sigsgaard and Schlunssen, 2004).

Hypersensitivity pneumonitis: Also called EAA, involves the inhalation of allergen and usually develops after years of exposure to organic dusts. A wide spectrum of antigens has been associated with HP and in some cases these antigens can be identified by laboratory testing for specific precipitating antibodies. It is important to remember that while the presence of precipitating antibodies supports the diagnosis of HP, their presence does not confirm disease; likewise, the failure to identify specific precipitating antibodies does not absolutely rule out HP. Hypersensitivity pneumonitis has been reported as acute, subacute, or chronic disease. There are current debates as to whether subacute HP is a clear separate entity. There is an overlap of symptomatology and some think that the classification should only include acute and chronic disease (Lacasse et al., 2009).

Signs and symptoms of HP include fever, malaise, cough, shortness of breath, weight loss, occasional fine basilar rales, and rarely wheezing. Other clinical findings include interstitial markings on chest radiographs, a lymphocytic alveolitis on BAL, and/or a granulomatous reaction on lung biopsies (Lacasse et al., 2012). Radiologic findings have included diffuse ground-glass opacification, centrilobular ground-glass opacities, air trapping, fibrosis, lung cysts, and emphysema. Pulmonary function testing studies typically show diminished lung volumes with a restrictive pattern, however, airway obstruction may also be seen in chronic cases. Impairment of gas diffusion and hypoxemia may be present. Bronchoalveolar lavage in HP shows high total cell and lymphocyte counts, moderate neutrophilia, mild eosinophilia, and mastocytosis (Caillaud et al., 2012; Ryu et al., 2007). While there are some reports of inversion of the CD4/CD8 cell count ratio in BAL fluid, various other studies have not shown consistent findings of the CD4/CD8 inversion (Ohshima et al. (2012). The histopathologic process of HP consists of chronic inflammation of the bronchi and peribronchiolar tissue, often with poorly defined granulomas and giant cells in the interstitium or alveoli (Hirschmann et al., 2009).

The most widely used diagnostic criteria for HP are those from Richerdson et al. (1989) and these criteria include the

following: (1) the history and physical findings and pulmonary function tests indicate an interstitial lung disease, (2) the X-ray film (CAT scan) is consistent, (3) there is an exposure to a recognized cause, (4) there is an antibody to that antigen (Richerdson et al., 1989; Girard et al., 2009). In a study by Lacasse et al. (2003) six significant predictors of HP were identified: (1) exposure to a known offending antigen, (2) positive precipitating antibodies to the offending antigen, (3) recurrent episodes of symptoms, (4) inspiratory crackles on physical examination, (5) symptoms occurring 4–8 h after exposure, and (6) weight loss.

Hypersensitivity pneumonitis vs. allergic asthma: Simply put, allergic (extrinsic) asthma and allergic rhinitis are both considered an IgE-mediated disease whereas the mechanism of HP is *not* considered to be an IgE-mediated disease. Hypersensitivity pneumonitis is thought to be either a type III immune complex and/or a type IV cell-mediated reaction demonstrating some pathologic findings to support both (Blatman and Grammer 2012). It is possible for both asthma and HP to be operant simultaneously in a given patient and as stated elsewhere in this chapter, multiple underlying mechanisms can share responsibility for a clinical picture.

Cancer: In the past, associations have been made between exposure to wood dusts and the development of nasal adenocarcinoma and carcinoma (ACGIH, 2005, Wood Dusts). Due to improvements in work practices and lower levels of dust exposure, it is thought that today's conditions in wood-working occupations do not pose an excess risk of nasal cancer for the worker.

INDUSTRIAL HYGIENE

Most organic dust components do not have specific exposure limits determined by the National Institute for Occupational Safety and Health (NIOSH), the Occupational Safety and Health Administration (OSHA), or the American Conference of Governmental Industrial Hygienists (ACGIH). For dust exposure in general, OSHA establishes an 8-h time-weighted average (TWA) permissible exposure limit (PEL) of 15 mg/m³, measured as total particulate, and 5-mg/m³ limit for respirable particulates for all particulates not otherwise regulated. For those physical irritants for which specific toxicologic data are available, OSHA has separately identified the substance in Table Z-1-A and has also promulgated a 10-mg/m³ 8-h TWA (measured as total particulate) and a 5-mg/m³ 8-h TWA PEL (measured as the respirable fraction). The ACGIH has a threshold limit value (TLV)–TWA of 10 mg/m³ (as total dust) for particulates having a quartz content of <1% (1988 OSHA PEL Project Documentation).

Specific dust standards exist for cotton, flour, grain, and wood dusts (see sections in this chapter). Diseases associated

with organic dusts often involve an allergic component; therefore, sensitization and subsequent reactions might occur with relatively low dose exposure.

Because the most important aspect of medical management of dust-induced respiratory disease is removing exposure to the inciting agent, industrial hygiene goes hand in hand with medical intervention; prevention of exposure from the outset being the best approach.

Prevention through industrial hygiene methods involves minimizing dust exposure by a variety of means, including ongoing worker education, engineering processes that minimize the production of dust, effective ventilation, wetting techniques, encapsulation of offending agents, administrative intervention and when indicated, the use of personal protective equipment (PPE). Administrative controls (e.g., changing work hours or locations) can sometimes help to reduce exposure for the symptomatic worker. Personal protective equipment such as dust masks or respirators can be used as a last resort to prevent inhalation of the dust when it is not possible to control the level of dust in the environment.

MEDICAL MANAGEMENT

First and foremost is that treatment of diseases due to dust exposure should always consider removal from the exposure or at least minimizing dust exposure to levels that will not cause or aggravate the disease symptomatology or progression. Medical treatment should not be used to mask symptoms while significant exposure to the suspected organic dust is allowed to continue. This concept is repeated throughout this chapter due to its importance in treating disease due to dust exposure.

Anti-inflammatory agents, including corticosteroids, non-steroidal anti-inflammatory medication, bronchodilators, and/or anti-histamines may be helpful in treating organic dust respiratory disease depending on the specific clinical situation.

In severe cases of HP, systemic corticosteroids represent the only reliable pharmacologic treatment, however, it has been reported that they do not alter the long-term outcome of the disease (Lacasse and Cormier, 2006). An empiric treatment schedule put forth by Ohshima et al. (2012) may consist of 40–50 mg per day of prednisone for 1 month, with subsequent gradual tapering during the next 2–3 months and a maintenance dose between 7.5 and 15 mg per day. In chronic progressive HP, immunosuppressants may be added as corticosteroid sparing agents, as is done in other fibrotic interstitial lung diseases. Routine follow-up should be more frequent immediately after diagnosis and during treatment (1–3 months is appropriate); later the interval can be extended to every 6–12 months. If the course is favorable, with complete remission after avoidance of further

exposure and/or corticosteroid treatment, routine follow-up can be stopped after 2–3 years. Inhaled steroids or pentoxifylline may be other options of treatment; however, their efficacy has not been evaluated. In chronic progressive HP not responding to corticosteroid and/or immunosuppressant therapy, lung transplantation should be recommended (Ohshima et al., 2012).

With removal of exposure the long-term prognosis of HP is usually good, but some patients develop severe respiratory insufficiency, and a few die of the disease (Hirschmann et al., 2009).

Occupational rhinitis, conjunctivitis, bronchitis, and asthma can be treated using standard medical approaches if symptoms continue after eliminating exposure.

Early recognition of disease with appropriate intervention is an important aspect of prevention and treatment. Screening and monitoring employees for early signs of respiratory disease in certain occupational environments may be indicated. Removal from exposure can often stabilize or even reverse the associated disease process. It is always critical for patients with respiratory disease to stop smoking. Smoking cessation programs may be helpful along with general patient education.

ANIMAL HANDLER DISEASES

Animal handler diseases include a variety of respiratory diseases usually involving immunologic mechanisms and allergic symptomatology. Skin irritation and sensitization can also occur in those exposed to animals.

SOURCES OF EXPOSURE

Occupations that involve exposure to animal dusts include researchers, laboratory workers and other investigative scientists, veterinarians, animal caretakers and groomers, hunters, farmers, food processors, and many others. Pet owners also experience risks of exposure to animal dusts and resultant disease.

Laboratory and research workers: Animal dander allergy has long been a significant problem in research institutions (Lutsky and Neuman, 1975; Sjostedt et al., 1993; Lincoln et al., 1974). It has been estimated that between 40,000 and 125,000 individuals are exposed to laboratory animals in the United States and that between 11 and 44% of individuals working with laboratory animals report work-related allergic symptoms (Bush and Stave, 2003). Such workers have the potential to develop skin rashes, rhinitis, conjunctivitis, asthma, and HP. Rhinitis and asthma are reported most commonly in workers exposed to animal antigens. Allergies to mice and rats are the most common clinical problems; however, allergic reactions can occur upon regular exposure to virtually all furred animals (Bush et al., 1998).

Typical cases of allergy occur in young adults who have a family history of atopy and who develop hypersensitivity within 3 years of close contact with laboratory animals. Prescreening and monitoring workers for atopy and skin reactivity to laboratory animal antigens enable those at risk to take precautions and avoid exposure.

Arthropods: Allergic rhinitis, conjunctivitis, and asthma have been reported in workers who are constantly in close contact with arthropods during the course of breeding and research. Correlations have been shown between a positive skin prick test (SPT), previous RAST positive reactions, clinical signs and symptoms, and exposure, all supporting the possibility of an occupationally associated illness. In such situations careful surveillance and environmental monitoring within the workplace may be beneficial.

Furrier's lung: A furrier's occupation involves selling, making, dressing, cleaning, or repairing fur garments. Excess complaints of rhinitis and eye symptoms have been reported in workers exposed to animal fur. Immunoglobulin E-mediated allergy, especially asthma but also rhinitis, occurs in workers exposed to fur and IgE-mediated allergy may force persons with symptoms to change jobs (Uitti et al., 1997). Zuskin et al. (1988) reported symptoms in furriers to include nasal discharge, sinusitis, chronic cough, and dyspnea, as well as decrements in forced vital capacity (FVC), forced expiratory volume (FEV1), and forced expiratory flow (FEF) 50% that were somewhat ameliorated with pre-shift administration of disodium cromoglycate. Pimental (1970) reported a case of hypersensitivity-like reaction of the lungs in a furrier exposed to animal hair for 18 years, with findings of a granulomatous interstitial pneumonia similar to previously reported cases of HP.

Food processing: There is an increasing global demand for seafood resulting in more fishing, aquaculture, and seafood-processing facilities. Workers involved with

manual or automated processing of shellfish, prawns, mussels, fish, and fishmeal are commonly exposed to allergens via inhalation of aerosolized product or by conjunctiva or skin contact. Other occupations associated with exposure to seafood include oyster shuckers, laboratory technicians and researchers, restaurant chefs, fishmongers (one who sells fish), and fishermen. Due to growth of the industry, there is an increased reporting of occupational disease, including allergic rhinitis, conjunctivitis and asthma, irritant-induced asthma or reactive airways dysfunction syndrome (RADS) associated with food preservatives and ammonia used as refrigerant. Reported skin manifestations include contact urticaria, eczematous contact dermatitis, and chronic protein dermatitis with diagnosis made by SPTs; workers with pre-existing atopy are at greater risk (Jeebhay and Lopata, 2012). Environmental monitoring in seafood processing has demonstrated clam and shrimp on air sampling filters. Cross reactivity between various species within a major seafood grouping occurs (Hjorth and Roed-Petersen, 1976; Jeebhay et al., 2001). Cases of OA associated with exposure to clams have been reported and supported by specific inhalation challenge. Subjects had skin reactivity and increased IgE antibodies to clam, shrimp, or both. Bronchial asthma has been recorded in oyster workers as far back as 1969 (Nakashima, 1969) and in workers exposed to prawn aerosols in a processing plant where compressed air was used to blow the edible meat out of the tails (Gaddie et al., 1980). Occupational exposure to moldy cheese has been associated with HP. Niinimäki and Saari, (1978) reported primary irritant hand dermatitis and asthma in workers with exposure to rennet and the spores of *Penicillium casei*.

Farmer's lung, ODTs, and bird handler diseases are discussed in their own section of this chapter.

ASSOCIATED AGENTS AND ANTIGENS

Animal dander, feathers, hair, serum and other proteins, urine and droppings.

MECHANISM OF ACTION AND CHEMICAL PATHOLOGY

Disease may result from sensitization to animal antigens causing allergic rhinitis, conjunctivitis, and asthma (IgE mediated), or HP (type III immune complex and/or a type IV cell mediated). Inflammatory reactions secondary to antigen sensitization are the most commonly described mechanisms; however, irritant reactions also occur.

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

Key to diagnosing disease due to animal exposure is to have a keen awareness of its possibility, to include it in the differential diagnosis when evaluating patients, and to maintain suspicion of it when completing a thorough exposure history.

There are many potential scenarios involving exposure to animals and animal products that can be occupational and nonoccupational; indoor or outdoor. It is common for people to have pets and hobbies that expose them to animal allergens and these exposures may be missed without skillfully elicited histories. Good examples involve respiratory illness related to pet birds.

Symptoms of allergic rhinitis, conjunctivitis, contact dermatitis, bronchitis, and asthma are commonly seen in workers with exposure to animal allergens (Cohen, 1974; Goransson, 1981; Hjorth, 1978; Kirkhorn and Garry, 2000). Although not as common, angioedema and HP have also been reported. Allergy screening and testing may be helpful in identification of disease, confirming diagnosis, and implementing preventive measures. See Tables I and II and the discussion on clinical and diagnostic considerations for OA and HP found in the introduction to this chapter as well as other specific sections of this chapter.

INDUSTRIAL HYGIENE

Good ventilation, cleanliness, worker education, implementation of general dust standards, and the use of PPE will reduce the exposure and respiratory disease risks for those exposed to animals. Monitoring the level of environment contaminants when feasible is important. Due to the wide range of occupational and nonoccupational settings involving animal exposure, specific industrial hygiene measures are not included here. See specific discussions in pertinent sections of this chapter.

MEDICAL MANAGEMENT

Standard medical treatment for rhinitis, dermatitis, conjunctivitis, asthma, and HP can be implemented if needed once the worker is removed from the exposure. Pre-placement screening of workers for animal allergies and atopy followed by comprehensive medical surveillance programs may reduce the risk of disease and prevent disease progression in certain occupational settings.

BAGASSOSIS

Bagassosis is considered as an HP associated with exposure to bagasse.

SOURCES OF EXPOSURE

Bagasse is the residual fiber remaining after sugar has been extracted from sugarcane. It has found many uses due to its low cost and wide availability. Bagasse is used in the production of paper products; the manufacture of acoustic and thermal insulation, fertilizers, building material, refractory brick, as cattle feed, as bedding in stables and for fowl, and as biofuel for electricity generation (Zhai et al., 2004;

Botha and von Blottnitz, 2006). Exposures have been studied in a variety of occupational settings, including sugarcane factories and paper mills. Bagassosis was first described by Jamison and Hopkins (1941) in a worker at a hard-board factory in New Orleans.

ASSOCIATED AGENTS AND ANTIGENS

Thermoactinomyces sacchari and *Thermoactinomyces vulgaris* have been identified as precipitating antigen associated with HP in the setting of exposure to moldy bagasse (Boiron et al., 1987; Rodriguez et al., 1990; Romeo et al., 2009).

MECHANISM OF ACTION AND CHEMICAL PATHOLOGY

Bagassosis was described decades ago as an EAA (HP) based on the findings of precipitating antibodies to bagasse in the sera of patients with typical clinical findings (Salvaggio et al., 1966; Hearn and Holford-Strevens, 1968; Lacey, 1971). Still, little is known about the crucial mediators involved in the inflammation and fibrogenesis in bagassosis (Zhai et al., 2004). Pathological material has been scarce since there have been few deaths, and most knowledge has been derived from the lung biopsy specimens (Sodeman and Pullen, 1944; Bradford et al., 1961; Boonpucknavig et al., 1973). Reported pathology in bagassosis includes bronchopneumonia, bronchiectasis, and, in a few reports, the appearance of giant cells and inflammatory changes closely resembling those of farmer's lung (Nicholson, 1968; Zaidi et al., 1983). Zhai et al. (2004) reports that endotoxin, mold cell wall constituents, lipopolysaccharide, glucan, neutrophil and lymphocyte recruitment, and the bagasse fiber itself may play a role in airway inflammation and granulomatous reactions in bagassosis and suggests that neutrophils, TNF-alpha, IL-1beta, IL-8, and IL-6 are involved in the pathogenesis in bagassosis. Still, little is known about the mediators that are involved in the processes of inflammation and fibrogenesis and further research is needed.

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

Bagassosis produces influenza-like signs and symptoms, including fever, severe dyspnea, and a dry, irritating cough. Other signs and symptoms include chronic bronchitis, chest pain, sputum production, in some cases blood-tinged sputum, and moist rales are heard especially over the upper lung fields (Hargrave et al., 1968; Rodriguez et al., 1990; Zhai et al., 2004).

Exposed employees have shown positive serum precipitin to stored bagasse (Ueda et al., 1992). Chest radiographs show

bilateral irregular areas of infiltration easily confused with a number of diseases, such as tuberculosis, partly because of the severity of the clinical illness. Reported CXR findings include reticulonodular infiltrates, reticular infiltrates, and miliary nodular infiltrates located diffusely with a predilection for the lower lung fields. Workers exposed to bagasse dust but who had not developed bagassosis have shown significantly reduced ventilatory capacity. Forced expiratory volume and FVC are reduced in affected workers and pulmonary function has been shown to improve when workers are moved away from worksite exposure (Hearn, 1968; Rodriguez et al., 1990). Miller et al. (1971) reported small but significant reductions in lung volumes, carbon monoxide transfer factor, and diffusion capacity of the alveolar-capillary membrane 7–10 years after acute exposure in workers with bagassosis.

Arterial blood gas may show hypoxemia (Hur et al., 1994). Bronchoalveolar lavage reveals a predominantly lymphocytic population typical of HP. In a study by Zhai et al. (2004), the BAL fluid was characterized by hypercellularity and neutrophilia; however, controls also showed an increase in lavage neutrophils, which was thought to be due to local air pollution. Biopsy specimens have shown chronic interstitial infiltrates of lymphocytes and macrophages in the alveolar walls with eventual interstitial alveolar fibrosis.

Some patients develop disabling pulmonary fibrosis and emphysema and with repeated exposure end-stage lung disease (Nicholson, 1968; Zhai et al., 2004).

INDUSTRIAL HYGIENE

Historically, studies have shown that bagassosis has been largely eliminated in many areas through better industrial hygiene practices, improved storage methods of bagasse, and increased awareness of management resulting in the implementation of greater safety measures (Anonymous, 1970; Lehrer et al., 1978). Currently there is no specific airborne dust concentration standard for bagasse; however, OSHA's general dust standard applies. In a study of sugarcane workers in Nicaragua, clinical findings by Romeo et al. (2009) led them to reemphasize the importance of implementing a surveillance and exposure prevention program for workers employed in sugarcane production and processing. Dust levels should always be brought to the lowest level possible.

MEDICAL MANAGEMENT

Satisfactory results have been reported with corticosteroid therapy in the treatment of bagassosis. As is always the case for organic dusts, prevention of exposure to bagasse dust through application of industrial hygiene principles is

helpful. Early diagnosis and avoidance is a cornerstone of management.

BAKER'S ASTHMA

Ramazzini described Baker's asthma in 1713. Baker's asthma and rhinitis are among the most common and well-known types of occupational respiratory disease (Baur et al., 1998). Armentia et al. (1990) reported a prevalence of 15–30% of exposed workers; Brant (2007) reported an annual incidence of baker's asthma between 1 and 10 cases per 1000 bakery workers. The risk of developing occupational respiratory disease in any particular job environment varies considerably depending on specific working conditions, and the degree of implementation of good industrial hygiene principles.

SOURCES OF EXPOSURE

Exposure can occur via flour dust inhalation or skin contact during the work of millers, dough makers, bread formers, bakers, confectioners, and food processors. Documentation of exposure levels, the type of sensitizing allergen, and the duration of exposure are all important to link asthma symptoms to the workplace.

ASSOCIATED AGENTS AND ANTIGENS

Goehte et al. (1983) reported that wheat flour is particularly sensitizing and that comparatively low levels of exposure ($1\text{--}2\text{ mg/m}^3$) pose a significant risk for developing an allergy. Brisman (2002) reported that the most common allergens associated with baker's asthma involve IgE antibodies against cereal flours such as wheat, rye, or barley. In a study of bakery workers by Patouchas et al. (2009) a high prevalence was found for sensitization to wheat flour (4–47%), and for fungal α -amylase (4.68–24%). Less common allergens that can be considered in the absence of antibodies to common allergens include: cereal flours: hops, rice, maize; non-cereal flours: buckwheat, soybean flour; additives: cellulase, xylanase, papain, glucose oxidase; color: carmine red; spices; egg powder; milk powder; insects: flour beetle (*Tribolium confusum*), flour moth (*Ephestia kuhniella*), cockroach (*Blattella* spp.), granary weevil (*Sitophilus granarius*); molds: Alternaria, Aspergillus; and sesame seeds (Brisman, 2002).

MECHANISM OF ACTION AND CHEMICAL PATHOLOGY

Baker's asthma is a form of allergic asthma to cereal flours mediated by specific IgE antibodies (Block et al., 1983; Sander et al., 2011; Dykewicz, 2009; Mapp et al., 1994). Both the level of serum IgE antibodies and the degree of nonspecific bronchial reactivity are important factors, which may influence a baker's bronchial response upon inhalation of cereal flours.

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

Symptoms usually develop after a period of months to years. Clinical findings include rhinitis, conjunctivitis, wheezing, chest tightness, and shortness of breath. The affected worker is often atopic as determined by skin or IgE testing. Important diagnostic findings for baker's asthma include a documented history of exposure to bakery allergens with a clear temporal relationship to work, characteristic PFT findings for reactive airways, and clinical tests demonstrating sensitization to specific IgE allergens by SPTs and RAST testing. Specific challenge testing may be needed in difficult diagnostic situations.

INDUSTRIAL HYGIENE

Flour dust: TLV-TWA, 0.5 mg/m³, inhalable particulate mass (ACGIH, 2001).

Reducing worker's exposure to flour dust can be accomplished in multiple ways, including: optimal ventilation, avoiding procedures that stir up dusts, wetting techniques, use of pastes, liquids, and dust-suppressed powders, use of protective clothing and equipment including respirators, implementation of health surveillance for early disease identification, preemployment screening questionnaires, allergy screening at start of the employment and annually, and education of workers regarding risks and prevention measures (Patouchas et al., 2009).

MEDICAL MANAGEMENT

Removal from exposure is the best treatment. After removal of exposure, standard treatment modalities for allergic rhinitis and asthma can be utilized. Some workers refuse to leave employment for various reasons. Armentia et al. (1990) applied immunotherapy with a standardized wheat flour extract and showed significant decrease in hyperresponsiveness to methacholine, skin sensitivity, and specific IgE, and

an improvement in subjective symptomatology after 20 months of therapy.

BIRD-HANDLERS OR BIRD-BREEDERS DISEASE

Bird handler's disease is also called bird fancier's disease, bird breeder's lung, pigeon breeder's disease, pigeon breeder's lung, poultry worker's lung, duck fever, and has other similar names.

SOURCES OF EXPOSURE

Bird handler diseases have been reported in connection with exposure to a wide variety of avian species, including pigeons, turkeys, chickens, canaries, cockatiels, lovebirds, parrots, parakeets, owls, and other raptors (hawks, eagles) (Kokkarinen et al., 1994; Tauer-Reich et al., 1994; Choy et al., 1995; Tanaka et al., 1995; McCluskey et al., 2002; Funke and Fellrath, 2008).

Thorough exposure histories are needed to discover and differentiate occupational and domestic exposure to birds.

ASSOCIATED AGENTS AND ANTIGENS

Sources of antigens associated with HP with birds are multiple and include bird proteins, bird droppings, and feathers. There is a large body of literature that has been developed to deal with various immunological aspects of the disease. Excreted intestinal mucin and immunoglobulins A (IgA) and G (IgG) from bird droppings and bloom (a waxy coating of feathers) are highly antigenic and are the most likely major sources for inhalant bird antigen. Additionally, bacteria, fungi, viruses, mites, and other parasites that are associated with birds may play a role (Chan et al., 2012). Inhalable feather dust contains several allergens that cross react with bird serum allergens (Tauer-Reich et al., 1994). Cessation of exposure to the provoking bird antigen results in recovery in some but not all patients (Allen et al., 1976).

MECHANISM OF ACTION(S) AND CHEMICAL PATHOLOGY

The exact pathogenesis of bird fancier's disease is unknown. A number of immunological and nonimmunological mechanisms have been described, but none is clearly or exclusively associated with the disease (Mendoza et al., 1996). Lengthy exposure to avian proteins can trigger a type III immune complex-mediated hypersensitivity reaction and type I and type IV reactions with predominant activation of alveolar macrophages and T-lymphocytes responsible for the inflammatory response leading to the disease (Morell et al., 2008). The most frequent histopathology observed in HP consists of a granulomatous interstitial bronchiocentric pneumonitis characterized by a prominent interstitial mononuclear infiltration, with the presence of non-necrotizing poorly formed granulomas. Chronic cases also show variable degrees of fibrosis (Myers and Tazelaar, 2008; Morell et al., 2008; Miguel et al., 2011).

Interestingly, cigarette smokers show a lower incidence of HP than nonsmokers, with smokers showing lower titers of IgA and IgG and lower levels of expression of immunostimulatory molecules such as peripheral membrane protein B7 on alveolar macrophages. Additionally, various genetic factors such as polymorphisms within the major histocompatibility complex and the presence of certain HLA haplotypes may modulate lung inflammatory responses and influence disease susceptibility to avian allergens (Morell et al., 2008; Chan et al., 2012).

Studies have shown that mucociliary clearance can be significantly impaired in patients tested positive for bird antigens (Hasani et al., 1992).

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

No single historical feature or laboratory test is found in the diagnosis of HP from birds. Making the diagnosis often requires a combination of findings, including clinical and exposure history, laboratory findings, CXR and chest CT, BAL, and in some cases lung biopsies. Although often misdiagnosed as influenza or viral or bacterial pneumonia, if a thorough exposure history leads the clinician to consider HP, diagnosis of the acute form is not so difficult. Four to eight hours after exposure the patient develops influenza-like symptoms, which may include cough, dyspnea, fever, chills, and nausea. Leukocytosis, lymphopenia, eosinophilia, and elevated erythrocyte sedimentation rates are common. Crackles may be heard over the lungs, and respiratory function tests typically show a restrictive abnormality with a reduction in lung volumes and alterations in the CO diffusion capacity. Chest X-ray abnormalities consist of diffuse, finely nodular shadows, and reticular linear densities, and chest CT may show ground glass areas, air trapping, and mosaic or nodular patterns (Zylak et al., 1975; Vincent et al., 1992; Remy-Jardin et al., 1993; Yoshizawa, 1995; Morais et al., 2004; Morell et al., 2008). The subacute presentation includes cough and dyspnea over days to weeks and can progress to chronic and permanent lung damage if unrecognized and untreated. The chronic form of the disease includes breathlessness, cough, obstructive as well as restrictive patterns on PFT's, and hypoxemia; symptoms may persist after removal from antigen exposure (Chan et al., 2012). As would be expected, once progression to the chronic form of the disease occurs, prognosis is reported to be worse than for patients with acute and subacute disease. Case fatalities have been reported (Edwards and Luntz, 1974). Hypersensitivity pneumonitis resulting from handling birds constitutes a spectrum of granulomatous, interstitial, and alveolar-filling lung diseases (Lacasse et al., 2009).

The finding of specific precipitating antibodies in the serum of a patient with suspected HP supports exposure. Morell et al. (2008) found positive IgG antibodies to bird antigens in 93% of patients with bird fancier's lung disease. Studies done decades ago found that agglutination reactions were mediated by antibodies directed against pigeon IgG and IgM. T-lymphocyte reactivity to pigeon antigens has also been demonstrated (Moore et al., 1974; Schatz et al., 1976; Diment and Pepys, 1977).

Examination of BAL usually shows lymphocytosis and an inversion of the CD4/CD8 T-lymphocyte ratio, however, the inversion in CD4/CD8 is not always seen.

Lung biopsy may be indicated in patients without sufficient clinical criteria for definitive diagnoses or to rule out other diseases requiring different treatment. Lung biopsy characteristically shows lymphocytic-histiocytic infiltrate, poorly formed granulomas, and bronchiolitis obliterans (Morell et al., 2008).

Chronic bronchitis is often associated with bird breeder's disease (Tanaka et al., 1995). Chan et al. (2012) reported an incidence of chronic bronchitis in 26.2% of nonsmoking pigeon breeders. In another study, Carrillo et al. (1991) reported an incidence of chronic bronchitis in 20% of a group who tested positive to bird antigens. This fraction was composed of nonsmokers with no risk factor for chronic bronchitis other than exposure to birds.

Rodriguez de Castro et al. (1993) studied 343 pigeon breeders and found that rhinitis was the most frequently reported clinical syndrome in 31%, followed by immediate bronchial symptoms in 18%.

Sansores et al. (1990) noted an association between clubbing of the fingers in bird breeder's disease patients and poor outcome. The authors suggested that digital clubbing may be used as a prognostic tool to predict clinical deterioration. Morell et al. (2008) reported that the prevalence of clubbing was low in those with bird fancier's disease overall, however, it was seen in 1/3rd of patients with chronic disease.

Bird breeder's disease should be considered whenever a patient presents with interstitial lung disease or intermittent cough and dyspnea (Mangion and Delaney, 1993). Unrecognized exposure and disease may be common. For example, a female automobile repair garage worker had respiratory symptoms thought to be due to workplace exposures. After a careful review of her history, physical examination, and laboratory testing, she was diagnosed with HP related to exposure to pet cockatiels in her home (McCluskey et al., 2002). In another case, a patient initially diagnosed as having amiodarone pulmonary toxicity (APT) was subsequently diagnosed instead with HP upon further testing. A thorough exposure history discovered that he was exposed to his daughter's lovebirds (Funke and Fellrath, 2008).

It has been estimated that the prevalence of bird fancier's lung among bird owners in Britain is between 0.5 and 7.5%. With such a large population at risk, Judson and Sahn (2004) suggested that clinicians should ask about "bird-years" as well as cigarette pack-years.

A 98% maximum probability of diagnosing bird fancier's disease has been reported if the following six diagnostic criteria are met: (1) exposure to a known antigen, (2) recurrent symptomatic episodes, (3) symptoms occurring between 4 and 8 h after exposure, (4) weight loss, (5) positive IgG precipitating antibodies to the antigen, and (6) inspiratory crackles on chest auscultation. With these criteria being met, BAL and lung biopsies will probably not be necessary for confirmation, especially if a HRCT chest is also consistent with the diagnosis of HP (Chan et al., 2012).

INDUSTRIAL HYGIENE

It is crucial to recommend antigen avoidance when managing bird handler's disease. While complete avoidance is best,

certain environmental measures may be helpful such as thorough cleaning measures, however, the antigen may stay in the environment after cleaning (Chan et al., 2012). Craig et al. (1992) demonstrated that high levels of bird antigens can be detected in the home environment for prolonged periods after removing the bird.

Indoor and outdoor environments must be considered when determining potential exposure to bird antigens. When complete removal of the patient from exposure is not acceptable, PPE such as masks may help. Changing clothes (such as a lab coat or hat) after exposure may minimize antigen contamination and exposure. Improved air circulation in working or hobby areas may also help. A study by Edwards et al. (1991) demonstrated that switching from absorbent loft litter to regular cleaning for bird enclosures decreased the amount of airborne antigens and respirable particles.

MEDICAL MANAGEMENT

When bird breeder's disease is suspected, the clinician must perform appropriate historical, environmental, and clinical evaluations to prevent both progressive and irreversible lung damage.

After removal from exposure, standard medical treatment can be utilized for rhinitis, bronchitis, asthma, and HP, see introduction to this chapter.

Overall prognosis for recovery is good. Patients removed from exposure typically improve but retain elevated levels of avian-specific antibodies (Yoshizawa, 1995; Grammer et al., 1990).

BYSSINOSIS

Byssinosis has also been called strippers asthma or brown lung and is a bronchoconstrictive disease associated with cotton dust exposure.

SOURCES OF EXPOSURE

The unusual and somewhat misnamed diagnostic title “byssinosis,” derived from the Latin *byssinum*, linen garment, refers to a group of occupational respiratory diseases in workers exposed to the dusts of dirty cotton, flax, and hemp. The causative dusts represent a complex mixture of organic and inorganic compounds. Occupational exposures include operating cotton gins and baling cotton, opening bales, removing dust and impurities, carding, cleaning, stripping, and grinding the teeth of machines in cotton mills and textile plants.

In the United Kingdom, Schilling (1955) reported a prevalence rate of around 50% for workers in the dustiest parts of the cotton-spinning process. Later studies showed a marked improvement of the prevalence rates in the United Kingdom; 10% among the high risk workers, and an overall prevalence of 3%. However, similar prevalence rates of byssinosis as experienced in the United Kingdom in the 1950s have recently been experienced in developing countries involved with cotton production. Reported rates in textile workers vary from 30 to 50% in countries such as Indonesia, Sudan, and India (Parikh, 1992; Altin et al., 2002). As one would expect, byssinosis seems to be more of a problem in parts of the world where cheap labor can be exploited without the implementation of adequate industrial hygiene measures.

ASSOCIATED AGENTS AND ANTIGENS

The storage and handling conditions of cotton products can promote the growth of Gram-negative bacteria. Strong, yet indirect, evidence suggests that contaminating bacterial

endotoxin may play a major role in the adverse pulmonary effects of cotton dust (Castellan et al., 1987; Jacobs, 1989). Many other biologically active agents are known to contaminate cotton dusts and hemp and natural constituents include such pharmacologically active agents as tannins, gossypol, and quercetin.

MECHANISM OF ACTION AND CHEMICAL PATHOLOGY

The underlying mechanisms responsible for byssinosis are not certain; however, it is thought that inflammatory reactions occur secondary to endotoxin- or immunologic-induced processes (Rooke, 1981; Niven and Pickering, 1996; Christiani et al., 1993; Kirkhorn and Garry, 2000; Thorn, 2001).

Endotoxin-contaminated organic dusts have been associated with a variety of adverse pulmonary effects, including: chronic bronchitis and increased sputum production, an increase in the volume density of mucus substances, an increase in the secretion of mucus substances by mucous goblet cells, and the induction of goblet cell metaplasia and hyperplasia. An increase in stored mucus substances is accompanied by the presence of excess luminal mucus, secretory cell hyperplasia, and an influx of neutrophils (Harkema, 1991; Gordon and Harkema, 1995).

Overproduction and hypersecretion of mucin glycoproteins can contribute directly to airway obstruction, airway plugging, and harboring of bacterial infections associated with a variety of chronic pulmonary diseases, including asthma, chronic bronchitis, bronchiectasis, and cystic fibrosis (Kilburn, 1981). Several studies have shown a decrease in FEV₁ following inhalation to endotoxin (Thorn, 2001). Inhalation of lipopolysaccharide has been shown to result in an increased amount of fibronectin in BAL fluid. Recent studies of textile workers suggest an exposure-dependent effect of endotoxin on lung function impairments (Wang et al., 2003; Oldenburg et al., 2007).

Some researchers suspect airborne fungi contaminants such as Cladosporium, Alternaria, Penicillium, Fusarium, and Aspergillus as a cause of byssinosis while other researchers have suspected chemical constituents in plants such as terpenoid, quercetins, gossypol, scopoletin, and laciniliene (McPartland, 2003).

O'Neil et al. (1983) suggested that an IgE-mediated hypersensitivity against cotton or a fungal component of the dust may be important in byssinosis pathogenesis based on studies of precipitating antibodies against aqueous cotton dust extracts.

Jacobs et al. (1993) reported that atopic workers showed a greater decrease in FEV₁ after cotton dust exposure than did the non-atopic workers, suggesting a possible immunologic component to the disease. Wang et al. (2003) found that the IgE level in cotton workers was not related to lung function,

suggesting that IgE level might not be the basis for the airway obstruction observed in cotton workers.

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

The most commonly reported health effect from cotton dust exposure is eye and nasal irritation (Fishwick and Pickering, 1994). Reports of irritation did not correlate with incidence of byssinosis or cotton dust concentration.

Byssinosis can be divided into acute and chronic forms. Short-term exposure to cotton dust for some workers is associated with acute respiratory symptoms, and long-term exposure may be associated with the classic form of byssinosis.

Acute byssinosis refers to the acute response of airways that occurs in approximately 1/3rd of volunteers exposed to cotton dust for the first time. Substantial falls in FEV₁ exceeding 30% have been reported. A study of Finnish cotton spinning mills reported that 1 in 10 employees left work within 2 weeks and one in four left within 3 months of employment (Koskela et al., 1990).

The classic form of chronic byssinosis is characterized by a feeling of chest tightness, coughing, wheezing, and dyspnea, which the worker experiences as being most severe on the first day of the workweek after a period of absence from work (Niven and Pickering, 1996; McPartland, 2003). Symptoms continue after the individual has finished work and may even progress during the evening. However, they are perceived as being less troublesome on subsequent days.

Progression of byssinosis has been described in three stages: In stage I symptoms occur when textile work is resumed after a period of several days off work ("Monday disease"). In stage II symptoms may increase and persists for 2 or more days. In stage III employees develop chronic obstructive lung disease (Baur et al., 1993).

Textile workers have a considerably higher prevalence of chronic respiratory symptoms, including cough, dyspnea, bronchitis, chest tightness, and phlegm, as well as reductions of FVC and FEV₁ (Zuskin et al., 1992; Alemu et al., 2010). Studies have shown both atopic and non-atopic persons to have a significant decrease in FEV₁ after cotton dust exposure, but the average decrease in FEV₁ was larger for the atopic group than for the non-atopic group (Sepulveda et al., 1984; Beijer et al., 1995).

Although most studies have concentrated on decreases in FEVs, some studies have shown larger changes in the caliber of the small airways, which has led to the suggestion that the disease process starts in the smaller peripheral airways. In addition to changes in lung function, cotton workers can show increases in bronchial reactivity. The changes in both reactivity and small airway caliber have given rise to the suggestion that byssinosis is an asthma-like condition of the small airways (Fishwick and Picketing, 1992; Niven and Pickering, 1996).

Bronchoalveolar lavage studies have been performed on animals, volunteers, and patients after exposure to cotton dust or dust extracts. Variable changes have been identified, but neutrophil recruitment appears to be the most consistent finding. Byssinosis bodies up to $50\text{ }\mu\text{m} \times 200\text{ }\mu\text{m}$ and consisting of hyalinized fibrous nodules containing a dark staining core presumably of cellulose have been described in some lung specimens of workers exposed to cotton dust (Spencer, 1977; Baur et al., 1993). There is no specific CXR picture. Baur et al. (1993) reported CXR findings of linear bronchial shadowing compatible with peribronchitis in two case reports.

The affected worker may not experience the classic symptoms of chronic byssinosis disease until he or she has worked for many years in the industry; indeed, it may be seen for the first time 25 years after starting to work in the industry and is rare in individuals continuously exposed for <10 years.

As the disease of byssinosis becomes established, its clinical course is that of chronic bronchitis and emphysema. As far back as 1975, Edwards et al. described centrilobular or paracinar emphysema in 23% and 14%, respectively, of 43 patients with byssinosis, whereas the others were free of this complication (Edwards et al., 1975). Advanced byssinosis results in severe dyspnea and disability with exacerbation of symptoms at the time of any respiratory infection. Death is usually caused by right heart failure. As might be expected, cigarette smokers have a higher prevalence and greater severity of symptoms.

INDUSTRIAL HYGIENE

Cotton dust, raw: TLV-TWA, 0.2 mg/m^3 (fibers <15 mm in length) (ACGIH, 2001).

In the United States the current cotton dust standard promulgated by the OSHA became effective in 1980. As found in OSHA Table Z-1 (29 CFR 1910.1000), the PEL for cotton dust (raw) is 1 mg/m^3 for the cotton waste processing operations of waste recycling (sorting, blending, cleaning, and willowing) and garnetting.

Permissible exposure limits for other sectors (as found in 29 CFR 1910.1043) are 0.200 mg/m^3 for yarn-manufacturing and cotton-washing operations, 0.500 mg/m^3 for textile mill waste house operations or for dust from "lower grade washed cotton" used during yarn-manufacturing, and 0.750 mg/m^3 for textile-slashing and -weaving operations.

The OSHA standard in 29 CFR 1910.1043 does not apply to cotton harvesting, ginning, or the handling and processing of woven or knitted materials and washed cotton.

All PELs for cotton dust are mean concentrations of lint-free, respirable cotton dust collected by the vertical elutriator

or an equivalent method and averaged over an 8-h period (NIOSH, 2007).

The NIOSH (2007) recommends reducing cotton dust to the lowest level feasible to reduce the prevalence and severity of byssinosis.

The ACGIH (1996) has set the TLV for raw cotton dust (lint free) at $200\text{ }\mu\text{g/m}^3$.

Lung function tests performed at the time of preemployment can be used for routine medical surveillance to screen for early changes associated with exposure to cotton dust. Workers with reductions in serial FEV₁ measurements should be reassigned to work areas where there is less risk of exposure to dust. Improvement in ventilatory capacity as a result of reduced dust levels may be accomplished by steaming of the cotton (Imbus and Suh, 1974), which may also remove, at least temporarily, some of the bronchoconstricting properties of the dust. Textile mills should be properly ventilated and filtered; using exhaust hoods, improving ventilation, and employing wetting procedures may help to control cotton dust. A study by Altin et al. (2002) showed that closed cotton processing and air-conditioning are very effective in preventing byssinosis. Proper retting and storage of hemp will produce a higher quality hemp fiber with less contamination that reduces the risk of byssinosis in workers (McPartland, 2003). As has been demonstrated by the cotton industry in the United States, technological investment to reduce exposure can bring both improved productivity and reduced incidence of disease (Niven and Pickering, 1996).

MEDICAL MANAGEMENT

Medical treatment for affected individuals is similar to patients with occupational asthma.

Both bronchodilators and anti-inflammatory agents can be used to ameliorate symptoms, and inhaled steroids are probably more effective than sodium cromoglycate in the chronic form of the disease. Breathing treatments, including nebulizers, may be prescribed and home oxygen therapy, physical exercise programs, breathing exercises, and patient education may be helpful for people with chronic disease.

Workers with a personal history of respiratory allergy or a history of continued cigarette smoking should be considered at increased risk of developing byssinosis (McPartland, 2003). As with all respiratory disease, it is critical for patients with byssinosis to stop smoking. A study by Yih-Ming et al. (2003) supported that smoking potentiates the effects of cotton dust exposure on respiratory symptoms and byssinosis. Smoking cessation programs may be helpful along with general patient education.

Cessation of exposure following diagnosis of byssinosis should be recommended, particularly because studies have shown increased mortality in workers with byssinosis (Niven and Pickering, 1996).

COFFEE WORKERS DISEASE

Reported diseases associated with coffee exposure include coffee workers' lung disease and coffee worker's asthma.

SOURCES OF EXPOSURE

Coffee workers are exposed to coffee bean dust during shipment, processing, and manufacturing.

ASSOCIATED AGENTS AND ANTIGENS

Occupational allergic respiratory symptoms, including asthma in coffee industry workers have been frequently reported, but the ultimate cause of sensitization is still debated; the castor bean and green coffee bean have been implicated. Work involving the immunological responses of

mice (Lehrer et al., 1978) indicated that the green coffee bean is the major source of the allergen in this disease. Coffee workers lung disease is a HP that has been associated with antigens of *Thermoactinomyces* spp.

MECHANISM OF ACTION AND CHEMICAL PATHOLOGY

Immunoglobulin E antibodies specific for green coffee bean and castor bean have been detected in coffee workers and are capable of producing allergic asthma (Karr et al., 1978; Oldenburg et al., 2009).

Hypersensitivity pneumonitis has been reported to be associated with antigens of *Thermoactinomyces* spp. (Van Torn, 1970). Atopy and cigarette smoking have been suggested as promoting factors of sensitization. Larese et al. (1998) found a significant association between sensitization to green coffee beans and work-related symptoms, common allergic symptoms and atopy diagnosed by prick test.

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

As far back as 1973, illnesses reported in coffee workers included allergic rhinitis, asthma, conjunctivitis, pruritus, and dermatitis as a result of exposure to dust in manufacturing establishments (Bernton, 1973). Radioallergosorbent testing and/or SP testing for green coffee bean and castor bean may be helpful in establishing a diagnosis of coffee dust-associated disease.

A total of 211 coffee workers were examined by Romano et al. (1995). Of the workers, 10% complained of conjunctivitis and rhinitis alone and 16% complained of asthma. The overall prevalence of skin sensitization was 15% for green coffee beans, 22% for castor beans, and 22% for common allergens.

Ventilatory functional changes have been demonstrated and the decreases in flow rates at low lung volumes have been interpreted decades ago to indicate that the bronchoconstrictor action of the coffee bean dust mostly affects the smaller airways (Zuskin et al., 1979). These investigators have warned that continued exposure to dust in both green coffee handling and roasted coffee processing may lead to a persistent loss of pulmonary function. Zuskin et al. (1981) reported a higher prevalence of all chronic respiratory symptoms in coffee workers compared to controls, and those workers with positive skin test to coffee allergen also had a higher prevalence of chronic cough and chronic phlegm.

A study by Jones et al. (1982) found that men with lengthy employment and exposure to green coffee bean dust had lower mean residual FEV₁, likewise, those workers with serum IgE antibodies to green coffee beans had lower mean residual FEV₁.

A cross-sectional study by Oldenburg et al. (2009) concluded that workers involved with the transshipment and unloading of green coffee experienced a high exposure to irritative and sensitizing dust that was clinically relevant based on their evaluation of IgE antibodies, bronchial hyperresponsiveness, chest tightness, wheezing, erythematous symptoms, conjunctivitis, and sneezing.

INDUSTRIAL HYGIENE

There have been no specific standards promulgated for coffee beans; however, reducing coffee bean dust exposure to the lowest possible levels should be implemented based on the studies associating exposure with sensitization and adverse respiratory effects.

MEDICAL MANAGEMENT

Removal from exposure is the mainstay of intervention. Standard medical treatment for rhinitis and allergic asthma can be utilized, however, treatment should not mask symptoms while continued exposure and disease progression is allowed. In the case of HP, corticosteroid treatment may be helpful as in other types of HP.

DETERGENT WORKERS DISEASE

Enzymes are added to detergents to enhance their ability to remove certain stains. Occupational exposure to these enzymes have been associated with allergic sensitization and OA.

SOURCES OF EXPOSURE

The inhalation of the dust of microbiological products containing enzymes has led to the sensitization of workers exposed to high concentrations of enzymes. Most attention has been given to the exposures that occur in detergent manufacturing and is the focus of this discussion. Other industries with risk of exposure to enzymes include pharmaceutical manufacturing, bakers, and rubber workers. Historically, there were rare instances described where consumers experienced symptoms associated with detergent use. This problem has essentially been eliminated through improved products (encapsulation, granulation, and new formulations) that minimize consumer exposure.

ASSOCIATED AGENTS AND ANTIGENS

Enzymes used in the detergent industry are proteins derived from bacteria and fungi, and include proteases, amylases, lipases, and cellulases. The first enzyme to be associated with adverse respiratory health effects and one of the best known is the protease prepared from *Bacillus subtilis*, a non-pathogenic organism.

MECHANISM OF ACTION AND CHEMICAL PATHOLOGY

Adverse health effects associated with enzyme exposure include irritation of the skin, eye, and other mucosal sites, and antibody-mediated hypersensitivity.

Irritation has been reported after prolonged occupational exposure to high concentrations of enzymes. The irritation is mild, reversible, and resolves quickly with the removal of exposure. Irritation of consumers is not expected due to the low concentration of their exposure. Occupational controls have essentially eliminated the problem of irritation in the workplace.

Occupational allergy and asthma affecting the respiratory tract is more common and is thought to be an enzyme-specific IgE antibody-mediated response. The majority of reported allergic and asthma symptoms are immediate onset, although late onset asthma has been described. Enzymes are not contact allergens and do not induce delayed type hypersensitivity (Schweigert et al., 2000). Sensitization of

consumers is not expected to occur due to low levels of exposure (Pepys et al., 1985).

Pepys (1992) noted the appearance of asthma some hours after exposure (i.e., a “late” asthmatic reaction) and in some cases, subsequent exposures caused immediate reactions. Late asthmatic reactions can result in problems in diagnosis and in identification of the cause.

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

Historically, symptoms associated with heavy exposure to enzymes were striking and were progressively more severe with continued exposure. Lacrimation, rhinorrhea, cough with minimal sputum, and wheezing were the usual symptoms. The patient became increasingly breathless and had to sit upright at night to breathe. Occasionally, a worker reported mild hemoptysis and episodes of mild fever.

Before proper controls were installed, re-exposure after an interval, such as a vacation or holiday, resulted in return of symptoms. If, by accident or job change, a worker with mild symptoms received a heavy dose in a short period, he or she suffered a violent reaction with dyspnea, choking, and cyanosis severe enough to require oxygen treatment. At the time of such an episode, the CXR is said to have shown transient infiltrates.

Dermatitis resulting from sensitization was not seen in detergent factories, although palmar eczema did occur in workers producing the concentrated enzyme (Zachariae et al., 1973).

Shore et al. (1971) reported lung function abnormalities persisting in 8 of 17 workers after removal from exposure for periods up to 9 months. Weill et al. (1973) found reductions in lung volumes and in expiratory flow rates to be associated with past exposures, but they also noted in exposed workers a reversal in the downward trend in pulmonary function, presumably because of improved working conditions. Musk and Gandevia (1976) found a significant loss of pulmonary elastic recoil in workers formerly exposed to detergent proteolytic enzymes, with only partial recovery in some cases.

Pepys et al. (1969, 1973) considered the enzyme illness to be an allergic reaction on the basis of the results of skin testing and precipitins in sera. Atopic patients were more likely than non-atopic patients to have a positive SPT, and a good correlation was found between SPTs and the presence of enzyme-specific IgE in sera (Juniper et al., 1977).

J van Rooy et al. (2009) reported that workers exposed to liquid detergent enzymes reported more work-related symptoms of itching nose, sneezing, and wheezing. Additionally, 14.2% of exposed workers were sensitized to enzymes, indicating that workers exposed to liquid detergent enzymes are at risk of developing sensitization and respiratory allergy.

Diagnosis of enzyme-related OA depends on the usual methods for diagnosing asthma, including temporality of history, work-related wheezing, shortness of breath, obstructive

disease on PFT, serial peak flow measurements, specific bronchial challenge, RAST, and SP testing or ELISA.

Significant correlations were found by Belin and Norman (1977) in enzyme exposed affected subjects between the SPT, clinical histories, and the RAST for specific IgE antibodies. They concluded that “a single skin prick test with a representative test reagent at appropriate test concentration can disclose specific IgE sensitivity as precisely but more cheaply and more easily than an intradermal test or a RAST.” Schweigert et al. (2000) reported that, although the sensitivity and specificity of SPT is considered higher than for RAST, there is evidence demonstrating the use of serological tests as an effective alternative. For occupational health hazards, skin prick tests should be particularly useful for screening purposes.

INDUSTRIAL HYGIENE

The ACGIH established a TLV for the enzyme subtilisin (protease) of 60 ng of pure crystalline protein/m³. Individual manufacturing operations may use even lower occupational exposure guidelines (Schweigert et al., 2000).

Minute amounts of enzyme are capable of eliciting clinical signs making it important to implement occupational controls to minimize dust exposure. Significant progress has been made through methods that include encapsulation of the enzymes as well as improved engineering of the manufacturing process. The prilled material minimizes exposure; however, enzyme dust can be liberated from the granules.

Minimizing dust exposure, applying engineering controls, and implementing medical surveillance programs are effective in creating and maintaining a safe working environment and have eliminated much of the allergy and asthma symptoms associated with enzymes.

Those manufacturing facilities that follow all of the guidelines, including industrial hygiene standards, medical prescreening (including SP testing), prospective surveillance, and continuing interventions enjoy very low or no cases of asthma and allergy among workers exposed to enzymes. With the present control of exposure to the enzymes, a working environment safe for atopic subjects can be achieved. Lessons learned in the detergent industry can be used to avoid OA due to enzyme exposure in other industries (Schweigert et al., 2000; Sarlo and Kirchner, 2002; Nicholson et al., 2001).

MEDICAL MANAGEMENT

After eliminating or minimizing enzyme exposure, OA and allergic symptoms can be treated using standard medical practice.

FARMER'S LUNG

Farmer's lung disease is one of the most common forms of HP.

SOURCES OF EXPOSURE

Farmer's lung disease has been associated with exposure to the dust of moldy hay, oats, barley, and millet grain in a variety of agricultural occupations.

FARMER'S LUNG VERSUS ORGANIC TOXIC DUST SYNDROME (ODTS)

A similar but distinct and more common respiratory illness affecting farmers has been labeled as ODTD. Making the distinction between farmer's lung and ODTD is important for both clinicians and researchers. Whereas farmer's lung disease is associated with exposure to specific antigens and is thought to be an allergic process affecting the alveoli and resulting in HP, ODTD is not considered an allergic disease; it is thought to be due to inhalation of toxins, and disease is more likely when the worker is exposed to higher concentrations of a variety of organic dusts. Organic dust toxic syndrome will be discussed in a separate section of this chapter.

ASSOCIATED AGENTS AND ANTIGENS

Farmer's lung disease has classically been associated with exposure to the antigens of thermophilic actinomycetes, *Aspergillus* species, *Saccharopolyspora rectivirgula*, (*Micro-polyspora faeni*). Reboux et al. (2001) studied farmer's lung disease in France and found *Absidia corymbifera* to be the only microorganism able to discriminate farmers with disease from control farmers both in terms of exposure and of sensitization, whereas classic antigens did not seem to be involved. The authors concluded that agriculture techniques continually evolve and that there needs to be a periodic study of species and antigens involved with farmer's lung disease.

MECHANISM OF ACTION AND CHEMICAL PATHOLOGY

Farmer's lung disease is currently thought to be an EAA or HP, supported by the finding of precipitins in the sera of patients with farmer's lung and thought to be mediated by IgG antibodies (Reboux et al., 2001).

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

The onset of farmer's lung disease may occur insidiously or may take place several hours after the exposure. Most commonly, severe dyspnea, cough, cyanosis, and fever are reported after exposure to the spore-laden dust of moldy hay or grain (Emanuel et al., 1964; Ames et al., 1990). These symptoms occur after the worker has been sensitized by previous exposure to the causative agents present in the dust; usually repeated exposure to high concentrations or prolonged exposure to low concentrations (Reboux et al., 2001). Wheezing, expectoration, malaise, and occasionally hemoptysis also occur (Donham, 1990).

The acute stage of farmer's lung disease may be accompanied by rales audible throughout the chest and by bilateral densities on the CXR (Barbee et al., 1968; Atwood et al., 1987). High resolution CAT scanning features are characterized by centrilobular nodules, ground-glass opacities, a mosaic pattern, air trapping on expiratory images, or some combination of these features (Ryu et al., 2007). Biopsy at this stage shows pulmonary edema as well as inflammatory changes in the alveolar walls, typical of a type III Arthus reaction (Iversen et al., 1991). Freedom from exposure will bring about relief of symptoms and reversal of the CXR changes to normal unless the disease is advanced and fibrosis has occurred. Spores of thermophilic actinomycetes can be detected by electron microscopy in pulmonary alveolar macrophages obtained by simple lavage (Romet-Lemonne et al., 1980). Both the absolute numbers and the percentages of T lymphocytes are reduced in the peripheral blood of patients with farmer's lung disease or even of those exposed to moldy hay, whereas B lymphocytes are unaffected (Flaherty et al., 1976).

Terho (1986) proposed the following *main* criteria for diagnosing farmer's lung disease: (1) exposure to antigens documented by environmental sampling or by identification of precipitating antibodies, (2) typical symptoms that worsen with exposure, and (3) lung infiltrates visible on CXR that are consistent with EAA.

Additional criteria were added to include (1) basal crepitant rales, (2) impairment of diffusing capacity, (3) decreased O₂ tension or saturation at rest or normal at rest and decreased with exercise, (4) PFT showing restrictive pattern, (5) lung biopsy histology compatible with the diagnosis, and (6) positive provocation tests by work exposure or controlled inhalation challenge. To confirm the diagnosis of farmer's lung disease using Terho's criteria, all three of the main criteria and at least two of the additional criteria must be met while other similar diseases are ruled out. If CXR findings are normal, the diagnosis can be confirmed with lung biopsy. It should be noted that radiologic (e.g., HRCT) and immunologic diagnostic tools have advanced since 1986 and can be used to enhance this diagnostic criteria.

INDUSTRIAL HYGIENE

Grain dust (oat, wheat, and barley): TLV-TWA, 4 mg/m³ (ACGIH, 2001).

One of the main preventive measures of farmer's lung disease is to prevent the inhalation exposure to moldy hay and grain. Possible interventions include adequate ventilation in working areas, forced air ventilatory systems, mechanization of the feeding process, controlling the growth of mold on stored hay and grain, and the use of PPE. The use of hay conditioners and hay-dryer systems decreases the quantity of

microorganism in hay, but their installation and usage costs are often prohibitive. Alternatively, the use of commercial additives for hay, such as propionic acid could be used to limit the growth of the mold (Reboux et al., 2002). Kusaka et al. (1993) suggested that the practical use of dust masks can effectively protect against farmer's lung disease. Dust masks with filters have been recommended. It has been debated whether farmers who have developed farmer's lung disease should leave the occupation of farming. One approach is to recommend continued farming, take all possible preventive measures, have regular evaluation of pulmonary functions, and consult physicians at the slightest suspicion of recurrence (Reboux et al., 2002). For highly sensitive patients, changing occupations may be advisable.

MEDICAL MANAGEMENT

As with other types of HP, the acute disease can be treated with corticosteroid therapy, however, its long-term efficacy has not been evaluated in prospective clinical trials (Ohshima et al., 2012). Kokkarinen et al. (1992) found corticosteroid therapy for farmer's lung disease to help improve pulmonary function more rapidly; however, such treatment did not influence the long-term result. Early diagnosis and avoidance of exposure is the cornerstone of management.

ORGANIC DUST TOXIC SYNDROME

Organic dust toxic syndrome is also known as pulmonary mycotoxicosis, grain fever, toxic alveolitis, and inhalation fever.

SOURCES OF EXPOSURE

Agriculture and farming involves production technology and work practices that generate substantial amounts of dusts. The usual exposures associated with ODTD include silage, moldy grain, hay, and straw. These exposures may be generated by silos, by chopping straw for bedding, unloading grain silos, shoveling feed, opening bales of hay for feed, and cleaning old animal housing structures. The physical and chemical components of organic dust vary and are affected by the dust source, geographic region, temperature, humidity, and other factors (Seifert et al., 2003). Confinement facilities generate dusts that include animal feces, endotoxins, and pollens. The occurrence of ODTD is especially common among swine workers, poultry producers, and grain workers, affecting up to 30% of exposed subjects. The higher the dust level, the more likely an exposed worker will develop signs and symptoms. Dust levels can occur up to about 15 mg/m³ in swine operations, 12 mg/m³ in poultry environments, and 72 mg/m³ in grain operations (Kirkhorn and Garry, 2000).

The degree of respiratory dysfunction depends on the biological potency and concentration of exposure, as well as on individual susceptibility. Airborne contaminants frequently occur in concentrations and compositions that challenge the defense mechanisms of the lung.

Airborne concentrations of endotoxin in the farming environment may range between 0.01 and 50 µg/m³ during feeding and cleaning operations on dairy farms. In swine confinement buildings, endotoxin is found in mean concentrations between 0.02 and 0.08 µg/m³, and a similar range has been reported in poultry confinement environments. The variability of airborne endotoxin concentrations depends on the geographical location of the farm, type of ventilation, and livestock production techniques, including feeding methods (Donham, 1990).

Factors determining the intensity of exposure include meteorological conditions of the region, construction of the building, and type of farming activity.

ASSOCIATED AGENTS AND ANTIGENS

The most important airborne substances include grain dust and its constituents, bacteria and endotoxin, mycotoxins, fungal spores, fungal metabolites, glucan, and storage mites. Approximately 70 species of mites have been identified in various agricultural environments (Van Hage-Hamsten et al., 1991; Seifert et al., 2003). The most common species are *Acarus*, *Tyrophagus*, *Lepidoglyphus*, *Glycophagus*, and *Tydeus*, *Tarsonemus*.

The most common bacteria occurring in the farm environment are Gram-positive cocci (*Staphylococcus*, *Streptococcus*) and bacilli rods (*Corynebacterium*). Gram-negative species (*Proteus*, *Pseudomonas*, *Escherichia*) are, in general, less common but are potentially more pathogenic.

MECHANISM OF ACTION AND CHEMICAL PATHOLOGY

The pathogenesis of ODTs is unclear, but clinical findings and the results of BAL examination suggest a nonspecific acute inflammatory process. Direct toxic response to inhaled mycotoxin, proteinase enzymes, or endotoxin may be etiological factors (Barber, 1989; Crook et al., 1991; Seifert et al., 2003; Boehmer et al., 2009). Organic dust toxic syndrome is not considered as an infectious or allergic process. Mold and grain dust extract can contribute to inflammatory pulmonary reactions. Endotoxins are heat stable lipopolysaccharides (LPSs) found in dusts that can cause flu-like symptoms and promote bronchoconstriction. Other microbial products may be inflammatory or immunomodulatory, including: (1,3) beta-D-glucans, exotoxins from Gram-positive and Gram-negative bacteria, phytotoxins, heat shock proteins, and T-cell-activating superantigens (Kirkhorn and Garry, 2000).

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

A thorough occupational history should elicit heavy exposure to organic dust. Symptoms resemble a flu-like illness and may include one or more of the following, irritation of the upper respiratory tract, eyes and skin, fever, chills, malaise, myalgia, fatigue, a dry cough, dyspnea, chest tightness, headache and nausea; the severity of which depends on the intensity and duration of the exposure (Seifert et al., 2003). It is difficult to distinguish ODTs from farmer's lung disease based on clinical symptoms alone; both occurring 4–8 h after exposure. An adequate exposure history along with diagnostic studies is needed to make the distinction.

Organic dust toxic syndrome is thought to be much more common than HP. Unlike HP, ODTs is not associated with sensitization, and neither skin tests nor serological tests identify the apparent immunological involvement (Pepys and Jenkins, 1965; Seifert et al., 2003). The lungs may be clear or rales may be heard. The CBC may show leukocytosis without infection that may be misleading.

In contrast to HP, the CXR in ODTs is usually normal without infiltrates and lung function is normal, although minor and transient changes have been described. Similar to HP, ODTs can show an increase of neutrophils on BAL (Lecours et al., 1986). Severe hypoxemia does not occur (Von Essen et al., 1990, 2005).

Respiratory symptoms of ODTs resemble those of the acute stage of HP, but the condition is considered benign, without persistent respiratory sequelae of physiologic significance. It should always be remembered that multiple disease processes may be at play when dealing with complex mixtures of organic dust particulates, and farmer's lung disease and ODTs can occur together.

INDUSTRIAL HYGIENE

Grain dust (oat, wheat, and barley): ACGIH TLV-TWA, 4 mg/m³; NIOSH REL-TWA, 4 mg/m³; OSHA PEL-TWA, 10 mg/m³.

Nuisance dust: TLV, 10 mg/m³ inhalable, 3 mg/m³ respirable (ACGIH, 2000).

Dust exposure should be minimized through workplace engineering and or use of respirators. General standards for dust exposure should be implemented (see introduction to this chapter). More specifically, grain dust has been assigned a TLV intended to minimize the potential for acute irritation of the upper respiratory tract, eyes, and skin, bronchitis symptoms, and chronic decrements in pulmonary function. The recommended TLV applies to the whole grain of oat, wheat, and barley before the milling

operation. Data are scant or not available on which to base skin or sensitization (SEN) notations or a carcinogenicity classification. Kirkhorn and Garry (2000) reports are based on studies of post shift decrements in FEV1 where environmental dust is below current standards, recommendations have been made for the development of more stringent threshold-limit standards to adequately protect workers in the confinement industry.

MEDICAL MANAGEMENT

Most cases of ODTs are self-limiting and medical treatment is not sought. Treatment for myalgia and fever with non-steroidal anti-inflammatory agents and acetaminophen has been recommended. Corticosteroids have not been shown to be helpful. Severe cases with respiratory failure should be managed with supportive care (Von Essen et al., 2005).

TEA MAKERS ASTHMA

Exposure to tea dust has been associated with illness called tea taster's disease, tea factory cough, and tea maker's asthma.

SOURCES OF EXPOSURE

Manufacturing of tea is a dusty process that exposes workers to a fine tea fluff; occupational illness has been reported as far back as 1919 among some workers who process or taste the tea (Castellani and Chalmers, 1919).

ASSOCIATED AGENTS OR ANTIGENS

The agent associated with illness is tea dust or a fine dust called tea fluff.

MECHANISM OF ACTION AND CHEMICAL PATHOLOGY

Tea taster's disease has been thought to result from the inhalation of microorganisms while sniffing tea leaves. Both cough and asthma have been associated with inhaling the fine dust known as tea fluff and studies have suggested sensitization to tea dust with resulting respiratory symptoms (Uragoda, 1970). Currently, the underlying mechanism for tea-associated disease is unclear, although tea-induced asthma probably results from allergic sensitization similar to many other organic dust syndromes (Abramson et al., 2001).

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

Rhinitis, cough, chest tightness, reductions in FEF indices, bronchitis, asthma, and chronic respiratory symptoms have been reported in tea workers (Uragoda, 1970; Zuskin and Skuric, 1984; Rask-Andersen, 1989; Mirbod et al., 1995; Hill and Waldron, 1996).

Historically, Castellani and Chalmers (1919) described two related occupational conditions, which they called tea factory cough and tea taster's disease. Workers with tea factory cough suffered from weight loss, tiredness, and cough with mucopurulent expectoration. Occasional coarse rales could be heard on auscultation. When removed from exposure, the symptoms slowly resolved. Tea tasters had similar reactions. Tea tasters not only tasted the tea but also buried their noses in the leaves inhaling not only the tea dust, but also contaminants such as the fungi *Monilia*, *Aspergillus*, and *Penicillium* as well as a "peculiar *Streptococcus*" microorganism.

Uragoda (1970) reported a case of occupational asthma in a tea maker who when exposed to tea fluff experienced sneezing, watery nasal discharge, coughing, chest tightness, shortness of breath and production of copious amounts of mucoid sputum, accompanied by wheezing, bilateral rhonchi, and crepitations. Provocative inhalation of the tea fluff produced an attack within a few minutes. A positive reaction was obtained on skin testing with tea fluff antigen.

Zuskin and Skuric (1984) found reductions in maximum expiratory flow rates at low volumes during the work shift of tea workers suggesting a bronchoconstrictor effect of the dust acting mostly on small airways. Pre-shift administration of disodium cromoglycate diminished the acute reduction in flow rates. They also concluded that exposure to tea dust in some workers may lead to chronic respiratory effects. In 1985, Zuskin E. et al. studied 26 nonsmoking female tea workers and found that those who had positive skin tests had a higher prevalence of chronic respiratory symptoms, including cough, phlegm, bronchitis, asthma, and dyspnea, however, only coughing and dyspnea showed a significant difference (Zuskin et al., 1985). Pre-shift maximum expiratory flow rates (MEFR) were found to be lower than normal in tea workers. Maximum expiratory flow rate showed significant reductions over the work shift and the acute reductions were larger in those with positive skin tests. Provocative inhalation of tea allergens caused bronchoconstriction in four out of six subjects that were tested.

A systematic study of tea workers in Sri Lanka who were exposed to tea fluff during blending operations showed a prevalence of chronic bronchitis and asthma greater than the general population (Uragoda, 1980). Roberts and Thomson (1988) reported asthma in a 55-year-old female worker in a tea-packing production line. Although SP testing was negative, diagnosis was established by serial expiratory flow rates and bronchial provocation challenge with tea dust that elicited a late asthmatic reaction. Three cases of occupational asthma in tea workers were reported by Cartier and Malo (1990).

Abramson et al. (2001) studied 192 workers in a tea-packing plant and found the prevalence of asthma, wheezing, hay fever, and atopy to be higher than has been previously reported in tea workers, but similar to the general population in the area. Tea workers in certain operations did report an excess of respiratory and nasal symptoms. The authors concluded in this study that the work-related respiratory and nasal symptoms probably represented nonspecific irritation.

Shieh et al. (2012) found tea workers in certain areas of production to have a higher prevalence of rhinorrhea, sneezing, throat irritation, cough, chronic phlegm, chronic bronchitis, dyspnea, and reductions in FEV₁/FVC and maximum mid expiratory flow rates.

Previous studies have reported an association between tea drinking as well as other dietary factors and lung cancer. This was investigated in a case-control study in the west of

Sweden by Axelsson et al. (1996). This study could not demonstrate an increased risk of cancer due to tea consumption, contrary to the findings of some previous studies.

Furthermore, a study was conducted in Okinawa, Japan, from 1988 to 1991 to evaluate the relationship between tea consumption and lung cancer risk (Ohino et al., 1995). Paradoxically, the greater the intake of Okinawan tea (a partially fermented tea), the smaller the risk, particularly in women. The risk reduction by Okinawan tea consumption was detected mainly in squamous cell carcinoma. Daily tea consumption significantly decreased the risk of squamous cell carcinoma in males and females, suggesting a protective effect of tea consumption against lung cancer in humans.

INDUSTRIAL HYGIENE

There are no specific standards for airborne tea dust. Tea dust exposure should be minimized, and for workers with disease, eliminated.

MEDICAL MANAGEMENT

Management includes removal from exposure and symptomatic treatment of rhinitis, coughing, and asthma.

WOOD DUSTS

SOURCES OF EXPOSURE

Exposure to wood dust occurs in many occupations such as furniture and cabinet making, carpentry, logging, lumber mills, sawmills, pulp mills, and construction. The intensity (concentration) of exposure varies depending on the types of processes (such as sawing vs. grinding), ventilation, and use of PPE; these are important considerations when implementing preventive measures or determining causation. Most studies showing associations with sinonasal cancer involved hard wood exposure in furniture workers (ACGIH, 2005, Wood Dusts; Kauppinen et al., 2006).

ASSOCIATED AGENTS AND ANTIGENS

Endotoxins of Gram-negative bacteria and the allergenic fungi that grow on wood are reported to be the main hazardous agents found in wood-processing workplaces (Dutkiewicz et al., 1988; Alwis et al., 1999). Wood contains hundreds of high and low molecular weight compounds known as “wood extractives” that protect trees from attack by bacteria and fungi, and also give color to the wood (ACGIH, 2005, Wood Dusts). Plicatic acid has been determined to be the cause of asthma associated with exposure to western red cedar. Wood dust contaminated with bacteria and fungi may contribute to irritation and sensitization. In wood pulp workers, HP has been associated with exposure to antigens of Alternaria and Penicillium. The specific causative agents of sinonasal cancer associated with wood dust exposure have not been determined (Nylander and Dement, 1993).

MECHANISM OF ACTION AND CHEMICAL PATHOLOGY

Being that wood dusts are complex mixtures of high and low molecular weight organic compounds that contain various irritants, endotoxins, and allergens, we expect the mechanisms of disease to include irritant, toxicologic, pharmacologic, and immunologic mechanisms; however, as already stated, and as

is the case with most organic dusts, the mechanisms of disease for wood dust exposure have not been clearly delineated. Endotoxins have been linked to chest tightness, shortness of breath, fever, and wheezing. (1–3)- β -D-glucan, a fungal constituent and an inflammatory agent, is found in organic dusts and thought to react synergistically with endotoxin and other inflammatory agents (Fogelmark et al., 1992). (1–3)- β -D-glucan is also thought to play an important role in the development of HP (Fogelmark and Rylander, 1993).

One of the best known associations is OA due to exposure to Western Red Cedar. In this case plicatic acid, a unique component of Western Red Cedar, has been identified as a causative agent responsible for asthma, however, the pathologic mechanism is not clear. Apart from plicatic acid in Western Red Cedar wood, no causative agent for wood-related asthma has consistently been reported. Type 1 allergy is not suspected to be a major cause of wood dust-induced asthma (Jacobsen et al., 2010).

Similarly, the specific agent in hard wood dust responsible for cases of nasal cancer in furniture workers thought to be associated with wood dust exposure has not been determined.

CLINICAL AND DIAGNOSTIC CONSIDERATIONS

Health problems that have been reported to be associated with various wood dusts include dermatitis, rhinitis, conjunctivitis, sinusitis, bronchitis, OA, HP, ODTD, non-asthmatic chronic airflow obstruction, and nasal cancer (Enarson and Chan-Yeung, 1990; Chan-Yeung and Malo, 1994; ACGIH, 2005, Wood Dusts). Symptoms of cough, phlegm, chronic bronchitis, frequent headaches, eye irritation, throat irritation, and nasal symptoms have been found to be more prevalent in woodworkers (Alwis et al., 1999). While standard methods are used to diagnose these conditions, causation is not always clear. Radioallergosorbent testing, SP testing, and ELISA may be helpful in establishing immunologic vs. irritant causes.

Hildesheim et al. (2001), reported the risk for nasal cancer in those exposed to wood dust to increase with exposure for >10 years, those first exposed before the age of 25 years, and those seropositive to Epstein–Barr virus.

Jacobsen et al. (2010) reviewed 37 articles and reported support for an association between dry wood dust exposure and asthma, rhino-conjunctivitis, coughing, bronchitis, and acute and chronic impairment of the lung function.

Associations between wood dust exposure and nasal adenocarcinomas have been consistently stronger than that between wood dust and nasopharyngeal squamous carcinoma. Additionally, it has also been reported that while nasal adenocarcinomas have been mostly associated with occupational exposure to hardwood, nasopharyngeal cancer (a squamous cell tumor) may be more closely linked to softwood exposure (Hildesheim et al., 2001).

Signs of nasal cancer may include nosebleeds, nasal obstruction, or discharge, changes in the sense of smell, headache, dysphagia, tinnitus, and cranial nerve involvement with weakness of the muscles of the face, tongue, or throat, and cervical lymphadenopathy. Prevention or early diagnosis is of course optimal when managing cancer risks.

While previous studies have been inconclusive regarding associations between wood dust exposure and cancers other than sinonasal cancer, Barcenas et al. (2005) concluded that wood dust is a potential risk for lung cancer based on their case control study of 1368 lung cancer patients.

INDUSTRIAL HYGIENE

Western Red Cedar: TLV-TWA, 0.5 mg/m³, inhalable particulate mass. Sensitizer (SEN): A4—not classifiable as a human carcinogen.

All other species: TLV-TWA, 1 mg/m³, inhalable particulate mass. Carcinogenicity: A1—confirmed human carcinogen: Oak, beech. A2—suspected human carcinogen: Birch, mahogany, teak, and walnut. A4—not classifiable as a human carcinogen: All other wood dusts. (ACGIH, 2005).

All TLVs for wood dust are measured as *inhalable* particulate mass because of the evidence of an increased risk of upper and lower respiratory symptoms and sinonasal cancer.

MEDICAL MANAGEMENT

Successful treatment of symptoms depends on an accurate diagnosis of irritation vs. allergic vs. carcinogenic responses. Application of standard medical care for dermatitis, rhinitis, bronchitis, asthma, and HP can be implemented. Identification and documentation of involved wood exposure is challenging yet crucial in accurately determining the cause and for effective exposure mitigation. Once the offending agent is identified and exposure eliminated some but not all cases show reversal and improvement of disease.

The treatment of diagnosed cancer is beyond the scope of this chapter. Prevention of cancer through appropriate exposure control is the best approach. Monitoring the health status of the occupationally exposed worker may help to achieve early diagnosis, treatment, and exposure intervention, which may improve outcomes.

NATURALLY OCCURRING MINERAL FIBERS

ALI K. HAMADE, CHRISTOPHER M. LONG, AND PETER A. VALBERG

ASBESTOS

First aid: Remove to fresh air free of airborne asbestos fibers. Decontaminate clothing and skin surfaces

Target organ(s): Lung

Occupational exposure limits: OSHA 8-h TWA 0.1 f/cc; ACGIH 8-h TWA 0.1 f/cc; OSHA PEL (excursion limit) averaged over a 30 min sampling period 1.0 f/ml

Reference values: No RfC derived; inhalation unit risk = 0.23 per (f/cc); MCL = MCLG = 7 million fibers per liter (MFL); no MRLs derived

Risk/safety phrases: IARC Group 1 carcinogen; ACGIH, A1; NIOSH “considers asbestos a potential occupational carcinogen and recommends that exposures be reduced to the lowest possible concentration.”

ASBESTOS MINERALS: BACKGROUND AND USES

Historical Overview

Asbestos refers to a group of naturally occurring, fibrous, hydrated mineral silicates; i.e., asbestiform minerals are made up of thin, fiber-like crystals. These minerals have been historically used in a wide variety of products where resistance to heat has been of crucial importance, for example, thermal insulation of high pressure steam pipes, fireproofing of building materials, and refractory bricks in high temperature furnaces. The fact that asbestiform minerals could be woven into textiles also allowed for their use in fire blankets, insulating gloves, and fire-resistant garments. Asbestos is also very durable, insoluble, and chemically inert, and hence, found in

siding and roofing shingles, vinyl asbestos floor tiles, asbestos boards, and friction products.

Asbestos minerals have been known for their useful properties for millennia, and were widely used in the early twentieth century because of characteristics such as superb performance as a flame retardant, low thermal conductivity, good sound absorption, tensile strength, and resistance to thermal, electrical, and chemical damage (Alleman and Mossman, 1997). However, because of serious health consequences resulting from elevated exposures to airborne asbestos, particularly in the occupational environment, the use of asbestos minerals is currently federally regulated, and is banned in many countries.

Straif (2008) estimated that 85–90% of pleural mesotheliomas and about 4.5% of lung cancers arise in men due to exposure to asbestos.. In women, the asbestos-attributable risks for pleural and peritoneal mesotheliomas combined are estimated at 23% (Spirtas et al., 1994). The role of asbestos in these diseases has changed over time due to changes in asbestos usage and control of exposure, and it appears to be decreasing at present (Craighead, 2011; Pukkala et al., 2009; Moolgavkar et al., 2009).

Asbestos use in the United States and around the world has been steadily decreasing, as described by the United States Environmental Protection Agency (US EPA), United States Geological Survey (USGS), National Institute for Occupational Safety and Health (NIOSH), and World Health Organization (WHO) on the following websites (and illustrated in Figure 96.1).

<http://www.epa.gov/asbestos/pubs/ban.html>

http://whqlibdoc.who.int/hq/2006/WHO_SDE_OEH_06.03_eng.pdf

The regulatory definition of a “fiber” is a structure with a length $>5\text{ }\mu\text{m}$, diameter $<3\text{ }\mu\text{m}$, and an aspect ratio (length-to-diameter ratio) $>3:1$. However, many asbestos fibers found in insulation products are longer and thinner than this prescription, typically with an aspect ratio of 20:1. The number of fibers detected in air samples or in body tissues depends on the method used [e.g., phase contrast microscopy (PCM) *versus* scanning or transmission electron microscopy]. Guidelines for limiting asbestos exposure in the occupational environment are generally given in terms of fiber counts per volume of air, e.g., fibers per cubic centimeter (f/cc) of air. The Occupational Safety and Health Administration (OSHA) 8-h time-weighted average (TWA) concentration allowable in the workplace is 0.1 f/cc. However, there are numerous other guidelines from OSHA on appropriate asbestos work practices and exposure restrictions (<http://www.osha.gov/SLTC/asbestos/standards.html>). The American Conference of Governmental Industrial Hygienists (ACGIH) has the same guideline level for asbestos, namely an 8-h TWA of 0.1 f/cc. These airborne concentrations are specified as being measured by PCM.

Types of Asbestos Mineral Fibers

“Asbestos” includes the following six naturally occurring, hydrated-silicate minerals with fibrous habits, i.e., made up of thin, fiber-like crystals (HEI-AR, 1991). The mineralogy

of asbestos has been recently reviewed (Sporn, 2011; Case et al., 2011).

Serpentine asbestos, which forms polymeric sheets that tend to wrap into curved and flexible tubular fibers (i.e., hollow tubules):

chrysotile—“white asbestos”—CAS # 12001-29-5, e.g.,
 $\text{Mg}_3(\text{OH})_4(\text{Si}_2\text{O}_5)$

Amphibole asbestos, which is made up of thin, straight, needlelike fibers, consists of:

actinolite—CAS # 13768-00-8, e.g., $\text{Ca}_2(\text{Mg}, \text{Fe})_5(\text{OH})_2(\text{Si}_8\text{O}_{22})$

amosite¹—“brown asbestos”—CAS # 12172-73-5, e.g.,
 $\text{Fe}_7(\text{OH})_2(\text{Si}_8\text{O}_{22})$

anthophyllite—CAS # 17068-78-9 e.g., $(\text{Mg}, \text{Fe})_7(\text{OH})_2(\text{Si}_8\text{O}_{22})$

crocidolite—“blue asbestos”—CAS # 12001-28-4 e.g.,
 $\text{Na}_2\text{Fe}_5(\text{OH})_2(\text{Si}_8\text{O}_{22})$

tremolite—CAS # 14567-73-8 e.g., $\text{Ca}_2\text{Mg}_5(\text{OH})_2(\text{Si}_8\text{O}_{22})$

Chrysotile asbestos is more flexible than amphibole types of asbestos, and it has often been spun and woven into fabric and embedded into various matrices (for example, joint compound, corrugated asbestos-cement roofing sheets, and friction products) so as to contribute to strength, heat resistance, and chemical inertness. Amphibole fibers were more frequently used in thermal insulation (lagging). Crocidolite and amosite are the only amphiboles that have had significant industrial uses over the years. For example, amosite was used in insulation Batts, asbestos sheets, pipe insulation, block insulation, and ceiling tiles. The other three amphiboles, actinolite, anthophyllite, and tremolite, have had only infrequent industrial application.

In the post-WWII time period, some asbestos could be found in products as diverse as pipe insulation, boiler insulation, fire retardant coatings, brake linings, bricks, cement pipe, and fireplace cement, heat-, fire-, and acid-resistant gaskets, ceiling tiles and insulation, fireproof drywall, flooring, roofing, lawn furniture, and drywall joint compound. Chrysotile has been used more than any other type of asbestos, and accounts for about 95% of the asbestos found in buildings in the United States (HEI-AR, 1991).

General Epidemiology and Impact on Occupational Health

Asbestos exposure and the subsequent development of disease have been frequently evaluated over the years, and many

¹ Amosite is a trade name for the amphiboles in the cummingtonite-grunerite series, i.e., asbestos that came from the Asbestos Mines of South Africa (AMOSA) mine.

reviews are available (Doll and Peto, 1985; US EPA, 1986; HEI-AR, 1991; ATSDR, 2001; Roggli et al., 2004; Craighead and Gibbs, 2008; Dodson and Hammar, 2011).

Airborne asbestos fibers can be a health hazard, if inhaled at sufficient doses, because of the physical and chemical properties of the asbestos fibers. The primary route of exposure is *via* inhalation of fibers released during asbestos mining, manufacture of asbestos-based products, and breakdown of asbestos-based materials. Depending on fiber size (length and diameter), inhaled fibers deposit onto lung airway surfaces, and subsequently are removed from the lung (cleared), retained in lung tissues, or translocated to nearby sites. Because the fibers are insoluble and resistant to chemical attack, retained fibers are not readily broken down. Of the various asbestos species, chrysotile is the most soluble and most rapidly cleared from the lungs, which contrasts to the amphibole varieties of asbestos, which are considerably more resistant to dissolution and clearance.

Inhalation of sufficient quantities of asbestos fibers over protracted periods of time can lead to serious illnesses, including asbestosis (a type of pneumoconiosis), pleural plaques, pleural effusions, lung cancer, and mesothelioma (a rare cancer of the lung or peritoneal pleura, associated with exposure to amphibole asbestos). Asbestos is classified as a known human carcinogen by International Agency for Research on Cancer (IARC) [(1977, 2012; Straif et al., 2009)]. A low concentration of asbestos fibers exists in the ambient air, due to both natural sources and society's long use of asbestos in construction and commerce (HEI-AR, 1991). Exposure at the low levels found in nonoccupational settings is less likely to cause health problems (Pierce et al., 2008).

PHYSICAL AND CHEMICAL PROPERTIES

Overall Structure

Because asbestos fibers are all silicates, they exhibit properties common to silicates, such as incombustibility, thermal stability, resistance to biodegradation, non-reactivity toward most chemicals, and low electrical conductivity. In fact, the word "asbestos" comes from the Greek, meaning "unquenchable" or "inextinguishable" (Alleman and Mossman, 1997). Asbestos minerals are found in bundles of fibers, which can be easily separated from the host matrix or cleaved into thinner fibers. Chrysotile may form very fine fibrils that range between 0.02 and 0.08 µm in diameter; amosite diameters range between 0.06 and 0.35 µm, and crocidolite between 0.04 and 0.15 µm (HEI-AR, 1991).

The basic building blocks of asbestos fibers are the silicate tetrahedra, which may occur as double chains (Si_4O_{11}), as in the amphiboles, or in sheets (Si_2O_5), as in chrysotile. In the case of chrysotile, an octahedral brucite layer having the formula ($\text{Mg}_3\text{O}_4(\text{OH})_8$) is intercalated between each silicate

tetrahedra sheet. Asbestos fibers used in most industrial applications consist of aggregates of smaller units (fibrils). This is most evident with chrysotile, which exhibits an inherent, well-defined unit fiber.

Chemical Constituents

Asbestos fibers are virtually inert; they do not evaporate, dissolve, or burn, and react only minimally with other substances. Although asbestos minerals share the silicate tetrahedral group, the main differences among them are the metal cations. In contrast to chrysotile, where the major metal is magnesium, amphiboles possess crystal structures accommodating cations of differing size and valence, and hence, can have significant calcium and iron content. It has often been suggested that the iron cations are significant contributors to amphibole asbestos toxicity.

Shapes of Fibers

Chrysotile fibers are composed of aggregates of long, thin, and curly fibrils. In contrast, amphibole fibers are straight, needlelike, and splintery. Crocidolite fibrils are shorter and thinner than other amphibole fibrils, but not as thin as chrysotile fibrils. Amosite fibril diameter is thicker than either chrysotile or crocidolite.

Fibers Versus Cleavage Fragments

Some asbestos minerals can exist in forms called "cleavage fragments," which, because they are resistant to disaggregation into free fibers, are considered far less potent in their ability to trigger diseases characteristic of fibrous asbestos (Gamble and Gibbs, 2008). For example, besides the asbestiform varieties of tremolite and actinolite (which release long, thin fibers composed of fibrils), non-asbestiform varieties also occur, which release only cleavage fragments.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Asbestos fibers can be released into the air when asbestos-containing materials are mined, manufactured, used, or demolished. The vast majority of asbestos exposure has taken place in asbestos-worker occupational settings (Williams et al., 2007). A small amount of exposure is known to be present in some public and commercial buildings (HEI-AR, 1991; Lee and Van Orden, 2008). Unless one is in proximity to asbestos being manipulated in construction and/or demolition of asbestos-containing structures, one's outdoor, ambient-air exposures are relevant only in a few geographical locations where asbestos materials are present

in natural rocks and soils (Lee et al., 2008). Also, “environmental” exposures can sometimes be related to neighborhoods where historical manufacturing sites were located and societal uses of asbestos containing materials occurred (Case and Abraham, 2009; Craighead and Gibbs, 2008; Case et al., 2011; NIOSH, 2008; Pan et al., 2005).

Inhaled asbestos fibers deposit on lung surfaces, but because the fibers are insoluble, they do not dissolve readily into lung fluids and must be removed by physical or cellular processes. Fibers that deposit onto surfaces of major airways are removed from the lung by the upward movement of the mucociliary “escalator” to the pharynx, where they are swallowed. Fibers that deposit in the air-exchanges regions of the lung (the alveolar regions) attract alveolar macrophages, which attempt to “eat” (phagocytize) the fibers and remove them from alveolar surfaces. However, if the fibers are too long to be ingested by macrophages ($>12\text{--}17\ \mu\text{m}$), then removal from the lung is incomplete, and in fact, the “frustrated phagocytosis” can release damaging lysosomal enzymes on lung surfaces. Macrophages coat uningested fibers with a proteinaceous material and form “asbestos bodies” or “ferruginous bodies.” Clumps of fibers may fragment or split and form smaller fibrils, which may then be removed or slowly dissolve. Fibers may also penetrate cells that line alveolar surfaces (epithelial cells), and reach lung interstitial tissues and the lung pleura. Thus, asbestos fibers, particularly amphiboles, may accumulate during exposure, and amphibole asbestos fiber retention in the lungs persists long after exposure ceases.

Clearance of asbestos fibers from the lungs varies by fiber type, and chrysotile short fibers clear from the lungs more rapidly than amosite long fibers (ATSDR, 2001; Bernstein et al., 2008). In fact, for nonoccupationally exposed individuals, the greater biopersistence in the lungs of amosite fibers *versus* chrysotile fibers is illustrated by the higher fiber counts for the amphibole asbestos varieties in autopsy sample of lungs (Dodson et al., 1999). The differences in fiber size and chemistry between chrysotile and amphiboles result in chrysotile clearing very rapidly from the lung ($T_{1/2}=0.3\text{--}11$ days) while amphiboles are among the slowest clearing fibers known ($T_{1/2}=500$ to ∞ days) (Bernstein and Hoskins, 2006; Bernstein et al., 2011).

MAMMALIAN TOXICOLOGY

Acute Effects

Due to the insoluble, chemically inert nature of asbestos, there are no clinically significant acute or intermediate effects associated with exposure to asbestos fibers. In fact, the clinically significant effects of asbestos (i.e., asbestosis and cancer) require long-duration exposure, and generally, long-duration (20–40 year) latency periods.

Chronic Effects

Introduction and Historical Overview Alice Hamilton (1869–1970) was a physician and pioneer in industrial diseases and hygiene, and she became Harvard University’s first woman professor in 1919. Dr. Hamilton and Dr. Harriet Louise Hardy (1905–1993) published one of the first books on Industrial Toxicology in 1934, a 500+ page text, which was republished in the second edition in 1949 as a 574 page text, when both women were on the faculty of the Harvard School of Public Health. Dr. Hardy was also a physician and established an occupational medicine clinic at Massachusetts General Hospital in 1947 and was a clinical professor at Harvard from 1979 to 1993. Interestingly, the 1949 edition of Hamilton & Hardy’s Industrial Hygiene (Hamilton and Hardy, 1949) makes no mention of asbestos and its health hazards, but Dr. Hardy was one of the very first scientists to recognize the link between exposures to elevated levels of airborne asbestos and increased lung cancer risk in her 1965 article “Asbestos related disease” in the American Journal of Medical Science (Hardy, 1965). W.C. Hueper, in his 1942 compendium Occupational Tumors and Allied Diseases, does mention asbestos in the context of pneumoconiosis and lung cancer (Hueper, 1942). Although Dr. Hueper notes that, since 1935, cases of lung cancer in workers have appeared in conjunction with asbestosis, he goes on to say that at that point in time (1942) “[a]sbestosis carcinoma of the lung is not included in any group of occupational tumors recognized by any country.”

Asbestos fiber inhalation at elevated levels and over sufficiently long durations can cause lung cancer and fibrotic lung disease in exposed humans and animals. Likewise, excessive-exposure circumstances can lead to malignant mesothelioma of the thin (mesothelial) membrane lining the chest (pleura) and abdominal (peritoneum) cavities. Some studies of occupationally exposed workers also suggest an increased risk of gastrointestinal cancer. Asbestos is classified as a Group 1 carcinogen (human evidence is sufficient) by the IARC (IARC, 1977) and a Group A carcinogen (again, the human evidence is sufficient) by US EPA (US EPA, 1999). In addition to carcinogenesis, asbestos exposure can cause fibrotic lung and pleural disease, termed asbestosis. Experimental models have been used to elucidate the mechanisms by which asbestos causes cancer and lung disease and to determine what properties of the fiber are important for disease development (Aust et al., 2011; Ghio et al., 2004; Mossman et al., 2011).

Noncancer/Asbestosis/Pleural Plaques Asbestosis is a lung pneumoconiosis wherein a diffuse interstitial fibrosis develops over time. The effect of asbestosis on pulmonary function is primarily the reduction of lung volumes detected by reduced inspiratory capacity and vital capacity (Churg, 1993; Kishimoto et al., 2011). The role of asbestos in lung

function decrements is revealed by either occupational history of exposure to asbestos or the presence of asbestos fibers and asbestos bodies in lung tissues. Pleural plaques are generally a benign asbestos-related disease, which may occur in the absence of lung fibrosis, and the presence of which, *per se*, do not relate to lung cancer or mesothelioma risk (Ameille et al., 2009). Benign pleural plaques occur on the parietal pleura in locations of greatest respiratory movement and consist of collagenous connective tissue with secondary calcification.

Lung Cancer Subsequent to the classic 1954 publication of Doll and Hill on lung cancer risks from tobacco smoking, Doll (1955) examined the association between asbestos and lung cancer in British workers exposed before asbestos dust control efforts. He found that average lung cancer risk among men employed for more than 20 years under the old, dusty conditions was on the order of 10 times that experienced by the general population. In the US, Selikoff et al. (1964) identified neoplastic asbestos diseases in asbestos-insulated workers, and in 1968 Selikoff and colleagues reported on deaths in 370 asbestos workers over a 1-year period (Selikoff et al., 1968). In this group, there were 27 observed deaths from cancer of the lungs, with only 2.3 expected. In his 1977 review covering 9 years of observation of a cohort of 17,800 asbestos workers, Selikoff noted: "Asbestos workers who have no history of cigarette smoking are not likely to die of lung cancer" (Selikoff, 1977). As a further observation, Hammond et al. (1979) reported on lung cancer incidence in about 12,000 workers with at least 20 years of asbestos-insulation work experience. The authors reported that, compared to non-smoking, non-asbestos-workers, asbestos workers in various smoking categories showed mortality ratios of 87 (for >1 pack per day), 51 (for <1 pack per day), 37 (for ex-cigarette smokers), seven (for pipe and cigar smokers), and five (for workers who never smoked regularly).

Thus, the Hammond et al. (1979) data suggested that lung cancer risk showed a multiplicative relationship between smoking and asbestos exposure, such that the "combination of cigarette smoking and asbestos exposure among amosite asbestos factory workers was calculated to have increased their risk of lung cancer death about 80 times as compared with like men of the same age who neither smoked cigarettes nor worked with asbestos." Other analyses have suggested that the interaction is "less-than-multiplicative" (Liddell and Armstrong, 2002). In Great Britain, a study of nearly 100,000 asbestos workers reported that while there is a synergistic interaction between smoking and asbestos, the combined effect of the factors is more than additive, but less than multiplicative (Frost et al., 2011).

Jones et al. (1996) examined the association of lung cancer with asbestosis in a case-control study of 271 patients with a confirmed diagnosis of primary lung cancer. After adjusting for age, sex, smoking history, and area of

referral, the authors found that cases classified as having asbestosis had an odds ratio (OR) of 2.00 for lung cancer, whereas, those without asbestosis had an OR of 1.56. The authors concluded asbestosis is not a necessary step in the development of asbestos-related lung cancer. However, more recent studies have concluded that, even though asbestosis is not a prerequisite for lung cancer development, asbestosis is seemingly a better predictor of lung cancer risk than past history of asbestos exposure *per se* (Weiss, 1999; Zhong et al., 2008).

Mesothelioma Mesothelioma is a cancer of epithelial-lining cells (mesothelial cells) of the lung or peritoneal cavities. Mesotheliomas were first reported by Wagner et al. (1960) in crocidolite miners of North Western Cape Province, South Africa. The authors described 33 cases of mesothelioma with exposure to one type of asbestos, the so-called blue asbestos (crocidolite). In 1962, Wagner was able to produce mesothelial tumors of the pleura by direct implantation of asbestos dust or silica dust into laboratory rats (Wagner, 1962).

Mesothelioma has been shown to have occurred over the years in populations of asbestos workers (McDonald et al., 1997), and it has a latency period in the range of 20–40 years. Mesothelioma is strongly associated with exposure to amphibole (amosite and crocidolite) asbestos (Churg, 1982, 1998; Wagner et al., 1988; Kishimoto et al., 2004). Mesothelioma from chrysotile asbestos cannot be ruled out, but the potency appears to be much less (Pierce et al., 2008; Berman and Crump, 2008a), as discussed below.

In the U.S. studies mentioned above, Selikoff et al. (1968) reported finding 10 (pleural + peritoneal) mesothelioma deaths in a cohort of 370 asbestos workers, stating, "All three of the men who died of pleural mesothelioma had a history of regular cigarette smoking." Of the seven who died of peritoneal mesothelioma, five had a history of regular cigarette smoking, one never smoked regularly, and one smoked only pipes and cigars. In his 1977 review, Selikoff tabulated deaths among 17,800 asbestos insulation workers in the United States and Canada between 1967 and 1975, reporting 0.38 pleural mesothelioma deaths per 1000 man-years of observation in cigarette smokers compared to 0.16 such deaths per 1000 man-years of observation in "never smokers"; because of the results for a category listed as "no history of cigarette smoking," Selikoff stated that mesothelioma had not been associated with "cigarette smoking among asbestos workers" (Selikoff, 1977). However, Hammond et al. (1979) reported that, for pleural mesothelioma, among men who never smoked, "there were three observed deaths versus 4.8 expected deaths" (ratio 0.63), and "five observed deaths versus 3.2 expected deaths for pipe/cigar smokers (ratio 1.59)." Thus, the interaction of smoking and mesothelioma in the Selikoff studies is somewhat suggestive of a smoking effect. However, in a 1980 paper based on seven

pleural mesotheliomas and seven peritoneal mesotheliomas (Selikoff et al., 1980), the authors concluded that smoking history did not affect mesothelioma risk (even though $\frac{3}{4}$ of the mesothelioma deaths were in smokers).

Later studies on the role of smoking in asbestos-associated mesothelioma risk reported a lack of interaction (Muscat and Wynder, 1991), although the fact that tobacco smoke contains radioisotopes and ionizing radiation, which themselves are risk factors for mesothelioma (Goodman et al., 2009; Nakamura et al., 2009; Prueitt et al., 2009), suggests that a role for smoking in mesothelioma risk is biologically plausible. Pleural mesotheliomas have also been produced in animals through lung exposure to radionuclides (Sanders and Jackson, 1972; Sanders, 1992).

As noted earlier, mesothelioma risk is more closely associated with amphibole than chrysotile fibers (Neuberger and Kundi, 1990; Dodson et al., 1997; Rödelsperger et al., 1999; Yarborough, 2007; Roggli and Vollmer, 2008; Sichtelidis et al., 2009). A comprehensive analysis commissioned by US EPA (Berman and Crump, 2003, 2008a,b) concluded that the epidemiologic data are consistent with chrysotile exposure *per se* not contributing to risk of mesothelioma. Moreover, as discussed and summarized by Hodgson and Darnton (2000) and Berman and Crump (2003, 2008a,b), per unit fiber exposure mesothelioma risk from amphibole exposure is far more greater than that from chrysotile exposure. Hodgson and Darnton (2000) estimated that amosite is about 100 times, and crocidolite about 500 times, more potent than chrysotile in causing mesothelioma. Berman and Crump (2003, 2008a,b) concluded that amphiboles are about 750 times as potent as chrysotile in causing mesothelioma. As discussed by Pierce et al. (2008), cohorts exposed predominantly to chrysotile show that, if there is a mesothelioma risk for chrysotile at all, the dose threshold falls above 15–500 f/cc-year level; whereas, given that amphibole fibers are estimated to be about 500 times more potent, depending on fiber dimensions, the dose threshold level for amphiboles causing mesothelioma would be in the range 0.3–1.0 f/cc-year. For example, chrysotile used in brake pads does not appear to increase the risk of mesothelioma (Goodman et al., 2004; Laden et al., 2004); in those brake mechanics who develop mesothelioma, lung tissues show a presence of amphibole fibers (Butnor et al., 2003). Also, for patients believed to have developed mesothelioma from “bystander exposure” to asbestos, the predominant fiber type identified by electron microscopy is amphibole asbestos (crocidolite or amosite) (Neumann et al., 2011).

Given that the percentage of mesotheliomas attributable to asbestos exposure is about 85%, this disease has non-asbestos causes such as idiopathic origin, SV-40 virus infection, chronic inflammation, and ionizing radiation (Pelnar, 1988; Peterson et al., 1984; Toyooka et al., 2001; Huncharek, 2002; Goodman et al., 2009; Weiner and Neragi-Miandoab, 2009; de Bruin et al., 2009; Craighead, 2011). In fact, a large case-

control study of mesothelioma in Great Britain (Rake et al., 2009) concluded that 14% of male and 62% of female mesothelioma cases were not attributable to occupational or domestic asbestos exposure. For individuals not exposed to asbestos, the authors estimated a lifetime risk of mesothelioma (pleural and peritoneal combined) from other causes of about 1 in 1000.

Modes of Action

The diseases of greatest concern with regard to asbestos exposure are lung cancer and mesothelioma. As is the case with all cancers, DNA errors in key areas of the cell genome, namely, in proto-oncogenes and tumor-suppressor genes, are thought to be the key events that initiate uncontrolled cell division (i.e., carcinogenesis). DNA damage is a normal consequence of metabolic processes (active oxygen species), background ionizing radiation, and errors in cell division. The consequences of DNA errors can be innocuous, lead to cell death, initiate DNA repair, or, if at critical gene loci and unrepaired, trigger changes that lead to neoplasia. Tomlinson et al. (2002) estimated that by the time we reach age 15 we have accumulated thousands of mutations in our bodies, and this number increases with age. Because of the accumulation of DNA damage, the risk of all cancers increases dramatically with age.

The mechanism by which asbestos fibers in the body add to this mutation load is unclear, but the persistence of the fibers, their resistance to phagocytosis, and their surface chemistry likely lead to cancer through epigenetic pathways such as chronic inflammation, frustrated phagocytosis, and free-radical generation. Carcinogens that are not directly genotoxic have a threshold level for carcinogenesis, requiring a certain level of exposure before promotion of cell proliferation can occur, and asbestos-related cancers likely fall in this category (Butterworth, 1990; Schins, 2002; Mossman et al., 2011).

In terms of mechanisms of action related to fiber properties, it appears that carcinogenic potency of asbestos fibers depends on fiber type (with amphibole potency about 100-fold greater than serpentine potency) and on fiber length (with potency of fibers longer than 5 μm being greater than for short fibers) (Berman et al., 1995; ATSDR, 2001; Berman and Crump, 2008a,b; Stayner et al., 2008). Likewise, thin fibers are more potent than thick fibers (ATSDR, 2001; Hesterberg and Barrett, 1984), and cleavage fragments of the minerals are least potent (Gamble and Gibbs, 2008).

Some investigators place significant emphasis on the role of iron (Fe) in asbestos toxicity, oxygen-radical generation, and carcinogenicity (Aust et al., 2011; Ghio et al., 2004; Nakamura et al., 2009; Quinlan et al., 1994), whereas, others find the role of biopersistence to be predominant (Bernstein et al., 2003; Hesterberg et al., 1998).

SOURCES OF EXPOSURE

Occupational

Historically, thermal insulation work typically led to elevated airborne concentrations of free fibers (2–30 f/cc) (Balzer and Cooper, 1968; Peto, 1980; Williams et al., 2007). Working with asbestos in friable insulation releases far more fibers than work with products having encapsulated fibers (0.02–0.10 f/cc) (Faulring et al., 1975; Mlynarek et al., 1996; Mowat et al. 2005). Moreover, compared to work with other asbestos-containing materials, thermal insulation work can result in elevated exposures to amosite/amphibole asbestos fibers *versus* serpentine (chrysotile) asbestos fibers. In occupational settings, exposures to workers who are bystanders to asbestos work has been evaluated (Donovan et al., 2011), and air dispersion models suitable to estimating such exposures have been developed (Drivas et al., 1996).

Figure 96.1, prepared by NIOSH, shows how the use of asbestos (vertical axis) and permissible asbestos exposure limits (numbers next to arrows) have changed in the United States from 1900 to 2007, with use peaking in the early 1970s (<http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5815a3.htm>). In concordance with the latency period of asbestos-related cancers, time trends in these diseases over the past two decades have also shown a downward slope. For example, age-adjusted rates of pleural mesothelioma among men rose from about 7.5 per million person-years in 1973 to about 20 per million person-years in the early 1990s; rates appear to be stable or declining thereafter (Moolgavkar et al., 2009).

Interestingly, the geographical distribution of mesothelioma mortality in the United States (2000–2004) suggests a pattern of elevated mesothelioma rates for coastal, shipbuilding regions, where many workers outfitted military destroyers and battleships with asbestos insulation, as can be appreciated on a map: <http://www2.cdc.gov/drds/WorldReportData/FigureTableDetails.asp?FigureTableID=900&GroupRefNumber=F07-03>.

Environmental

Geographical Distribution Asbestos exposure occurs primarily in the “built environment,” although natural sources of asbestos exposure, e.g., soils and rocks in Montana and California, are well known (Gunter, 2010; Cooper et al., 1979).

As shown by the figure above, asbestos usage in the United States manufacturing and “built environment” has declined dramatically, but occasionally nonoccupational sources of asbestos exposure raise concerns. An example is the 9/11 destruction of the World Trade Center towers, which released asbestos-related building materials, both during the initial collapse and also during the subsequent cleanup (Lowers et al., 2009; Nolan et al., 2005).

Environmental Exposure Concentrations An overview of sources and types of asbestos exposure has been published recently (Case et al., 2011). Background concentrations inside residences and public buildings have been measured in the range of 0.002–0.027 f/cc, with personal exposure measurements averaging 0.016 f/cc (Lee and Van Orden, 2008 [Table 96.1]). Outdoor exposure concentrations in the ambient environment depend on the levels of human activity. Some assessments have been made in Libby, Montana, and San Jose, California (Adgate et al., 2011; Moolgavkar et al., 2010; Steiner et al., 1990). Outdoor concentrations in urban environments have been reported in the range 0.0008–0.0001 f/cc (HEI-AR, 1991; ATSDR, 2001).

INDUSTRIAL HYGIENE

Measurement Methods

Several measurement methods have been used over the years. The basic measurement principle involves optical visualization of the fibers and fiber counting to derive a concentration of airborne fibers, typically in units of f/cc of air (f/cc or f/cm³ or f/ml). As noted earlier, the focus is on fibers longer than 5 μm.

MI: Midget impinger

PCM: Phase contrast microscopy

SEM: Scanning electron microscopy

TEM: Transmission electron microscopy

EDS: Energy dispersive X-ray detection (for determination of fiber type)

PLM: Polarized light microscopy

Sampling for asbestos in the workplace was initially motivated by findings of health effects in workers. Initially, those effects were identified in industries with heavy exposures (i.e., the textile industry). Early exposures in the textile industry were extremely high, sometimes in the 100s of f/cc. When workers with exposure to asbestos in finished products, rather than to raw asbestos, showed indications of asbestos-related disease, additional monitoring was conducted in these populations (e.g., insulation workers). Among end-users of asbestos, insulators (workers installing and removing asbestos-based thermal insulation) were found to have particularly elevated exposures to free asbestos fibers compared to other craftsmen, especially during ship building, refitting, and repair. Insulation-related asbestos concentrations in shipyards during 1940s to 1960s/early 1970s were in the 10s and 100s of f/cc (Harries, 1968; Mangold et al., 2006; Marr, 1964). Later timeframes (i.e., 1970s and 80s) were characterized by the initiation of asbestos-exposure studies in worker populations expected to have relatively lower exposures to asbestos—in terms of

concentrations, frequency, and duration—than those in the textile, mining, and shipyard industries.

Quantification of exposure is crucial to assessment of asbestos-related disease risk. As already noted by Selikoff et al. (1965) more than four decades ago, exposures in “different occupations vary widely in important respects; in intimacy, intensity and duration of exposure, in variety and grade of asbestos used, in working conditions, in concomitant exposure to other dusts or inhalants.” The unit of asbestos dose most used is the “fibers per cc-years” (f/cc-year), which is the average 8-h workday-free asbestos fiber concentration in f/cc multiplied by the number of work-years over which that exposure occurred.

Numerical Values of the Standards/Exposure Limits

An exposure limit for asbestos in the United States was first established in 1938, when a U.S. Public Health Service study of asbestos textile workers indicated that asbestosis was not likely to occur at fiber concentrations (type not specified) <5 million particles per cubic foot (mppcf). The value of 5 mppcf was subsequently adopted as a threshold limit value (TLV) by ACGIH as well as the United States and several state governments. The 5 mppcf exposure value remained in use in the United States until 1971, when OSHA established a regulatory permissible exposure limit (PEL) of 12 f/cc, which was officially revised to 5 f/cc in June 1972. In 1980, the ACGIH adopted fiber-type specific values of 2 f/cc for chrysotile, 0.2 f/cc for crocidolite, and 0.5 f/cc for amosite and tremolite. In 1991, ACGIH proposed a value of 0.2 f/cc for all fiber types, which was subsequently lowered to 0.1 f/cc (for fibers with length >5 µm) before it was adopted in 1998. OSHA did not adopt fiber-type specific exposure limits, and the 1972 OSHA value of 5 f/cc was subsequently lowered over time to the current value (set in 1994) of 0.1 f/cc for fibers >5 µm in length. Finally, the Asbestos Hazard Emergency Response Act (AHERA) “clearance level” applicable to public exposure is 0.01 f/cc (measured by PCM). The AHERA transmission electron microscopy (TEM) method requires collecting five air-filter samples ($\geq 1199\text{ l}$ of air for a 25 mm filter or $\geq 2799\text{ l}$ of air for a 37 mm filter) under “aggressive” air disturbance conditions, with clearance achieved if the average result of the five filter samples is <70 s/mm² of filter surface (Federal Register, 1987).

RISK ASSESSMENTS

Assumptions Used in Human Health Risk Assessment

Human health risk assessment (HHRA) is a method whereby one can estimate quantitative bounds on the possible risks associated with specific exposure scenarios. A central problem in risk assessment is that, often, potential risks at low

levels of exposure, i.e., levels at which no direct observations (typically occupational data) are available, need to be estimated. In the absence of relevant data, a number of upper bound assumptions are used in the process of risk assessment, i.e., assumptions more likely to overstate, rather than underestimate, the risks associated with exposure. For all carcinogens, the US EPA and other regulatory agencies, as a matter of policy, assume a “linear, no threshold” model of dose response. For asbestos, quantitative dose-response relations are based on occupational cohorts where average exposures were greater than about 15 f/cc-year. The quantitative risk assessments for asbestos include those of US EPA-IRIS (2001) [unit risk (UR)=0.23 per f/cc];² Lash et al. (1997); Hodgson and Darnton (2000); Berman and Crump (2008a,b); Pierce et al. (2008); and Moolgavkar et al. (2010).

Threshold Considerations

Thresholds of effect, specifically for asbestos-related diseases, have been examined by numerous investigators (Doll and Peto, 1985; Ilgren and Browne, 1991; Hodgson and Darnton, 2000, 2010), with the general conclusion that such “no-adverse-effect” thresholds do exist. Pierce et al. (2008) evaluated over 350 asbestos studies to determine thresholds for mesothelioma and lung cancer from exposure to predominantly chrysotile asbestos (i.e., $\geq 90\%$) in mining and manufacturing settings. For chrysotile, they reported the “no-effects” exposure levels for lung cancer and mesothelioma to fall in a range of approximately 25–1000 f/cc-year and 15–500 f/cc-year, respectively. For mesothelioma, two studies reported no increase in mesothelioma risk at the highest exposure levels >400 and ≥ 112 f/cc-year, respectively, while two studies reported chrysotile thresholds between 800 f/cc-year and <15 f/cc-year, respectively. The authors acknowledge that many studies likely lacked sufficient power (e.g., due to small cohort size) to assess whether there could have been a significant increase in risk at the reported no-observed-adverse-effects level (NOAEL).

ERIONITE AND OTHER ZEOLITES

First aid: Inhalation: Move person to an area with fresh air.
Eyes: irrigate eyes immediately with water.

Target organ(s): Lung

Occupational exposure limits: Erionite: None; other zeolites, e.g., mordenite, OSHA PEL, 15 mg/m³ total dust and 5 mg/m³ respirable. ACGIH TLV, 10 mg/m³ total dust and 3 mg/m³ respirable.

Reference values: None determined.

Risk/safety phrases: None specified.

BACKGROUND AND USES

Types of Fibers and Their Uses

Zeolites are a group of hydrated aluminosilicates of the alkaline and alkaline-earth metals, which contain

exchangeable cations of groups IA and IIA, such as sodium, potassium, magnesium, and calcium. Approximately 40 natural types of zeolites have been identified, with erionite (CAS: 66733-21-9; CAS: 12510-42-8) being one of the common types. Other common natural zeolites are analcime, chabazite, mordenite, ferrierite, heulandite, faujasite, clinoptilolite, phillipsite, and laumontite. Out of the large number of natural zeolites, only some are fibrous, including erionite, mesolite, mordenite, natrolite, scolecite, and thomsonite. Although not the subject of this chapter, more than 150 types of synthetic zeolites exist (IARC, 1997).

Erionite has no commercial uses and is not currently mined. It is reported that erionite was one of several commercially important zeolites in the 1960s and 1970s when commercial mining of zeolites began, with some prior use as a noble metal-impregnated catalyst in a hydrocarbon-cracking process (IARC, 1987; NTP, 2011). Other natural zeolites continue to have commercial uses, owing to their thermal stability and ability to selectively adsorb molecules from both air and liquids. Virta (2010) lists a number of domestic uses for natural zeolites in the United States, including animal feed, odor control, pet litter, water purification, fungicide or pesticide carrier, wastewater cleanup, gas absorbent, horticultural applications (soil conditioners and growth media), oil absorbent, desiccant, and aquaculture. More than 75% of these uses are reported to be for animal feed, odor control, and pet litter (Virta, 2010).

General Epidemiology and Impact on Occupational Health

Analogous to asbestos, airborne free erionite fibers can be hazardous to health because of their physical and chemical properties. The primary route of exposure is by inhalation of fibers released during production and mining of other zeolites, during commercial use of other zeolites in various processes and products (e.g., pet litter, animal feed, horticultural applications), and from production and use of erionite-containing materials such as gravel. Depending on fiber size (length and diameter), inhaled fibers deposit onto lung surfaces, and subsequently are removed from the lung, are retained in lung tissues, or penetrate to nearby sites. Because the fibers are resistant to chemical attack, retained fibers are not readily broken down.

Erionite is classified as a known human carcinogen (IARC; National Toxicology Program (NTP) based on epidemiological studies reporting an excess of mortality from mesothelioma in three Turkish villages with elevated long-term exposures to airborne erionite fibers due to the use of erionite-containing building materials. Chronic inhalation exposures to airborne erionite fibers, such as those that have occurred in the Cappadocian region of Turkey, are thus believed to increase the risk of serious illnesses, including mesothelioma, lung cancer, and fibrogenic lung disease.

Fiber concentration data are cross sectional in nature and are therefore not sufficient to assess quantitative exposure-response relationship for erionite. With the exception of a recent study suggesting that occupational exposure to gravel containing erionite may be associated with chest radiographic abnormalities, including mild pleural and possible interstitial changes in the lung (Ryan et al., 2011), there remains a general absence of epidemiologic data for occupational exposures to erionite. Thus, there remains uncertainty regarding the impact of erionite on occupational health in workplaces with potential low to moderate exposure to erionite fibers, such as during mining, processing, and use of other natural zeolites and materials, such as gravel, which may contain erionite.

PHYSICAL AND CHEMICAL PROPERTIES

Consisting of brittle, wool-like fibrous masses, erionite can be found naturally in volcanic ash that has been compressed and altered by weathering (volcanic “tuff”). It is rarely found in pure form, instead occurring with other natural zeolites. Like other zeolites, it has a basic hexagonal structure that is composed of a framework of linked aluminosilicate tetrahedra (SiO_4 and AlO_4). Erionite has been classified into three main series, Na-erionite, Ca-erionite, and K-erionite, based on the respective cation prevalence. Its color varies from white to clear, and it resembles transparent, glass-like fibers. It has been reported to have a molecular weight of 715.68 (Lewis, 2004) and a density of 2.02–2.08 (IARC, 1987).

While erionite is a fibrous mineral that has a morphological resemblance to amphibole asbestos (IARC, 1987), it has different physical and chemical properties. It is silica rich, having varying amounts of sodium, calcium, and potassium cations. It consists of “bundles” that are composed of many fibers and fibrils, with the number of fibrils and the Si/Al ratio correlating with the surface area of this mineral. Its surface area has been approximated to be $200\text{ m}^2/\text{g}$ (Baris and Baris, 1993), a surface-area-per-gram that is 10-fold higher than that of crocidolite amphibole asbestos (Bish and Chipera, 1991).

Accurate detection and differentiation of trace amounts of erionite is difficult, due to its similarity to other minerals such as smectite and clinoptilolite (Bish and Chipera, 1991). Elemental composition analyses [e.g., energy-dispersive X-ray analysis (EDXA)] alone cannot reliably differentiate erionite from chemically similar minerals. The complexity of identifying erionite is highlighted in a recent article (Dogan and Dogan, 2008), in which the authors identified two tests, the E%-balance test (i.e., a test that compares proportions of the various cations) and the Mg-content test [which quantifies the number of Mg (magnesium) atoms per cell], which can be used to identify erionite. The authors analyzed dozens of

erionite samples from Turkey and the United States, finding that some of the “erionite” samples from various parts of Turkey (e.g., Cappadocia, Karain, and Tuzkoy) failed these tests. In addition, they reported that some U.S. erionite samples (e.g., from Rome, Oregon) were consistent with true erionite while others (e.g., from Agatate, Oregon) were not.

Comparisons of erionite samples from Turkey and the United States have shown that samples are comparable in terms of physical properties and mineral and chemical content [based on various microscopic analyses, including X-ray diffraction (XRD), scanning electron microscope-energy dispersive spectroscopy (SEM-EDS), and TEM] (Dogan et al., 2006, 2008; Carbone et al., 2011; Lowers and Meeker, 2007). For example, Carbone et al. (2011) concluded that the physical and chemical properties of erionite from North Dakota and Cappadocia, Turkey were “very similar,” including an identical average fiber width of $0.31\text{ }\mu\text{m}$ and a small difference in the atomic Si/(Si+Al) ratio indicating Turkish erionite to be slightly richer in Si. Lowers and Meeker (2007) concluded that there was some overlap in the chemical composition of “erionite” observed in dust samples³ from North Dakota with Turkish erionite and/or offretite (Figure 96.2). Other studies have reported some differences in fiber size distributions, with data indicating a higher proportion of longer fibers ($>4\text{ }\mu\text{m}$) in erionite from Oregon than from Karain, Turkey (11 versus 32%; as reported in Ilgren et al., 2008a).

As mentioned above, the other 40 or so known natural zeolites share the same framework of SiO_4 and AlO_4 tetrahedra as erionite. However, in contrast to erionite that is known to only occur in fibrous form, other natural zeolites are more typically found as plates, prisms, or laths. For example, of the commonly found natural zeolites, clinoptilolite can be found as euhedral (idiomorphic) plates and laths that are several micrometers in length and $1\text{--}2\text{ }\mu\text{m}$ thick, and phillipsite as prisms and laths that are $3\text{--}30\text{ }\mu\text{m}$ in length and $0.3\text{--}3\text{ }\mu\text{m}$ thick, typically with pseudo-orthorhombic symmetry (IARC, 1997). Given that different natural zeolites have similar chemical compositions, crystalline structure is generally used for identification of the various zeolites.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Fibrous zeolites are not expected to bioaccumulate. However, some zeolite fibers are relatively biopersistent and can stay in the lung or elsewhere for prolonged periods of time.

³ Only identification given by the authors: “20 soil and roadbed samples collected from North Dakota.”

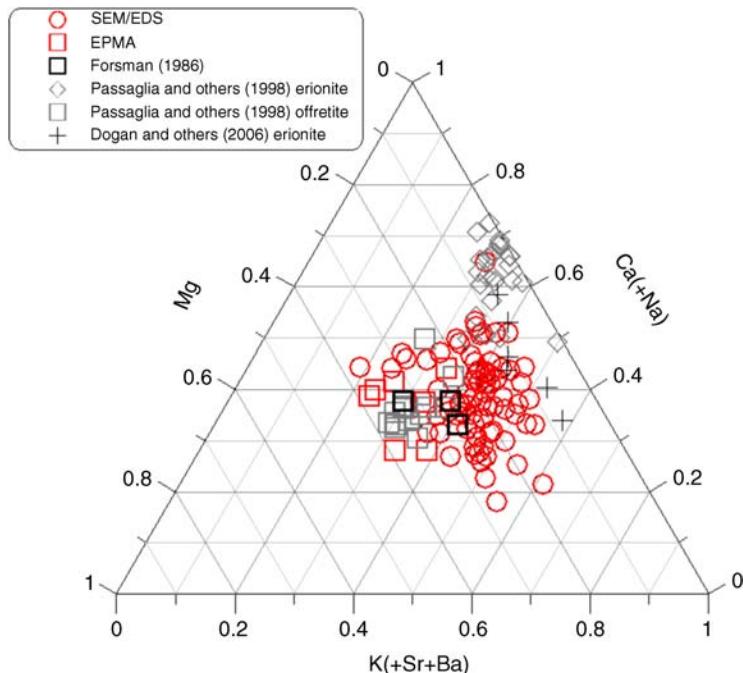

FIGURE 96.2 SEM/EDS analysis of samples from North Dakota zeolite (in red) falls between the Ca(+Na)-Mg-K erionite and offretite fields described by Passaglia and others (1998). The electron microprobe data (EPMA) fall in the offretite field. However, the best structural match based on X-ray diffraction data is to erionite. While falling overall between the erionite and offretite fields, some of the SEM/EDS data overlap compositionally with zeolite compositions that were associated with malignant diseases (Dogan et al., 2006). Note that the Forsman (1986) samples are from the Killdeer Mountains in North Dakota, while the Dogan et al. (2006) samples are from the Cappadocian villages in Turkey. Adapted from Lowers and Meeker (2007)

ECOTOXICOLOGY

Natural fibrous zeolites can be released to the environment from mining or in refined form. However, there are no published studies on the ecotoxicity of these zeolites.

MAMMALIAN TOXICOLOGY

Acute Effects

Animal Zeolites generally have not shown adverse acute effects in short-term studies, except at massive inhaled or ingested doses (Tátrai et al., 1991, 1992). There are no studies available that investigated the acute health effects of erionite or other naturally occurring fibrous zeolites in humans or in animals.

Human No studies were identified that have examined the short-term health effects of zeolite fibers in humans.

Chronic Effects

Animal Only a few animal studies examining the carcinogenicity of zeolites are available. For nonfibrous zeolites, available studies generally do not show evidence of carcinogenicity. For example, in BALB/c mice given a single intraperitoneal injection of 10 mg per animal mordenite (particle length, 94% <3 µm and 4% >3.8 µm), no tumors were observed for up to 23 months. However, the authors noted mild peritoneal fibrosis for the mordenite- vs. saline-treated mice (Suzuki and Kohyama, 1984).

For rats exposed by inhalation or by intrapleural instillation, albeit to very high concentrations or doses of erionite or asbestos (10 mg/m³ and 20 mg, respectively), Wagner et al. (1985) reported findings indicating a considerably greater potency for erionite than for asbestos. For example, 27 of 28 erionite-exposed rats (erionite source: Oregon) developed mesotheliomas, compared to 11 of 648 rats for various types of asbestos and 1 of 28 for a nonfibrous zeolite having a similar chemical makeup as the Oregon erionite (Wagner

et al., 1974, 1985). Moreover, Wagner et al. (1985) observed reduced survival times for erionite-associated mesotheliomas than for asbestos-associated mesotheliomas (for inhalation, mean survival times of 580 days and 917 days for Oregon erionite and crocidolite, respectively; for intrapleural inoculation, mean survival times of 390 days and 678 days for Oregon erionite and chrysotile, respectively). This reduction in survival time for erionite-induced mesotheliomas agrees with human clinical findings from Selçuk et al. (1992); who reported a significantly shorter survival time for mesothelioma patients from the erionite villages of Karain, Tuzkoy, and Sarihidir, as compared to patients with asbestos-associated mesothelioma (13.52 months for erionite-associated malignant pleural mesothelioma versus 21.56 months for erionite-associated malignant pleural mesothelioma) in their study of 135 Turkish patients with malignant pleural mesothelioma.

In the Wagner et al. (1985) experiments, erionite samples (20 mg dose) from Karain, Turkey, and Rome, Oregon, were found to be similar in carcinogenic potency when delivered intrapleurally to rats (38/40 and 40/40 exposed rats developed mesothelioma, respectively). Maltoni et al. (1982) exposed rats to 25 mg erionite intrapleurally (erionite source: Prof. Gottardi, Italy), observing lower mesothelioma rates than Wagner et al. (9/40 for erionite vs. 0/40 for crocidolite). One possible explanation for these variable findings between studies may involve the shorter monitoring period in this study (53 weeks) as compared to that of Wagner et al. (1985) (>2 years). Yet another animal study (Fraire et al., 1997) injected erionite from Pine Valley, Nevada directly into the pleural cavity of rats (20 mg per rat). For time periods of up to 480 days postexposure, the authors observed evidence of pulmonary fibrosis and pleural aplasia, as well as hyperplasia, in most erionite-exposed rats, but a lower yield of mesotheliomas (1/21) compared to previous studies. The exact determinants of the interstudy differences in biological responses are uncertain and may be related to the type and source of erionite used.

A meta-analysis of studies that exposed rats by inhalation or intrapleural administration found a much greater cancer potency for erionite by both mass and fiber size classification than for any type of asbestos (Carthew et al., 1992). For example, with intrapleural inoculation in rats, the authors estimated that erionite was 300- to 800-fold more potent than chrysotile and 100- to 500-fold more potent than crocidolite.

It is uncertain whether the specific erionite samples used in the animal carcinogenicity studies were included in the analysis by Dogan and Dogan (2008); since the study authors were not sufficiently specific about the source of the erionite used. It is possible that, even if some of these samples were not to meet the Dogan and Dogan (2008) definition of erionite, they may still possess chemical and physical attributes that can increase the risk of mesothelioma or lung cancer given sufficient exposure.

Human Epidemiologic studies from several Turkish villages in the Cappadocia region show elevated mesothelioma mortality (up to 50% of all deaths in some villages), which has generally been attributed to exposure to erionite. A study that followed immigrants from Turkey to Sweden found that risk of mesothelioma decreased with decreasing age at immigration (Metintas et al., 1999). The latest update of mortality rates from mesothelioma in the Turkish villages shows that some villages continue to have much higher rates than others (Baris et al., 1987; Baris and Grandjean, 2006). The elevated rates of mesothelioma deaths exceed those observed for *occupational* asbestos exposures (Metintas et al., 1999). A genetic component to mesothelioma risk has been suggested based on a pedigree analysis of some families from several Turkish villages (Dogan et al., 2006) and the results of human leukocyte antigen typing of biological samples from the villagers (Karakoca et al., 1998). However, the researchers who are most involved in these studies have suggested that the etiology of the mesotheliomas is not fully understood (Carbone et al., 2007), and some even suggest a larger role for fiber exposures than genetic influence (Metintas et al., 2010).

A nongenetic cause for elevated mesothelioma rates in these Turkish villages may be related to fiber exposures and properties. However, assessment of exposure to material reported to be erionite has been limited to a cross-sectional collection of samples and may not be representative of the true exposure that these villagers have experienced over the past decades (Baris et al., 1987). This cross-sectional assessment showed differences in erionite fiber airborne concentrations that were not consistent with the variation in mesothelioma rates among the villages examined in the study. However, it may be that the potency of each dust is modulated by how it is sequestered or by type and quantity of the minerals associated with it. For example, Baris and Grandjean (2006) reported age-adjusted annual mortality rates from pleural mesothelioma for the 25-year period 1979–2003 of 697, 197, and 11/100,000 for the Turkish villages of Karain, Sarihidir, and Karlik, respectively. The cross-sectional sampling scheme showed that the zeolite content of airborne street dust for these villages was 80, 60, and 20%, respectively (Baris et al., 1987), suggesting that zeolite content may be associated with mesothelioma risk.

In Mexico, two recent case studies (Kliment et al., 2009; Ilgren et al., 2008b) each claim to have reported the first case of a patient with erionite-associated pleural mesothelioma in North America. Kliment et al. (2009) described a 47-year-old male diagnosed with pleural mesothelioma and showing evidence of classic pathological changes commonly associated with asbestos-related disease, including ferruginous body formation, interstitial fibrosis, and pleural plaque development. The study authors reported an absence of any evidence indicating that this patient had significant asbestos exposure. Microscopic analyses identified 124,000 uncoated

fibers and 2480 ferruginous bodies per gram of wet lung tissue, with 24 of the 30 uncoated fibers analyzed by EDXA containing various combinations of Al, Si, K, Na, and Ca in ratios consistent with erionite.

Ilgren et al. (2008b) also reported a single confirmed case of erionite-associated pleural mesothelioma in a Mexican male. Over one million fibers per gram lung dry weight of fibrous erionite were identified using EDXA and selected area electron diffraction (SAED). Ilgren et al. (2008b) stated that this confirmed mesothelioma case is one of two mesothelioma cases they identified among residents of a small village, reportedly located within a zeolite-rich plain in the northern part of the Mexican state of Jalisco. Both individuals were involved in agricultural tilling and may also have been exposed to zeolite-containing materials used as preservatives for vegetables, additives to fertilizers, and nutritional supplements for animals.

Further, Ilgren et al. (2008b) claimed to have identified an additional 11 mesothelioma cases among Mexican villagers in the state of Zacatecas, including a father and son now living in California. The Ilgren et al. (2008a) publication investigated the mesothelioma cases of the father and son (44 and 27 years old, respectively, at diagnosis), also identifying an additional nine cases “clustered” around the small ancestral village where the father was born and the son spent some time as a child. Given the absence of any detections of erionite in this area, Ilgren et al. (2008a) acknowledged that the attribution of a causal role of erionite in these cases requires additional confirmation, especially given the presence of asbestos in both roofing and slate materials in this village (Los Sabinos).

Earlier, Casey et al. (1985) reported on a patient who lived and worked in an area rich in zeolite deposits, showing evidence of pulmonary deposition of fibrous and nonfibrous aluminum silicate particles with an EDXA pattern characteristic of zeolites. This patient's histologic picture was similar to the characteristic of asbestosis, with evidence of pleuropulmonary fibrosis, pleural thickening, and infiltrate; however, no asbestos fibers could be identified. Energy-dispersive X-ray Analysis analysis of over 100 particles and fibers analyzed by EDXA revealed the presence of aluminum, the absence of magnesium, and very low iron content, findings that were all consistent with those of a sample of northern Nevada fibrous erionite. In addition, there was no history of exposure to asbestos. The authors claimed this as the first case of zeolite-associated pulmonary disease reported in the United States.

Recently, a team of investigators, including scientists from the US EPA, the University of Cincinnati, and the North Dakota Department of Health sampled road dust and gravel for fibers in response to concerns of potential erionite exposures in several western North Dakota counties known to have used gravel containing erionite to surface roads, parking lots, and other areas (Ryan et al., 2011). In addition, investigators conducted a health study of the possible health effects of erionite exposure in these western North Dakota

counties, recruiting 34 residents and workers considered to represent those with the greatest potential exposure to erionite-containing gravel and using a questionnaire, chest radiograph, and high resolution computed tomography (HRCT) scan to assess the rate of interstitial and pleural changes, which have been associated with fibrous mineral exposure. Study participants included individuals having worked in gravel pits, road maintenance, or both, as well as ranchers/farmers and individuals in occupations with frequent driving (e.g., delivery truck drivers, mail carriers). Chest X-ray results did not indicate a significant increase in interstitial changes or localized pleural changes above background prevalence. Consistent with the increased sensitivity and specificity of HCRT for identifying subtle pleural and interstitial changes, the HRCT scan results did indicate a statistically significant *increase* in the rate of pulmonary interstitial changes of 12.5% ($n = 4$, $p < 0.01$), compared to 1.5% for a study of male urban transportation workers with low cumulative asbestos fiber exposure. Two of these individuals, both of whom were ex-smokers (3 and 7 pack-years) with prolonged occupational exposure to road gravel via gravel pits, road maintenance, or both, were also observed to have bilateral localized pleural changes with calcification. These study results thus suggest that occupational exposures to erionite via erionite-containing gravel in western North Dakota counties, particularly for workers employed in road maintenance or gravel pits, could result in mild pleural and possible interstitial changes that have been historically associated with commercial asbestos exposure.

Overall, a number of epidemiologic studies of Turkish populations have thus reported elevated mesothelioma rates in the Cappadocia region, which have been linked with exposure to fibrous erionite. Such reports have raised concerns regarding potential erionite exposures of health concern in other areas having erionite-like formations, including the United States in particular. Although there is now anecdotal evidence of a limited number of possible erionite-related mesothelioma cases among Mexican villagers, no U.S. cases of mesothelioma have been specifically linked to erionite exposures in western U.S. states with prevalent erionite-like formations.

Mode of Action(s)

Using Chinese hamster lung V79 cells, Palekar et al. (1988) compared the cytotoxicity of mordenite; two preparations of fibrous erionite from Rome, Oregon, including erionite with a mean length of 2.2 μm , and erionite prepared by ball milling and with a mean length of 1.4 μm ; Union Internationale Contre le Cancer (UICC) standard crocidolite, with a mean length of 1.3 μm ; and UICC chrysotile, with a mean length of 2.4 μm . Mordenite was found to be nontoxic, while the other minerals, which have all been observed to be tumorigenic in animal studies, exhibited evidence of cytotoxicity.

Fach et al. (2002) also compared the *in vitro* toxicity of erionite and an essentially benign mordenite in a rat macrophage model. The authors reported that oxidative burst increased with decreasing particle size regardless of zeolite chemical composition, but that the Fenton reaction depended on the type of zeolite, with erionite producing more reactive oxygen species than mordenite for the same amount of iron. Related to these findings, Baris and Baris (1993) estimated a surface area-to-mass ratio of approximately 200 m²/g for a sample of Turkish erionite—i.e., 10-fold higher than that of amphibole crocidolite asbestos—thus suggesting that some of the reported differences in toxicity may be related to surface area.

Moreover, Timblin et al. (1998) reported that while both erionites and crocidolite exposure induced genetic damage, as supported by increased unscheduled DNA synthesis, crocidolite was much faster and more effective than erionite at inducing apoptosis. This suggests that erionite may tip the balance in favor of cell proliferation *versus* apoptosis, and crocidolite may be more likely to induce apoptosis faster and at lower doses than erionite. These findings thus provide a possible explanation for the higher mesothelioma rates of erionite *versus* crocidolite asbestos, as reported by Wagner et al. (1974, 1985). This is further supported by findings from Bertino et al. (2007) that compared cell proliferation induction by Oregon erionite and asbestos samples.

In summary, elevated rates of mesothelioma in the Turkish villages and in erionite-exposed rats suggest the potential health risk significance of some forms of erionite exposure. However, the determinants of the toxicity and carcinogenicity of various forms of erionite and/or zeolite fibers similar to erionite remain inadequately characterized. There are some indications that erionite toxicity may increase with fiber surface area. The shape of fibers and fiber bundles may also be important factors, and are candidates for further investigation. Erionite has a higher surface area than asbestos, and it has been hypothesized that this may be one factor for its greater potency due to an increased potential of adverse chemical reactions (Dogan et al., 2006, 2008). Erionite may exert its adverse effects *via* oxidative stress, cytotoxicity, genetic damage, and favoring of proliferation pathways over apoptosis, as compared to some asbestos species. Additional comparative evaluation of the chemical composition and fiber shapes of erionite from sites outside Turkey with erionite from the mesothelioma-affected villages in Turkey may provide further insights on the indicators of potential toxicity and carcinogenicity of different erionite-like materials.

SOURCES OF EXPOSURE

Geographical Distribution

Erionite and other natural zeolites can be found in different parts of the world in over 40 countries (IARC, 1997). Most

notably, erionite has been reported to be highly prevalent in volcanic tuffs in the Cappadocian region of central Turkey. Erionite-like formations are known to occur in 12 states in the western U.S.; referred to as the Intermountain West, these states include Arizona, California, Idaho, Montana, Nevada, New Mexico, North Dakota, Oregon, South Dakota, Texas, Utah, and Wyoming. Areas noted to have naturally-occurring deposits of fibrous erionites include Shoshone, California; Jersey Valley, Nevada; and Rome, Oregon (Ilgren et al., 2008a). Many of these states also have commercial zeolite deposits.

In addition to the United States, countries that mine natural zeolites include Japan, Hungary, Bulgaria, Cuba, Italy, and South Africa, while Australia, the former Czechoslovakia, Greece, and Turkey are reported to have large unexploited reserves of natural zeolites (IARC, 1997). Countries reported to have mineable deposits of erionite include Kenya, Mexico, New Zealand, the United Republic of Tanzania, and the former Yugoslavia (IARC, 1987). Ilgren et al. (2008a) hypothesized that fibrous erionites in central Mexico are significant contributors to mesothelioma cases in the Valley of Jalpa, which is located in the southern part of the state of Zacatecas. Although there is an absence of any reported detections of erionite in this area, Ilgren et al. (2008a) point to the scarcity of mineralogical studies in this area and to the identification of other zeolite species (clinoptilolite, chabazite, and phillipsite), which have been shown to co-occur with fibrous erionite. In addition, this part of Mexico contains the Sierra Madre Occidental (SMO), a plateau rich in zeolites that is contiguous with regions in Mexico and the United States and shown to have fibrous erionite formations.

Industries and Populations at Risk

Occupational populations at risk include those involved in the mining and processing of natural zeolites and materials, such as gravel, which may contain erionite. In addition, workers involved in the manufacture and application of natural zeolite products that may contain erionite, such as animal feed, odor control products, and pet litter, are at potential risk. Although it has been reported that in the past erionite-rich blocks were quarried for use as building materials in some western U.S. states, this is not considered to be a common current practice and construction workers are not considered to be a population at risk (IARC, 1987).

Exposure Concentrations

There are few reported measurements of airborne exposure levels of erionite fibers of relevance to occupational exposure settings. Although themselves limited, the largest number of measurements of airborne exposure levels of erionite fibers is available from studies conducted in several villages in the Cappadocian region of Turkey, where erionite is a common

constituent of rocks and soil and erionite-containing building materials have historically been used (e.g., Baris et al., 1981; Baris et al., 1987). For example, Baris et al. (1987) reported airborne fiber ($>5\text{ }\mu\text{m}$ in length) levels as high as 0.029 fibers/ cm^3 for street samples from three Cappadocian villages where dominant portions of airborne fibers have been shown to have chemical compositions similar to erionite, and as high as 1 fiber/ cm^3 for samples collected during sweeping activities inside homes. Given the common occurrence of erionite in building materials, soils, and dust that is unique to this area, these measurements are not considered relevant to other geographic areas and potential exposure settings.

Perhaps of greater relevance to potential exposure concentrations of airborne erionite fibers in occupational settings are recent measurements conducted by a multi-agency team of investigators to characterize airborne levels of erionite fibers associated with erionite-containing gravel in North Dakota. Led by US EPA, this team conducted activity-based sampling during transportation scenarios (e.g., driving cars and school buses on gravel roads), measuring fiber concentrations that ranged from 0.0107 to 0.0391 fibers/ cm^3 (PCM equivalent) and averaged 0.0249 fibers/ cm^3 (Ryan et al., 2011). Concentrations ranging from 0 to 0.0012 fibers/ cm^3 (average of 0.0008 fibers/ cm^3) were measured at stationary air samplers located near the roadways. Ryan et al. (2011) suggested that these sampling results may not fully represent the range of potential exposure concentrations that road maintenance workers may experience during gravel pit and road grading activities. For indoor air samples collected in North Dakota in areas with use of erionite-containing gravel, Carbone et al. (2011) reported average concentrations of 0 and 0.06 fibers/ cm^3 (PCM equivalent) for a social services office and a road maintenance garage, respectively, during sweeping and house-keeping activities.

Few measurement data are available to assess potential exposure levels of airborne erionite fibers during mining activities. IARC (1987) reported that a 1979 monitoring study conducted at an open-pit zeolite mining operation in Bowie, Arizona did not provide evidence of significant fiber exposures levels despite the known presence of erionite.

INDUSTRIAL HYGIENE

No health standards are currently available for erionite, although it is considered by both IARC and NTP to be a known human carcinogen due to its effects on the lung, and specifically the lung pleura.

Given its similarity in both morphology and toxicity to asbestos, it is recommended that standard industrial hygiene practices for asbestos (e.g., OSHA asbestos regulations at 29 CFR 1910.1001) also be applied to occupational environments with possible erionite exposures. In particular, initial personal air sampling is recommended to assess levels of

airborne erionite fibers and to determine the need for personal protective equipment such as respiratory protection.

RISK ASSESSMENTS

Erionite has been classified by IARC as a Group 1 substance, i.e., known to be carcinogenic to humans (IARC, 1987). According to IARC (1997); zeolites other than erionite (e.g., clinoptilolite, phillipsite, mordenite, nonfibrous Japanese zeolite, and synthetic zeolites) cannot be evaluated as carcinogenic to humans (Group 3). NTP, which is part of the U.S. Department of Health and Human Services, lists erionite in Part A of the 12th Report on Human Carcinogens (2011), i.e., among those substances known to be human carcinogens. The German MAK Commission (Federal Republic of Germany Maximum Concentration Values in the Workplace) classifies erionite as a “MAK-1” substance, with “adequate epidemiological evidence for a positive correlation between the exposure of humans and the occurrence of cancer,” but no quantitative exposure limit value was derived.

MINERAL TALC

First aid: Inhalation: Move person to an area with fresh air.
Eyes: Irrigate eyes immediately with water

Target organ(s): Occupational: lung; Cosmetic: female reproductive system

Occupational exposure limits: ACGIH: TLV = 2 mg/m³, respirable fraction, 8-h TWA; OSHA PEL = 20 mppcf air over an 8-h workshift (for talc with <1% quartz content and no asbestos); NIOSH REL = 2 mg/m³, respirable fraction, over a 10-h workshift; IDLH = 1000 mg/m³

Reference values: None specified.

BACKGROUND AND USES

Types of Fibers and Their Uses

Mineral talc can be found in a variety of different forms, with the most common form consisting of nonfibrous plate-like particles. Although these plate-like particles are sometimes identified as fibers in microscopic analyses (IARC, 2010), normal or platform talc is considered to be free of asbestiform fibers. True mineral fibers can be present in other forms of talc, either due to asbestos contamination (this form of talc is referred to as talc containing asbestos) or due to the presence of asbestiform fibers of talc (this talc is referred to as asbestiform talc). Note that asbestiform talc should not be confused with talc containing asbestos, and that the section of asbestos should be consulted regarding potential occupational exposures and health risks from talc containing asbestos. In addition, talc may also contain elongated mineral fragments that resemble fibers but are not asbestiform, with an example being the tremolitic talc found in New York State, which contains mineral fragments or cleavage fragments of nonasbestiform amphiboles such as tremolite and anthophyllite. Note that there remains some scientific disagreement regarding the classification of particles from the Gouverneur talc district of Upstate New York, with some concluding that the talc contains amphibole asbestos fibers (NIOSH, 2011a).

Mineral talc has a variety of common uses, given its many beneficial physical and chemical properties, which include its softness, purity, fragrance retention, whiteness, luster, moisture content, oil and grease adsorption, chemical inertness, low electrical conductivity, high dielectric strength, and high thermal conductivity (USGS, undated). In the United States, it is estimated that 562,000 tons of talc

were sold in 2010, with major applications, including ceramics (23%), paint and paper (19% each), plastics (9%), roofing (7%), cosmetics (4%), rubber (3%), and other (16%) (Virta, 2011). Talc also has uses in construction materials (e.g., caulks, flooring, joint compounds), car parts (in ceramic substrates of catalytic converters, auto body putty, gaskets, hoses, belts), and in agricultural applications (e.g., fertilizer, seeds, insecticides, animal feed). Examples of everyday consumer products that may contain talc include pharmaceuticals, chewing gum, candy, and baby and body powders (USGS, undated; IARC, 2010).

General Epidemiology and Impact on Occupational Health

Based on a number of epidemiological studies of talc-exposed mine and mill workers, talc not containing asbestos or asbestiform fibers is generally regarded as a poorly soluble nuisance dust, which presents similar health hazards to particulate materials such as carbon black and titanium dioxide. It is well known that long-term exposures of miners and millers to elevated levels of airborne talc are associated with an increased risk of pulmonary fibrosis, also referred to as talc pneumoconiosis, as well as other forms of non-malignant respiratory disease, including pleural and lung function abnormalities. Inhaled talc that lacks asbestos or asbestiform fibers is not regarded as a human carcinogen, with the IARC re-affirming its Group 3 classification (inadequate evidence in humans) for talc not containing asbestos or asbestiform fibers in 2006, based on a lack of epidemiological evidence (IARC, 2010).

There remains scientific debate regarding the impact of occupational exposures to asbestiform talc on the risk of lung cancer and mesothelioma. It has been hypothesized that the presence of long, thin amphibole fibers in talc may elicit adverse health effects similar to those associated with asbestos, including mesothelioma and lung cancer (NIOSH, 2011a). Others question whether there are any mineral talc deposits containing sufficient quantities of asbestiform talc fibers to constitute a health hazard. While the talc deposits of the Gouverneur talc district of Upstate New York are among those that have been identified as containing asbestiform minerals (NIOSH, 2011a), Gamble and Gibbs (2008) recently concluded, based on a comprehensive literature review, that the epidemiologic evidence did not support a role of talc in the risk of lung cancer or mesothelioma among New York State talc workers.

Although of uncertain relevance to occupational health, there is mixed epidemiologic evidence linking perineal use of talc-containing products (e.g., body powders) with risk of ovarian cancer. Based on this epidemiologic evidence, IARC classified perineal use of talc-based body powder as a Group 2B, or possible, human carcinogen, during its 2006 review of talc carcinogenicity (IARC, 2010).

PHYSICAL AND CHEMICAL PROPERTIES

With an ideal formula of $Mg_3Si_4O_{10}(OH)_2$, mineral talc is a hydrous silicate material that contains magnesium (Mg), silicon and oxygen (SiO_2 , silica), and water. Talc-rich rocks or mineral composites include agalite, potstone, soapstone, and talcite. Although generally very pure in composition, small amounts of impurities, including aluminum, iron, manganese, and titanium, are common. Other impurities can include fluorine, nickel, chromium, calcium, potassium, and sodium. Talc can have a variety of different colors depending on its composition, including white, green, and brown. Having a Mohs hardness of 1, talc is known as the softest mineral. Talc is also well known as a low solubility material. Pure talc has a molecular weight of 379.26 and a density of 2.58–2.83 (IARC, 2010).

As mentioned earlier, mineral talc is most commonly found in the form of plates. Generally consisting of thin tabular crystals that are up to 1 μm in width, these plates are described as massive, fine-grained, and compact (IARC, 2010). Although rarer, mineral talc can also be found in the form of long thin fibers (fibrous talc) or bundles of long, thin, flexible fibrils, which can be easily separated along grain boundaries between the fibrils (asbestiform talc). Talc can also contain mineral fibers due to asbestos contamination, but it is important to emphasize that talc-containing asbestos is not the same thing as asbestiform talc. Some talc deposits, including most notably those of the Gouverneur talc district of Upstate New York, have been shown to contain mineral fragments or cleavage fragments of nonasbestiform amphiboles such as tremolite and anthophyllite.

Importantly, the chemical and mineral compositions of talc can be highly variable between different geologic deposits, as well as within a single deposit (Table 96.1). This is due in part to differences in the geological mechanisms by which it can be formed, including from alteration of mafic and ultramafic rocks and from replacement of carbonate and sandy carbonates such as dolomite and limestone. Mineral

talc is often found with a number of other minerals, including calcite, dolomite, magnesite, tremolite, anthophyllite, antigorite, quartz, pyrophyllite, micas, and chlorites. While industrial talcs can be highly variable in their talc content and amounts of other minerals, it is important to note that cosmetic talc typically contains >98% talc, while pharmaceutical-grade talc is >99% talc (IARC, 2010).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Talc fibers are not expected to bioaccumulate, although some may be absorbed with massive ingested or inhaled doses. However, they are relatively biopersistent and can stay in the lung or elsewhere for prolonged periods of time (as reviewed by IARC, 2010).

ECOTOXICOLOGY

There are no known adverse ecotoxicologic effects of talc. The European Chemicals Bureau found no damageable effect of talc on the environment around large open pit talc mines. The Bureau also found no data to support possible effects of talc on environment, fauna, or flora (European Chemicals Bureau, 2000).

MAMMALIAN TOXICOLOGY

Acute and Subacute Effects

Animal Talc inhalation exposures of <1 month at concentrations as high as 18 mg/m³ have only been shown to produce mild inflammation and histopathologic changes limited to macrophage increases in the pulmonary tissue. For example, Pickrell et al. (1989) exposed F344/Crl rats and

TABLE 96.1 Variability in Mineral Composition of Talc from Different Locations

Mineral	Montana	Vermont	North Carolina	New York ^a	California	France
Talc	90–95	80–92	80–92	35–60	85–90	70–90

^aGouverneur District.

B6C3F1 mice to asbestos-free talc aerosol concentrations of up to 20 mg/m³ (mass median aerodynamic diameter [MMAD], 3 µm), observing a modest, diffuse increase of talc-containing free macrophages in the alveolar spaces of mice and rats exposed to the highest concentration, but no clinical signs within 24 h after the end of exposure. The NTP (NTP, 1993) also conducted a 4-week exposure in which B6C3F1 mice and F344/N rats were exposed to 0, 6, or 18 mg/m³ talc. Most particles were in the respirable range for the animals and 90% of particle aspect ratios were between 1 and 1.41. Samples consisted primarily of talc, free of asbestos and SiO₂, with small quantities of chlorite and dolomite. NTP (1993) reported that inhaled talc concentrations above 18 mg/m³ of talc overwhelmed lung clearance mechanisms and impaired lung function in mice and rats after 4 weeks of exposure.

Human There is a scarcity of reports of the adverse health effects of acute occupational and environmental exposures to talc in the literature, suggesting that such exposures do not generally pose significant health risks. However, some case reports are available for adverse effects in susceptible populations. For example, acute respiratory failure was noted in an infant (Patarino et al., 2010) and in an immunocompromised patient (Bandhakavi et al., 2010), both of whom had inhaled large quantities of talc powder.

Chronic and Subchronic Effects

Animal

Nonmalignant Disease NTP (1993) exposed B6C3F₁ mice and F344/N rats to 0, 6, or 18 mg/m³ talc (MMAD, ~3 µm) for over 24 months. Animals were examined physiologically and histopathologically at 6-, 11-, 18-, and 24-month intervals from the start of the study. This study reported time- and concentration-dependent reductions in several pulmonary function parameters in rats (NTP, 1993). The study also found concentration-dependent increases in indicators of pulmonary inflammation, cell proliferation, and fibrosis in male and female rats, but only evidence of chronic pulmonary inflammation without fibrosis in mice (NTP, 1993). Other studies have reported evidence of talc-dependent pulmonary fibrosis in rats with chronic inhalation exposures to talc (e.g., Wagner et al., 1977; for 10 mg/m³ Italian 00000 grade talc, free from asbestos), but an absence of pulmonary histopathological changes in hamsters (e.g., Wehner et al., 1977; for 27.4 mg/m³ total and 8.1 mg/m³ respirable fraction concentrations of cosmetic-grade talc).

Malignant Disease NTP (1993) exposed B6C3F₁ mice and F344/N rats to 0, 6, or 18 mg/m³ talc (MMAD, ~3 µm) for over 24 months, finding no exposure-related tumors in mice. However, they reported “some evidence” of a talc effect on

increased benign or malignant pheochromocytoma (adrenal gland tumors) in male rats (tumors/animals in study: 26/49, 32/48, 37/47 for 0, 6, 18 mg/m³ talc, respectively). Female rats were also reported to have talc-elevated rates of pheochromocytoma (tumors/animals in study: 13/48, 14/47, 23/49 for 0, 6, 18 mg/m³ talc, respectively) and benign or malignant alveolar or bronchiolar adenoma or carcinoma (tumors/animals in study: 1/50, 0/48, 13/50 for 0, 6, 18 mg/m³ talc, respectively). The NTP concluded that these findings provided sufficient evidence for carcinogenicity of talc, although others have questioned the relevance to humans of these findings. For example, in reviewing the NTP (1993) 2-year bioassay results, Oberdörster (1995) observed that lung overload was reached in both rats and mice at the talc exposure concentrations of 6 and 18 mg/m³, and proposed that the relevancy of pulmonary tumors found only in female rats at the high exposure may be questionable for comparison to occupational exposures, since lung overload conditions frequently lead to tumor formation, which is independent of the nature of the exposure. In addition, Goodman (1995) concluded that the high rate of spontaneous pheochromocytomas in the control group precluded any reliable determination that these tumors were talc related. IARC (2010) also concluded that these tumors may not be related to talc since NTP studies have observed them in this rat strain in conjunction with other particulates.

Wagner et al. (1977) exposed Wistar rats intrapleurally with a single dose of 20 mg of either SFA chrysotile asbestos or Italian 00000 grade talc, free from asbestos, from an Italian mine. Following lifetime monitoring, no mesothelioma cases and only one small pulmonary adenoma were observed in 48 talc-exposed rats, while 18/48 of the chrysotile-exposed rats developed pleural mesothelioma. Moreover, as reviewed by IARC (2010); this finding is consistent with other studies that have administered up to 40 mg of talc intrapleurally and failed to observe a significant increase in occurrence of mesothelioma.

As illustrated in the following section, talc has surfaced as a potential risk factor for ovarian cancer among women engaging in perineal use of talc-based body powders. The NTP talc oral exposure study (NTP, 1993) found no talc-related lesions or tumors in exposed mice or rats, and a histopathological examination of ovarian tissue found no evidence of talc particles in this tissue in exposed rats (Boorman and Seely, 1995). The authors noted that there was ample opportunity for perineal and oral exposure to talc in these animals from fur and cage bars. Further, Hamilton et al. (1984) found that even injection of talc particles into rat ovary bursa did not produce ovarian tumors. Overall, these animal studies do not provide support for a causal linkage between talc exposure and risk of ovarian cancer.

Human

Nonmalignant Disease A major issue in talc toxicology and epidemiology is the uncertainty surrounding its mineral

characteristics. Four forms of pulmonary disease illustrate talc's diverse mineral characteristics and occurrence.

Talcosilicosis is caused by mined talc with high silica-content mineralogy, and its pulmonary findings are similar to those of silicosis.

Talcoasbestosis is produced by talc inhaled with asbestos fibers and is characterized by a similar set of pathologic and radiographic abnormalities as asbestosis (Bezerra et al., 2003).

Talcosis is caused by inhalation of pure talc and can manifest in bronchitis, interstitial inflammation, and pulmonary interstitial reticulations, or small, irregular nodules.

Intravenous administration of talc among drug users injecting talc-containing medications intended for oral use has been reported to contribute to a specific form of talc pulmonary disease characterized by vascular granulomas and pulmonary nodules, pleural effusions and lymph node enlargement (Lockey, 1981; Feigin, 1986; Marchiori et al., 2010).

Based on a body of epidemiologic studies, it is well known that long-term exposures of miners and millers to elevated levels of airborne talc are associated with an increased risk of pulmonary fibrosis, also referred to as talc pneumoconiosis, as well as other forms of nonmalignant respiratory disease, including pleural and lung function abnormalities. For example, respiratory symptoms and lung function decrements were observed in a cohort of Vermont millers and miners of talc ore free of asbestos and silica (Wegman et al., 1982; Boundy et al., 1979). The authors reported talc effects that were independent of smoking, including lung function decrements and increases in the prevalence of cough and phlegm. The authors also observed an increased occurrence of small round and irregular opacities in the lung that were associated with length of employment and length of exposure to talc. Mean dust exposure levels were 1.8 mg/m^3 and generally lower than 3 mg/m^3 (Wegman et al., 1982). In a series of studies following a cohort of talc miners in France and Austria exposed to chlorite talc reported to be free from asbestosiform fibers but containing small amounts of quartz, Wild et al. (1995, 2008) observed associations between talc exposures ranging from 8 to 20 mg/m^3 and prevalence of small pulmonary radiological opacities or lung function parameters, but a general absence of such associations for talc exposures below 2 mg/m^3 . Wild et al. (2002) observed elevated rates of nonmalignant respiratory disease in a cohort of talc miners in France and Austria exposed to chlorite talc reported to be free from asbestosiform fibers ($\text{OR}/100 \text{ year-mg talc/m}^3 = 1.08$, 95% confidence interval (CI), CI: 1.02–1.16). Pneumoconiosis was significantly elevated in the French but not Austrian workers ($\text{OR} = 5.56$, 95% CI: 1.12–16.2).

Rubino et al. (1976) reported that talc miners and millers exposed to high purity talc in Piedmont, Italy had statistically

significantly elevated rates of respiratory disease, particularly those miners exposed for ≥ 20 years to $\geq 1700 \text{ mppcf/years}$. This finding was confirmed in a follow-up study of this cohort (Coggiola et al., 2003).

Honda et al. (2002) reported an increase in nonmalignant respiratory disease mortality among a cohort of talc miners and millers at a mining facility in Upstate New York (Honda et al., 2002). The authors noted a disease association with pulmonary fibrosis in both miners and millers and that the disease increased with duration of employment (Honda et al., 2002). The authors noted that the talc ore from this mine has high nonasbestiform amphibole content.

Malignant Disease

MESOTHELIOMA AND LUNG CANCER Epidemiologic studies do not generally support the linkage between talc exposure and mesothelioma (Honda et al., 2002; Selevan et al., 1979; Wild et al., 2002).

There is inconsistent epidemiologic evidence linking talc exposure and lung cancer. For example, studies of miners and millers exposed to pure talc in an Italian mine have not observed an increased risk of lung cancer deaths (Rubino et al., 1976; Coggiola et al., 2003). Wild et al. (2002) found no association between lung cancer mortality and talc exposure in a cohort of talc miners in France and Austria exposed to chlorite talc reported to be free from asbestosiform fibers ($\text{OR}/100 \text{ year-mg talc/m}^3 = 0.98$, 95% CI: 0.88–1.10). Chiazzé et al. (1993) found no association between lung cancer or nonmalignant respiratory diseases and exposure to talc up to $>1000 \text{ fibers/ml}$ in workers at a U.S. fiberglass wool manufacturing facility, although the authors provided no information concerning the chemical characteristics of talc in this study.

Honda et al. (2002) observed a statistically significant increase in lung cancer mortality in miners and millers working at a talc mine in Upstate New York; however, as the authors specified, this mortality was limited to workers who had been working at the mine for approximately 1 year, but not longer. As the authors suggested, this finding supports a possible role of previous exposures not related to this talc mine. In addition, the authors noted that this mine has high nonasbestiform amphibole content in the talc ore, pointing to several animal and human studies that showed no association between these cleavage fragments and lung cancer. Likewise, Gamble (1993) reported no association between exposure to nonasbestiform talc cleavage fragments and lung cancer mortality in a cohort of Upstate New York talc miners. Steenland and Brown (1995) observed an association between exposure to nonasbestiform talc cleavage fragments and silica and increased lung cancer mortality among gold miners in South Dakota when county data were used for reference but not when federal data were used. However, the authors found that lung cancer mortality did

not show a positive exposure-response trend with estimated cumulative dust exposure.

In Vermont, where talc is relatively free of asbestos and has small amounts of quartz, increased lung cancer risk has been reported among talc miners, but not millers; however, these associations have generally been attributed to radon and quartz exposure, and not talc, in the miners (Selevan et al., 1979; Baan et al., 2006).

OVARIAN CANCER A number of epidemiologic studies have investigated the association between cosmetic use of talc and ovarian cancer. The only cohort study (Gertig et al., 2000) to examine this association observed no statistically significant risk when “all serous ovarian cancers” were considered (relative risk (RR), RR = 1.26, 95% CI: 0.94–1.69) in 78,630 nurses in the Nurses’ Health Study. However, the authors reported a statistically significant association for “serous invasive cancers” (RR = 1.40, 95% CI: 1.02–1.91). The larger number of case-control studies that have examined the association between talc use and ovarian cancer have reported mixed findings, but evidence of homogeneity in the magnitude of the observed risk. In reviewing findings from 20 of these case-control studies, Langseth et al. (2008) found a striking similarity in the outcomes of ovarian cancer among 14 population-based studies, with a pooled odds ratio of 1.40 (95% CI: 1.29–1.52), although a pooled odds ratio for the six hospital-based studies that does not support a significant talc-related risk (OR = 1.12, 95% CI: 0.92–1.36). The authors noted that studies conducted both before and after 1976, when talc became relatively free of asbestos, had similar outcomes, diminishing support for potential confounding by asbestos. An uncertainty in these studies is the potential contamination of talc by quartz, which has been shown to cause cancer or inflammatory reactions contributing to cancer occurrence. Moreover, these studies generally relied on questionnaires of cosmetic talc use without proper exposure assessment and seldom a complete history of use of talc. Overall, although there are some epidemiologic associations supporting an increased risk of ovarian cancer with perineal talc use, there remains some uncertainty regarding the causal nature of such an association.

Mode of Action(s)

In vitro experiments have shown that various samples of talc can produce cytotoxicity in mouse peritoneal macrophages (Davies et al., 1983), the release of chemokines and cytokines (Nasreen et al., 1998), and basic fibroblast growth factor (Antony et al., 2004) in human pleural mesothelial cells. These findings provide mechanistic support for the known fibrotic and inflammatory effects of talc in animals and humans exposed to sufficiently high concentrations.

SOURCES OF EXPOSURE

Geographical Distribution

Talc deposits can be found throughout the world, with the world’s leading producers, including China, the United States, India, Finland, and France (Virta, 2010). World talc production is dominated by talc deposits derived from magnesium carbonates (e.g., dolomite, limestone), which are found in locations such as Austria (Leogen), Australia (Mount Seabrook and Three Springs), Brazil (Brumado), Canada (Madoc), China, France (Trimouns), Germany (Wunsiedel), India, Italy (Chisone Valley), the Republic of Korea, the Russian Federation (Onot, Krasnoyarsk), Slovakia (Gemerska Poloma), Spain (Respina), and the US (Alabama-Winterboro, California-Talc City and Death Valley-Kingston Range, Georgia-Chatsworth, Montana-Yellowstone, New York-Gouverneur District, North Carolina-Murphy Marble belt, Washington-Metaline Falls, and western Texas) (IARC, 2010). In the United States, large talc deposits are particularly prevalent in the Appalachian and Piedmont regions, from Vermont to Alabama, as well as in the western U.S. (e.g., Montana, California, Nevada, Washington, Idaho, and New Mexico) and Texas.

As discussed in the Physical and Chemical Properties section, the mineral and chemical composition of talc can vary considerably among geographic regions. For example, some New York talc has been shown to contain up to 55% by weight tremolite, while talc from other geographic locations contains no detectable levels of tremolite. Also, French talc is estimated to contain up to 30% chlorite, while other talc deposits have been shown to contain little or no chlorite.

Industries and Populations at Risk

The primary route of occupational exposure to mineral talc is by inhalation of particles and/or fibers released during mining and handling (e.g., crushing, separating, bagging, loading) of talc during its production and during its industrial use in the manufacture of a variety of commercial products. User industries with potential occupational exposures to talc include those involved in the manufacture of paints, paper, plastics, ceramics, roofing and other construction materials (e.g., caulk, flooring, joint compounds), rubber, some agricultural applications (e.g., fertilizers, seeds, insecticides, animal feed), and cosmetics and pharmaceuticals (see Background and Uses section).

Exposure to talc may also occur *via* consumer use of talc-containing products. Talc-based body powders are considered to present the most significant source of consumer exposures to talc given that talc in other product classes is generally bound within a product matrix (e.g., ceramics, paint, paper, construction materials). IARC (2010) summarized prevalence data of ever use of talc for feminine hygiene

purposes in various countries; these range from 1.8% in the United States (Washington, D.C.) to 59% in the United Kingdom.

Exposure Concentrations

Gravimetric measurements of respirable dust in talc mining and milling environments are available from a number of studies (ACGIH, 2010; IARC, 2010). These studies have reported data indicating elevated historical exposure levels of respirable dust in talc operations, in particular for European talc mills and mines (IARC, 2010). For example, in an epidemiologic study of French talc quarry and mill workers, Wild et al. (2002) reported dust levels for the 1960s and 1970s ranging from below 5 mg/m³ to more than 30 mg/m³. More recent studies have generally reported reduced respirable dust levels, with Wild et al. (2008) reporting geometric mean exposure concentrations for respirable talc dust of 0.80 mg/m³ (geometric standard deviation (GSD): 4.3) and 0.30 mg/m³ (GSD: 3.3) for the years 2003 and 1996–2003 in a French mill and an Austrian mill, respectively. Wild et al. (2008) also reported a decrease from 0.67 to 0.37 mg/m³ in exposure levels of respirable talc dust at a French mine for the period 1990–2003.

Studies of U.S. talc mines and mills have generally reported respirable dust levels of less than a few mg/m³. For example, for a survey of 362 personal samples collected over a full shift at U.S. talc mines and mills by the Mine Safety and Health Administration, the NIOSH reported a median dust exposure level of 1.20 mg/m³, with 90% of all exposure levels being <2.78 mg/m³ (IARC, 2010). For a study of Vermont talc miners and millers, Wegman et al. (1982) reported a geometric mean respirable dust level of 1.8 mg/m³ based on 312 personal samples. For a respiratory survey of nearly 300 talc miners and millers in three states (Montana, Texas, and North Carolina), Gamble et al. (1982) reported average talc exposures of 1.2 mg/m³ (Montana), 2.6 mg/m³ (Texas), and 0.3 mg/m³ (North Carolina). Based on analysis of bulk samples by TEM, Gamble et al. (1982) reported an absence of any fibers in samples of Montana talc, but evidence of antigorite and tremolite fibers in the Texas talc. In addition, the North Carolina talc was found to contain particles with length:diameter ratios as high as 100:1, although it was described as acicular in nature, with fragmentation of platy particles being a possible source of the high aspect ratio particles (ACGIH, 2010; IARC, 2010). ACGIH (2010) reported that none of the observed fibers were identified as being asbestos by the study authors.

Fewer exposure measurement data are available for talc user industries (IARC, 2010), with the limited data that are available being historical in nature and unlikely to be representative of current exposure levels.

INDUSTRIAL HYGIENE

For talc *not* containing asbestos, the following occupational exposure limits are in place:

- ACGIH: TLV = 2 mg/m³, respirable fraction, 8-h TWA
- OSHA PEL = 20 mppcf air over an 8-h workshift (for talc with <1% quartz content and no asbestos)
- NIOSH REL = 2 mg/m³ over a 10-h workshift; IDLH = 1,000 mg/m³

The following maximum-use concentrations and protective respirators are recommended by NIOSH (2011b):

- 10 mg/m³: Any quarter-mask respirator
- 20 mg/m³: Any particulate respirator equipped with an N95, R95, or P95 filter or facepiece, except quarter-mask respirators
- 50 mg/m³: Any powered, air-purifying respirator with a high efficiency particulate filter
- 100 mg/m³: Any air-purifying, full-facepiece respirator with an N100, R100, or P100 filter
- 1000 mg/m³: any supplied-air respirator operated in a pressure-demand or other positive-pressure mode

For talc containing asbestos, asbestos limits and industrial hygiene practices should be followed per 29 CFR 1910.1001 (also described in the asbestos section of this chapter).

RISK ASSESSMENTS

IARC

The IARC has reviewed talc on three occasions, each time making determinations for different variations of talc:

1987: Talc not containing asbestos (Group 3) and talc containing asbestos (Group 1). The Group 1 classification for talc containing asbestos is based on early studies of New York talc miners and millers that appear to have made claims of exposures to talc containing asbestos tremolite and anthophyllite, resulting in some uncertainty as to whether these studies provide findings of relevance to talc contaminated with asbestos—i.e., asbestos amphibole minerals—rather than “asbestos talc.”

2006: Inhaled talc not containing asbestos or asbestos (Group 3) and perineal use of talc-based body powder (Group 2B) (Baan et al., 2006).

2009: Based on the article by Straif et al. (2009); it appears that talc containing asbestos will be classified as Group 1 while there is no mention of talc containing asbestos-form fibers, which appears to have been dropped from consideration in this review due to confusion as to how to define asbestos-form fibers and as to whether New York State talc contained them.

NTP

Talc was nominated for the 12th Report on Carcinogens (12th RoC) by the National Institute of Environmental Health Sciences for both cosmetic talc use and occupational exposure to talc. However, the NTP deferred consideration of listing talc (asbestos-form and non-asbestos-form talc) in the RoC based on its review in the year 2000 that identified persisting confusion over the mineral nature and consequences of exposure to talc, both containing asbestos-form fibers and not containing asbestos-form fibers.

NANOPARTICLES

DANIEL A. NEWFANG, GIFFE T. JOHNSON, AND RAYMOND D. HARBISON

BACKGROUND AND USES

Nanoparticles are currently defined in the literature as particles that have a diameter of 100 nanometers or less (although the scientific community has not collectively agreed with this definition). Nanomaterials or Engineered Nanomaterials (ENMs) are similarly defined as a man-made material having particles *or constituents* in nanoscale dimensions. Nanotechnology is the process and science used to build or manipulate nanomaterials. This chapter will use the term nanoparticle, nanomaterial and nanotechnology interchangeably. Regardless of their creation (i.e. naturally occurring or man-made), they have a large surface area to volume ratio that enhances the nanoparticle's ability to interact with other molecules. Nanomaterials exist naturally in the environment, for examples, viruses, bacteria, and byproducts of nature, such as ash from volcanoes. They may also be a result from industrial in the forms of byproducts of combustion, for example, soot and air pollution. Nanoparticles may be present as gases, liquids, or dust.

Nanoparticles may enter the body via respiratory, oral, dermal routes, as well as may enter the body by intravascular penetration via dermal injections (Pompa et al., 2011). Nanoparticles may even be introduced into the body by mucous membranes and ocular routes. They can stay airborne longer, which increases exposure times and penetrate the dermal layers, which may enhance their ability to be toxic (Madl and Pinkerton, 2009). Nanoparticles are currently being used in technology, such as medical imaging, electronics, and therapeutics (Madl and Pinkerton, 2009). In the medical setting, nanoparticles are being used in both *in vivo* and *in vitro* research. In the occupational setting, nanomaterials may act

as chemical catalysts and some may be considered to be highly combustible and toxic.

MAMMALIAN TOXICOLOGY

Nanomaterials are considered to be free unbound particles that are capable of mobility in the environment and in the body (Elaesser and Howard, 2012). The toxicity of a nanoparticle depends on its size, shape, surface charge, chemistry composition, and stability. A toxicological concern is that the immune system may not be able to detect the presence of nanoparticles (Pompa et al., 2011). As well, there are difficulties in determining the toxic effects of nanomaterials because of impurities or other components present in the materials. Nanoparticles have an increased reactivity due to higher surface to volume ratio (Elaesser and Howard, 2012). Once in the environment, nanoparticles interact with all aspects of air, land, and water.

In vitro nanotoxicology testing methods, due to the small size of the particles, uses endocytosis to evaluate the distribution of effects from cell to cell (Elaesser and Howard, 2012). Depending on reactivity, nanoparticles generate reactive oxygen species leading to the disruption of membranes, protein aggregation, and DNA damage potentially inducing apoptosis or necrosis (Elaesser and Howard, 2012).

Nanoparticles have an effect on epithelial cells. There are chemotactic properties on the skin that generate an inflammatory response. There are nanoparticles that stimulate epithelial cells such as carbon black nanoparticles that are byproducts of incomplete combustion of petroleum products. The central nervous system is susceptible to injury by nanoparticles due to their small size, they are able to penetrate the

tight junctions of the blood–brain barrier and enter the central nervous system.

SOURCES OF EXPOSURE

Occupational

Nanotechnology is the use of nanomaterials to create new chemical structures, materials, and devices. Quantum dots, nanotubes are currently being investigated for use in technology. In addition, other nanoparticles such as titanium dioxide, and silver are being used in commercial products. Nanoparticles are being used to deliver medications to specific organs to reduce systematic adverse medication reactions and increase the potency of medications (Yildirimer et al., 2011).

Quantum dots are used in medical applications; because of their fluorescent properties they are able to visualize cancer cells in the body. Quantum dots are metalloid crystalline cores covered with a shell (Madl and Pinkerton, 2011). Caution should be used because they may be considered toxic due to size and electronic properties as in the case of cadmium and zinc. However, if coated with a polymer of polyethylene glycol, a quantum dot creates a barrier that is not recognized by the body, thus not initiating an inflammatory response (Stone et al., 2007). Quantum dots are being used to deliver medicals such as antibiotics and receptor ligands to specific body sites (Madl and Pinkerton, 2009). Quantum dots can penetrate the skin and may induce an irritant or contact dermatitis (Crosera et al., 2009). For Occupational Safety and Health Administration (OSHA) specific permissible exposure levels (PEL), use those for specific minerals, such as cadmium levels.

Carbon nanotubes are carbon-based nanoparticles that are hollow graphite tubes and are being investigated for use in cell growth, tumor imaging, and drug delivery as well as in industries (Madl and Pinkerton, 2009). Workers are exposed to carbon nanotubes via inhalation. Carbon nanotubes and nanofibers may cause pulmonary inflammation and fibrosis. The OSHA recommends that exposure levels do not exceed $1.0 \mu\text{g}/\text{m}^3$ in an 8-h time weighted, as recommended by National Institute for Occupational Safety and Health (NIOSH).

Titanium dioxide nanoparticles are currently being studied because of their ability to study nanoparticles' influence on biological fate and toxicity, for example, in pulmonary disease (Madl and Pinkerton, 2009). Titanium dioxide can also penetrate the dermal layers and cause an irritant and contact dermatitis (Crosera et al., 2009). Titanium dioxide is used in sunscreen to absorb UV light. Titanium dioxide is also used in paint, paper, as well as foods. The OSHA recommends exposure levels not to exceed $0.3 \mu\text{g}/\text{m}^3$. The NIOSH recommends exposure levels do not exceed

$2.4 \mu\text{g}/\text{m}^3$. Titanium dioxide is considered a potential occupational carcinogen.

Silver nanoparticles have antimicrobial abilities and are used in wound dressings. However, silver dust is considered harmful if inhaled, as well as oral ingestion that causes argyria and may cause liver damage or dermal exposure may cause transitional damage to the stratum corneum (Yildirimer et al., 2011). The OSHA PEL for silver dust and fumes is (including the metal dust and fume) is $0.01 \text{ mg}/\text{m}^3$, as Ag. The NIOSH does not have a recommended exposure level. The ACGIH has established a $0.1 \text{ mg}/\text{m}^3$ TLV for silver metal dust and fume.

Gold may be used as a carrier molecule because of its biocompatibilities (Yildirimer et al., 2011). Gold nanoparticles may penetrate the skin, may cause an irritant dermatitis. If inhaled, gold may induce pulmonary irritation.

Silica nanoparticles may be used as biomarkers, cancer therapeutics, and drug delivery vehicles. For OSHA permissible exposure levels, follow silica protocols.

As a final paragraph in this section, it needs to be emphasized that future-use prospects, global demands for innovative products, novel and inexpensive manufacturing processes will present new challenges for assessment, exposure monitoring, fate analysis & risk evaluation *and* what their impacts on humans and the environment will be. For example, the simple act of quantifying background concentrations from a work process (e.g. near & far field sampling) can be extremely challenging with nanomaterials. The future is exciting and the authors believe the benefits will be maximized with regard to nanomaterial design, manufacturing and use. A good strategy to follow for managing potential exposure to nanomaterials is to continue classical industrial hygiene and medical practices, keep up-to-date with guidance documents, identify the potential exposure group (for future epidemiological cohort reference/studies).

INDUSTRIAL HYGIENE

Elimination of nanoparticle exposure is optimal; however, may not be possible. Engineering controls consist of controlling aerosols such as gases, dust, chemical vapors that require local exhaust ventilation with filtration. A high efficiency particulate air filter is effective in removing nanoparticles in the workplace. Administrative practices consist of good personal hygiene such as hand washing and using proper procedures in the workplace. It may be appropriate to use a wet wiping technique with solvent to solubilize the nanoparticle. Safety Data Sheets (SDS) may be available for specific compounds. Currently, data are not conclusive as per the actual workplace exposure of workers to specific nanoparticles (Brouwer, 2010).

Proper selection of personal protective equipment is required and may consist of gloves, clothing, and respirators.

Personal protective equipment should be resistant to nanoparticle penetration. Respirators may consist of filters particles of 300 nanometers or less. Depending on the nanoparticles, N-95/N-100 respirators may be adequate.

When cleaning a worksite that had been contaminated by nanoparticles, place absorbents, all towels, and other materials used to clean, place in a plastic bag, seal, then place in a double bag and label in accordance with the National Institute of Health, Division of Environmental Protection (EPA, 2013).

RADIO-FREQUENCY RADIATION

R. TIMOTHY HITCHCOCK

BACKGROUND AND USES

Radio-frequency radiation (RFR) is a form of nonionizing, electromagnetic energy. Electromagnetic energy is the propagation of energy through space or matter by time-varying electric and magnetic fields. These energies are distributed across the electromagnetic spectrum, which is characterized by three related quantities: wavelength, frequency, and energy. The continuum is divided into various spectral regions. By convention, RFR is described by frequency, in hertz (Hz). The RFR part of the electromagnetic spectrum extends from 300 gigahertz (GHz) down to 3 kilohertz (kHz). Usually, microwave radiation is considered to be a subset of RFR between 300 GHz and 300 megahertz (MHz).

Other nomenclature is used for RFR at times. For example, in the global community, frequencies between 300 Hz and 10 MHz are sometimes called the intermediate frequency (IF) range. A professional society, the American Conference of Governmental Industrial Hygienists (ACGIH), that publishes exposure guidelines, including those for RFR, includes a portion of the RFR spectrum (3–30 kHz) in a region they call the sub-RF spectral region.

The RF spectrum is further divided into bands, which are order-of-magnitude ranges with the designations described in Table 98.1. Frequencies in the various bands are allocated for uses such as aeronautical radio, broadcasting, citizens band radio, and cellular communications. The band that includes 30–300 Hz is the extremely low frequency (ELF) band. The ELF band contains the frequencies at which electric power is generated, transmitted, distributed, and used. This is 60 Hz in North America and 50 Hz in the rest of the world.

PHYSICAL PROPERTIES

Radio-frequency electromagnetic energies are considered nonionizing because the photon energies are well below the 12 eV needed to ionize water molecules. The energy is electromagnetic because it is characterized by two fields, the electric and the magnetic.

Electromagnetic quantities and units used are shown in Table 98.2 where it is noted if the quantity is a basic restriction or a derived limit. Basic restrictions are essentially dosimetric quantities that are used to derive the exposure limits. The basic restrictions include *in situ* electric field strength, specific absorption rate (SAR), specific absorption (SA), and power density. Power density is both a basic restriction and derived limit.

The SAR, which is the RF dose rate, and power density are basic restrictions for the portion of the RFR spectrum that can produce adverse heating in tissues, 300 GHz to 100 kHz (IEEE, 2005a). Power density is used for the highest frequencies, 300 GHz to 3 GHz, and SAR applies from 3 GHz to 100 kHz. The time integral of the SAR is the SA or the RF dose.

The *in situ* electric field strength is the basic restriction from 5 MHz to 3 kHz. This basic restriction applies to electric fields within the human body. It is not to protect from adverse heating but from a family of potential effects called electrostimulation (e.g., excitation of muscle, cardiac tissue, or neurons). There is a region of overlap where both SAR and *in situ* electric field strength apply, 5 MHz to 100 kHz.

The derived limits are in terms of power density, electric field strength, and magnetic field strength. Power density is

TABLE 98.1 Nomenclature of Band Designations

Frequency Range	Designation	Abbreviation
<30 Hz	Sub-extremely low frequency	Sub-ELF
30–300 Hz	Extremely low frequency	ELF
300–3000 Hz	Voice frequency	VF
3–30 kHz	Very low frequency	VLF
30–300 kHz	Low frequency	LF
300–3000 kHz	Medium frequency	MF
3–30 MHz	High frequency	HF
30–300 MHz	Very high frequency	VHF
300–3000 MHz	Ultrahigh frequency	UHF
3–30 GHz	Superhigh frequency	SHF
30–300 GHz	Extremely high frequency	EHF

TABLE 98.2 Important Electromagnetic Quantities with Their Symbols and Units

Quantity	Symbol	Units	Unit Abbreviation
Frequency	f	Hertz	Hz (GHz, MHz, kHz)
Energy	Q	Joule	J
Power	P	Watt	W
Electric field strength	E	Volt/meter	V/m, V ² /m ²
Magnetic field strength	H	Ampere/meter	A/m, A ² /m ²
Magnetic flux density	B	Tesla	T (μ T, mT)
Power density ^a	W, S	Watt/square meter	W/m ² , mW/cm ²
In situ electric field ^b	E _o	Volt/meter	V/m
Specific absorption rate ^b	SAR	Watts/kilogram	W/kg
Specific absorption ^b	SA	Joules/kilogram	J/kg

^aPower density is both basic restriction and derived limit.

^bBasic restrictions.

the power incident on a surface, divided by the area of that surface. Electric and magnetic field strengths are vector quantities that are used to relate the intensity of the two fields. The potential for biological effects is associated with the power deposition, and the squares of the electric-and magnetic field strengths are proportional to power. Hence, the squares of the field strength units (V/m, A/m) are often used in biological sciences. Radio-frequency magnetic fields may sometimes be described in terms of the magnetic flux density, B. B is related to the magnetic field strength where $B = \mu H$, where μ is the permeability of free space, 1.26×10^{-6} T(m/A). The SI unit of magnetic flux density is tesla (T), although the cgs unit, gauss (G), may be used in the United States. The conversion factor is 1 T = 10,000 G.

MAMMALIAN TOXICOLOGY

Human data are limited and present no clear trends. Therefore scientists have had to rely on animals as models to establish the biological effects. Animal studies have found effects in most major animal systems, including the nervous, neuroendocrine, reproductive, immune, and sensory systems.¹ Combined interactions of RF fields with neuroactive drugs and chemicals have been reported (Lai et al., 1987; Frey and Wesler, 1990).

Acute Effects

Behavior: The effects established in test animals have been extrapolated to human beings and used in setting human exposure guidelines for thermal effects. Currently, the exposure criteria are based on a few well-established effects observed in studies with test animals. Reversible behavioral disruption in short-term studies is an effect often cited in the exposure guidelines. This is because this end point has been found to be a sensitive measure of RF exposure and has been demonstrated in different laboratories, at various frequencies, and with more than one animal species (DeLorge, 1976, 1978; D'Andrea et al., 1977, 2003). Generally, behavioral effects are a thermal effect resulting from significant increases in body temperature caused by the absorption of RF energy (DeLorge, 1983; D'Andrea, 1991; D'Andrea et al., 2003).

East European and Russian literature discusses the occurrence of certain nonspecific symptoms associated with the nervous system, with clinical signs extending to the cardiovascular system (Sadcikova, 1974). The signs and symptoms include headache, nervousness, dizziness, memory loss, fatigue, irritability, insomnia, loss of appetite, emotional instability, depression, thyroid enlargement, sweating, tremor of extended fingers, loss of sexual drive, and impotence (Silverman, 1973). Similar symptoms were described in Western medical literature in two case reports of apparently high, acute overexposure to microwaves (Williams and Webb, 1980; Forman et al., 1982).

Reproductive and Development: Radio-frequency overexposure can have reproductive and developmental effects in test animals if the exposures are quite high. Researchers at the National Institute for Occupational Safety and Health (NIOSH) have reproducibly demonstrated teratogenic effects at 27.12 MHz with rats, when the whole body average (WBA)-SAR (RF dose rate) is around 10 W/kg (Lary et al., 1982, 1983, 1986). These effects appear to be thermal

¹ Elder and Cahill, 1984; NCRP, 1986; Heynick, 1987; Beers, 1989; Saunders et al., 1991a, 1991b; Dennis et al., 1992; Murray et al., 1995; Hitchcock and Patterson 1995; Scientific Committee on Emerging and Newly Identified Health Risks, 2007; International Commission on Non-ionizing Radiation Protection, 2009a; Advisory Group on Nonionising Radiation, 2012; International Agency for Research on Cancer, 2013.

in nature because a dose-response effect was seen with high rectal temperatures (Lary et al., 1986). Researchers at the Environmental Protection Agency (EPA) observed developmental abnormalities in rodents exposed to 2450 MHz. Again, the effects appear at high values of WBA-SAR (Berman et al., 1982a, 1982b).

Epidemiological studies of reproductive end points have not demonstrated any trends.² Two studies reported effects on semen (Lancranjan et al., 1975; Weyandt, 1992), but the small sample of people involved and lack of exposure data make interpretation difficult.

Ocular: Cataracts have been demonstrated in laboratory animals, and the most effective frequencies were 1–10 GHz. Acute thresholds were determined for rabbits receiving ocular exposure in the near field of a 2450-MHz applicator (Carpenter and Van Ummersen, 1968; Guy et al., 1975). No cataracts were observed when the animals were unrestrained and exposed in the far field (Michaelson et al., 1971; Appleton et al., 1975), even if exposures were almost lethal. A number of epidemiological investigations and clinical evaluations have been performed, but none has found an excess of cataracts in populations purported to have received RF and microwave exposure (Cleary and Pasternack, 1966; Majewska, 1968; Siekierzynski et al., 1974; Cleary et al., 1965; Bonomi and Bellucci, 1989).

Carcinogenicity: Limited *in vivo* data suggest that microwaves may be a tumor promoter in laboratory animals (Szydzinski et al., 1982; Szmielski et al., 1982), whereas other studies demonstrated no significant differences in RF-exposed groups and controls (Santini et al., 1988; Svedenstal and Holmberg, 1993; Wu et al., 1994). In a study funded by the U.S. Air Force and performed at the University of Washington, significant differences were seen in primary malignancies in microwave-exposed animals when the tumor data for all tissue types were combined. However, evaluation of more than 100 end points supported the conclusion that the exposed animals were generally healthy and disease free (Guy et al., 1985; Chou et al., 1992). In sum, the animal data must be viewed as inconclusive.

Other researchers used C3H/HeJ mice, a strain that has a naturally high incidence of mammary tumors. There were no statistically significant findings for neoplasms of the mammary gland, uterus, liver, adrenal gland, and lungs with exposure to pulsed, 435-MHz microwaves. Bilateral ovarian epithelial stromal tumor was significantly elevated for the ovaries, whereas epithelial stromal tumors and total epithelial stromal tumors were not. There was no difference in longevity between the two groups (Toler, 1997). An evaluation with CW RFR (SAR = 0.3 W/kg) produced no significant differences in tumors of the mammary gland, ovary, liver, or uterus

in C3H/HeJ mice (Frei et al., 1998a). At an SAR of 1.0 W/kg, there were no significant differences in mammary tumors and neoplastic lesions of other tissues. There were statistically significant differences in the incidence of five types of neoplastic tumors in the control group and of two types in the RF-exposed group (Frei et al., 1998b). C3H/HeJ mice were chronically exposed at 2450 MHz and evaluated for genotoxicity. There were no differences in the micronucleus frequency in peripheral blood and bone marrow (Vijayalaxmi et al., 1997).

Chronic Effects

Historically, epidemiological studies have provided little evidence that RF energies are carcinogenic to human beings (Hitchcock and Patterson, 1995). Differences have not been observed in cancer mortality in military personnel (Robinette et al., 1980; Garland et al., 1990). A 40-year, follow-up study of Korean War naval personnel found that microwave exposure had little effect on mortality. The risk of nonlymphocytic leukemia was doubled in one of the three high exposure occupations, electronics technicians in aviation squadrons (Groves et al., 2002). An evaluation was performed of the staff at the Massachusetts Institute of Technology (MIT Rad Lab) who worked in radar development during World War II and members of the general population. A marginally significant difference in cancer of the gallbladder and bile ducts was reported when the workers were compared to a cohort of physician specialists. No other differences were reported (Hill, 1988). A number of evaluations were performed for reproductive effects in operators of cathode-ray-tube video display terminals (VDTs). Associations reported early in the evolution were not related to the actual exposures (Hitchcock and Patterson 1995). An evaluation performed by the NIOSH using measurement data did not find meaningful differences between exposed and control groups for live births, stillbirths, and spontaneous abortion during the first trimester of pregnancy (Schnorr et al., 1991). Milham (1982) determined proportionate mortality ratio (PMR) for death by acute leukemia and leukemia for various occupational classifications. Four of the occupational classes he defined (electrical engineers, radio and telegraph operators, welders, and TV and radio repairmen) have the potential for exposure to RF (and ELF) fields. Milham reported that the PMR for acute leukemia in TV and radio repairmen was significantly different from the U.S. population. Sheikh (1986) has commented on this study, suggesting that "the apparent associations between certain electrical occupations and leukemia could be chance occurrences." He observed that this study calculated 34,444 PMRs, and at the 5% level, one would expect 1700 PMRs to exceed the null value.

A hypothesis concerning testicular cancer and use of radar was formed in a study that found an excess of this cancer in a group of policemen in Washington State who used radar

² Kallen et al., 1982; Kolmodin-Hedman et al., 1988; Brandt and Nielsen, 1990; Nielsen and Brandt, 1990; Taskinen et al., 1990; Larsen et al., 1991; Schnorr et al., 1991.

guns (Davis and Mostofi, 1993). Finkelstein (1998) determined that the standardized incidence ratios (SIR) were statistically significant for melanoma for police officers in Ontario, Canada with 10–60 years from hire ($SIR = 1.49$, 90% confidence interval (CI) = 1.15–1.98), and for the total cohort ($SIR = 1.37$, 90% CI = 1.08–1.72). For testicular cancer, the SIR was non-significantly elevated for the 10-to-60 group ($SIR = 1.45$, 90% CI = 0.96–2.1) and of marginal statistical significance for the total group ($SIR = 1.33$, 90% CI = 1.0–1.74). For the 90% CI, the lower limit corresponds to the lower 5% limit for a one-tailed test for sites with *a priori* hypotheses, which was the case for melanoma and testicular cancer.

The results from a number of evaluations of potential exposures to cell phone emissions and brain cancer have been published and reviewed (Moulder et al., 1999; Mild et al., 2003; Ahlbom et al., 2009; Swerdlow et al., 2011). The list of studies is extensive but is highlighted by the findings of the large Interphone study, which involved the participation of 16 study groups in 13 countries. The general finding was that individuals who had ever used a cell phone had a decreased risk of brain cancer, glioma (odds ratio (OR) = 0.81, 95% CI = 0.70–0.94), and meningioma (OR = 0.79, 95% CI = 0.68–0.91), with no signs of an increased risk of meningioma. There were some statistically significantly elevated findings such as an increased risk of glioma for cumulative call time and ipsilateral use (OR = 1.96, 95% CI = 1.22–3.16). Call time is determined by the number and duration of calls, which may be viewed as surrogate for total RFR dose. With respect to this, it was noted that “the lack of a consistently increasing risk with dose, duration of exposure and time since first exposure weigh against cause and effect” for glioma (The INTERPHONE Study Group, 2010).

In May 2011, the International Agency for Research on Cancer (IARC) (IARC, 2011) categorized RFR as a possible human carcinogen (Category 2B) on the basis of the association between cell phone use and glioma. In 2013, the IARC published Monograph 102 that reviewed the literature and explained the rationale for the classification, which is based on limited evidence in humans and test animals with positive associations found with glioma and acoustic neuroma (International Agency for Research on Cancer, 2013).

SOURCES OF EXPOSURE

Occupational

Dielectric heaters may be used to weld, mold, seal, and emboss plastics and to cure glues, resins, and particleboard. Many of these devices operate at 27 MHz, although some may operate as low as 13.56 MHz and others as high as 70 MHz. A number of workplace evaluations have demonstrated the potential of an overexposure to individuals who

work with dielectric heaters (Stuchly et al., 1980; Cox et al., 1982; Gandhi et al., 1986; Conover et al., 1992).

Induction heating (50–60 Hz up to 27 MHz) is used to heat conducting materials. High values of magnetic field strength have been reported near induction heaters (Stuchly and Lecuyer, 1985). However, the intensity of the fields diminishes rapidly with distance from the source (Conover et al., 1980, 1986; Mild, 1980). Hence it is possible that workers who do not work near the source or who spend little time in the most intense regions will receive relatively low level exposures, when time averaged.

In the electronics industry, plasma processing (0.1–27 MHz) may be classified as either dry etching or deposition operations (e.g., sputtering). An etcher is used to etch the surface of a wafer, and a sputterer is used to metallize the surface of a wafer. Typically, evaluations have demonstrated that leakage from well-designed, well-installed, and well-maintained units is low. Viewing ports may be a potential problem if they are not shielded. One evaluation found that peripherally attached equipment could act as antennas because of conducted or coupled RF energy (Ungers et al., 1985).

Communication systems may be either mobile or fixed, or a combination of these two. Fixed systems are used in the telecommunications industry and include high frequency radio, tropospheric scatter, satellite communications (SATCOMs), and microwave radio (point-to-point radio relay) systems. Mobile systems include small portable transceivers such as radios, walkie-talkies, and vehicular units. Combination systems may be used for paging or cellular radio. Maintenance personnel who work on high power systems, such as SATCOM systems, have the greatest potential for an overexposure if they do not follow proper lockout, tagout procedures. In certain cases, it may be possible for personnel who maintain cell-site antennas to be exposed to relatively high levels, for example, while working near an energized antenna on a tower or building (Petersen and Testagrossa, 1992). In general, exposures to portable communication devices have shown that the output from two-way radios may produce high, momentary exposures (Chatterjee et al., 1985; Cleveland and Athey, 1989).

Most radar units operate in the extremely high frequency (EHF), superhigh frequency (SHF), and ultrahigh frequency (UHF) bands in a pulse-modulated mode and at high peak transmitter powers (Jordan, 1985; Skolnik, 1990). Evaluations of commercial radar (e.g., airport surveillance, airport approach traffic control) have not revealed potential overexposure during normal operation. It is possible that maintenance activities (work on or at the transmit-receive duplexer, magnetron cabinet, or trapdoor of the antenna pedestal) may result in relatively high exposure (Joyner and Bangay, 1986). Exposures in the cockpit of an aircraft (Tell and Nelson, 1974; Tell et al., 1976), near marine radar (Peak et al., 1975; Moss, 1990), and near the police radar

(Bitran et al., 1992; Fisher, 1993) have not been reported as a problem. Possible overexposures to the output from military units have been reported (Williams and Webb, 1980; Forman et al., 1982).

Diathermy units use ultrasonic, microwave (915 and 2450 MHz), or shortwave (13.56 or 27.12 MHz) frequencies. The leakage field around the applicator depends on the type of applicator used. Relatively high field strengths may be found in the vicinity of the cables (Ruggera, 1980; Stuchly et al., 1981b). If the physician or physiotherapist adjusts the equipment during operation, the greatest exposure will be to the hands (Mild, 1980; Kalliomaki et al., 1982). Service personnel may be exposed during the maintenance of an energized system. Fields near the back of an energized unit that had the access cover removed for servicing were approximately 1000 V/m and 3 A/m (Mild, 1980). A review of exposures reported in the literature found that measured levels at distances greater than a meter from the source did not exceed exposure guidelines recommended by the International Commission on Nonionizing Radiation Protection (ICNIRP) (Shah and Farrow 2013). Evaluations of stray emissions from shortwave units found that levels decreased to the exposure guidelines at 1 m for inductive units and at 2 m for capacitive units (Shields et al., 2004).

Electrosurgical units (0.5–2.4 MHz) are used for cauterizing or coagulating tissues. Evaluations of solid-state and spark-gap units demonstrated that field strengths increased with increasing output power, and levels were higher for solid-state units (Ruggera, 1977). Levels near the probe and unshielded leads may exceed the exposure criteria (Ruggera, 1977; Mild, 1980). Relatively high levels have been reported near the eye/forehead region, about 20 cm from the active lead (Paz, 1987). Exposures to the hand of the user estimated by calculation and measurement exceeded the ICNIRP criteria (Liljestrand et al., 2003).

Environmental

Naturally occurring background sources of RF include terrestrial, extraterrestrial, and atmospheric electrical discharges (lightning), and even the human body (Stuchly et al., 1981a). Although the list of artificial sources is lengthy (Hitchcock and Patterson, 1995), the major sources include dielectric heaters, induction heaters, broadcast and communications, radar, plasma processors, diathermy units, and electrosurgical devices.

An exposure to the radiation from base stations has not been shown to produce exposure to members of the general public that exceeds the exposure guidelines (Thansandote et al., 1999; Mann et al., 2000; Fuller et al., 2002; Lin et al., 2000). Evaluations of potential exposures to RFR from Wi-Fi have not found overexposures (Industry Canada, 2012; Foster and Moulder, 2013; Office of Telecommunications Authority, 2007).

Broadcasting includes standard amplitude-modulation (AM) audio broadcasting, frequency-modulation (FM) broadcasting, and educational and commercial TV. The frequencies are allocated by the Federal Communications Commission (FCC) (Stern, 1989). Areas of potential concern include work on “hot” (energized) AM towers (Tell, 1991), access on tower structures near energized FM and TV antennas, and leaks from transmitter cabinets in monitor buildings (Curtis, 1980; Mild, 1980).

Exposures to the output from mobile phones have been an issue since the early 1990s, although the technology has changed as has the manner of usage, i.e., voice communications vs. texting and voice communications, as well as the option for hands-free operation. Some early evaluations demonstrated that such exposures are within the acceptable levels (Joyner et al., 1992; Balzano et al., 1995). Kuhn reported the results of an evaluation of 668 cell phones based on compliance testing data finding that the data fit a Gaussian (normal) distribution and that the maximum SAR (RFR dose rate) in human head phantom at the peak frequency was around 1 W/kg for both 1 and 10 g SARs (Kuhn et al., 2005, 2007). Other studies have demonstrated that relatively high, localized exposures to parts of the ear and skin of the head, with decreasing exposure as the RFR penetrates more deeply and into the brain tissue nearest the antenna. The FCC adopted guidelines that include mobile communications such as cell phones and PCS in 1996 (FCC Report and Order 96-326). This includes a local SAR of 1.6 W/kg for phones sold within the United States. The FCC maintains an online SAR database for mobile communications devices as well as links to manufacturer’s data bases (<http://www.fcc.gov/encyclopedia/specific-absorption-rate-sar-cellular-telephones>).

The introduction of smart meter technology has received a lot of attention (California Council on Technology, 2011; Vermont Department of Health, 2012; Levy and Page, 2012; Michigan Public Service Commission, 2012; Rivaldo, 2012). One evaluation (Sage Associates, 2011) reported the possibility of overexposures where multiple smart meters are used and that reflected levels of microwave radiation are high. This report has been criticized for use of unrealistically high reflection factors and exposure guidelines that are not current (Electric Power Research Institute, 2011). One of the most thorough measurement reports on this topic was performed by Tell. He evaluated 37 locations in Vermont with sources operating between 902 and 928 MHz and a smaller sample that also emitted at 2.4 GHz. Measurements as close as 1 ft from the meter and measurements within structures were well beneath the limits specified by the FCC. Tell also reported that “there was no general correlation between overall higher RF fields associated with large banks of meters.” and that the peak RF fields associated with multiple meters approached levels associated with a single meter. Additionally, as would be anticipated, the strength of the field decreased with distance from the smart meters (Tell and Tell, 2013).

Whole body scanners used in airports utilize millimeter-wave microwave radiation (tens of GHz) to expose the subject. In general, at these frequencies, the penetration depth into the tissue is quite small and, when absorbed, results in localized heating of tissue. According to ICNIRP, the resulting exposure is about 1/10th of the exposure guideline for members of the general public (International Commission on Nonionizing Radiation Protection, 2012).

Industrial Hygiene

Guidelines for occupational exposure to RF radiation have been recommended by several groups, including the Institute of Electrical and Electronics Engineers (IEEE) (IEEE, 2005a), the ACGIH (ACGIH, 2013), the ICNIRP (International Commission on Nonionizing Radiation Protection, 1998, 2009b), and the National Council on Radiation Protection and Measurements (NCRP) (NCRP, 1986). The ICNIRP, NCRP, and the IEEE recommend dual limits for members of the general public and occupational limits. The IEEE also calls the occupational limits the upper tier or the controlled environment, while the general public limits also serve as the action level for the occupational setting. In general, the exposure limits for the two target groups are either the same or have a fivefold difference in their magnitudes.

The ACGIH values are called threshold limit values (TLVs). Radio-frequency radiation TLVs apply from 30 kHz to 300 GHz. The ACGIH includes the band between 3 and 30 kHz in the sub-RF exposure limit.

The exposure limits are based on the basic restrictions from which the exposure limits are derived, as discussed earlier. The derived limits recommended by the IEEE are called maximum permissible exposures (MPEs, see Tables 98.3 and 98.4). Many of the limits in Tables 98.3 and 98.4 have a 6-min averaging time or a 30-min averaging time when the exposure limits are fivefold greater in magnitude. The 6-min time is based on cooling time constants derived from partial body irradiation of test animals with microwaves at 3 GHz (Ely et al., 1964). The IEEE reduces the averaging time to protect against skin burns (Petersen, 1991) at frequencies at which the penetration depth is shallow. In this case, averaging time is reduced to 10 s at 300 GHz.

The IEEE discusses the use of the action level in the exposure guideline (IEEE, 2005a), as well as the IEEE recommended practice on establishing a radio-frequency safety program (IEEE, 2005b).

The IEEE limits are based on electrostimulation from 3 kHz to 5 MHz and thermal effects from 100 kHz to 300 GHz. This is reflected in Tables 98.3 and 98.4 most prominently in terms of averaging time where 0.2 s is used for electrostimulation and times between 30 min and 10 s used for thermal effects. There is an overlap that defines a

transition region between 100 kHz and 5 MHz. In the transition region, it is necessary to apply both sets of limits.

In the spectral region from 100 kHz to 3 GHz, the basic restriction is the SAR. This region includes the resonance range where the absorption of RFR electromagnetic energy is highest. Hence, the exposure limits are based upon WBA exposure. The WBA-SAR, or dose rate, is 0.4 W/kg for occupational exposure and is 1/5th that value, 0.08 W/kg, for the general public or action level (IEEE, 2005a). This fivefold difference is based upon an additional safety factor that is applied to the general public limits.

The IEEE (2005a) also allows spatial-peak excursions above the WBA levels. These excursion factors are called relaxations, and the magnitude of the relaxation is frequency dependent. Hence, to insure compliance with the guidelines, one must determine the WBA exposure and compare that to the WBA-MPE as well as compare the spatial-peak exposure levels to the relaxations.

Although the WBA-SAR is invariant, the derived limits are frequency dependent, as indicated in Tables 98.3 and 98.4. This is because the human body couples best to wavelengths that approach a certain body height-to-wavelength ratio. For a standard man, this ratio is established at a frequency around 70 MHz. Coupling and absorption would be maximized around this frequency and decrease for higher and lower frequencies up to a point. Hence, absorption is considered to be maximized in the human whole-body resonance region, which extends from about 30 to 300 MHz, while absorption is lowest at the lower frequencies, below about 3–5 MHz, which is where the limits are the highest.

Because of this frequency dependence, exposure at different frequencies has different allowable values, but exposure at these values still produces a WBA-SAR that does not exceed the basic limit. For example, the values of allowable electric field strength at 1 and 100 MHz are 1842 and 61.4 V/m, respectively. Occupational exposure at both limits would produce an SAR of 0.4 W/kg in standard man. Hence, if the measured value of field strength or power density does not exceed the applicable exposure limit, the WBA-SAR will not be exceeded.

Exposure to low frequency RFR may result in electrostimulation, burns, shock, and RFR currents that may pose contact-current and induced-current hazards. Shock and burns are important because ungrounded, conductive objects illuminated by an RFR source couple with the field and store the energy as an electrical charge. If a grounded person touches the object, excessive current could be discharged to the body.

To control for potentially hazardous effects associated with high current density, the guidelines, in general, recommend limiting field strengths and levels of current at low frequencies. Recommendations for control of RFR current are made between 110 MHz and 3 kHz. As with field exposure, the limits are based on electrostimulation with a 0.2-s

TABLE 98.3 IEEE MPEs for Controlled Environments (upper tier): Fields in Space

Frequency Range, MHz	E , V/m*	H , A/m*	Power Density (S), W/m ² *	Averaging Time, min
0.003–0.1 ^a	1842	—	—	0.0033 (0.2 s)
0.003–0.0035 ^a	—	1640/ f_M ^b 3016/ f_M ^c	—	0.0033 (0.2 s)
0.00035–5.0 ^a	—	490 ^b 900 ^c	—	0.0033 (0.2 s)
0.1–1.0	1842	16.3/ f_M	—	6

averaging time between 3 and 100 kHz. This is related to the sensation of warmth in the ankle that may become evident 5 s after the onset of exposure at lower frequencies (Gandhi et al., 1985). The current limits are based on thermal effects with a 6-min averaging time for frequencies between 100 kHz and 110 MHz (IEEE, 2005a). Note that the guidelines for contact current are for both grasping (whole hand) contact and touching (e.g., unintended finger contact) in the controlled environment, but just for touching contact for the general public limits.

AB HINC (FROM HERE ON . . .)

High visibility issues have become a fact of life with certain RFR emitters. This includes a number of sources such as the PAVE PAWs early warning system, cathode ray tube VDTs, cellular phones, and now, possibly, smart meters. Some of these issues will diminish in importance as technological changes replace an existing technology with newer technology (e.g., CRT-VDTs replaced by flat-panel displays).

As has been demonstrated a number of times in the past, when there are questions about possible health effects with newly introduced RFR emitters, the industry is unprepared with satisfactory answers. This occurred with cell phones when the issue of brain cancer was raised during a popular television show in the early 1990s. When this occurred, the industry response was to use information based upon RFR sources with different frequencies, modulations, operational power levels, and usage patterns than cell phones, because that was all that was available to them. In other words, there were no *a priori* evaluations of potential exposures and possible health effects of the source under question.

Following on the coattails of those inadequate responses, simple studies were designed, implemented, published and analyzed, leading to further studies using ever more sophisticated methodologies. However, as studies were planned

and implemented, the technology under evaluation evolved (analogue to digital modulation) and usage changed (voice communications to texting) so quickly that the results of studies just completed often no longer directly applied to the exposures of current users. Fast forward to 2011, and a highly respected organization, IARC, categorized RFR into a relatively weak hazard category, a possible human carcinogen.

No one has ever claimed that scientific understanding occurs with rapidity, but it is approaching 20 years since questions of brain cancer and exposure to RFR from wireless devices were first raised. The scientific understanding of how the RFR power is deposited in the tissue of the head and the brain is better understood, and a number of health effects studies using cells, animals, humans, and human populations have been performed. But, only the future will tell if RFR is truly a hazard to brain tissue, or if it is simply a source that heats the tissue.

Of course, this pattern will be repeated with some future RFR emitter. In some cases the repetition (i.e., not learning from history) will be because the industry did not perform the necessary studies of potential health hazards associated with a new product that emits “radiation.” Why not? The obvious answer is because of the additional cost to product development and potential delays to introducing the product to market. And, unfortunately, because of ongoing debates about topics such as nonthermal effects of RFR exposure, electrosensitivity, and the very RFR exposure guidelines themselves; it is often not adequate simply to evaluate by measurement the potential exposures users may receive and compare those measured levels to the exposure guidelines.

Hopefully, in the future, evaluations of potential exposures to RFR will occur prior to market, especially where the product has the potential to expose a large number of people and has a somewhat unique set of output characteristics. Of course, such proactive evaluations will not mean the end

to the debate, especially where people's health is potentially at stake. It will mean, however, that a prudent approach is being taken, one that recognizes the necessity of examining all of the possible ramifications of a new radiation source used in the public domain.

OPTICAL RADIATION: ULTRAVIOLET, VISIBLE LIGHT, INFRARED, AND LASERS

JOSEPH M. GRECO

Target organs: Eyes, skin

Occupational exposure limits:

Ultraviolet: Wavelength dependent. For ultraviolet radiation in the UV-A region, the ACGIH TLV suggests limiting long exposures (over 1000 s, about 16 min) to an irradiance of 1 mW/cm^2 . For shorter durations (up to 1000 s), the total energy should not exceed 1 J/cm^2 .

For the UV-B TLV, the effective irradiance (E_{eff}) (weighted as a function of wavelength and based on the action spectra for eyes and skin) should be limited to 3 mJ/cm^2 per 8-h day. Ultraviolet radiometers with a built-in spectral response, which mimics the relative spectral effectiveness, can provide results directly in E_{eff} .

Visible light/infrared: ACGIH TLV is wavelength dependent and complex to determine. Blue-light hazard and infrared hazards should be assessed separately, as appropriate.

Laser: Maximum permissible exposure for eye and skin, as defined by the ANSI Z136.1 standard. Dependent on wavelength, exposure duration, mode, and other factors. Recommend that a trained laser safety professional perform these calculations due to the many parameters involved. Non-beam hazards should also be assessed.

BACKGROUND AND USES

Optical radiation is comprised of the ultraviolet (UV), visible, and infrared (IR) portions of the electromagnetic spectrum. The International Commission on Illumination (the

CIE, i.e., Commission International d'Eclairage) Committee on Photobiology has designated the optical radiation spectral bands summarized in Table 99.1 (CIE, 1970). Most commonly used lasers will fall into the UV, visible, and IR wavelength regions of the electromagnetic spectrum.

While ionizing radiation is described in terms of photon energy (e.g., electron volts), and radiofrequency radiation in terms of frequency (Hz), optical radiation is normally described in terms of wavelength (i.e., nm, μm , or mm). Exposure to optical radiation is normally expressed in units of Watts/cm^2 (for continuous sources) or Joules/cm^2 (for pulsed or short-term exposure).

The intensity of radiant energy from conventional light sources usually falls off markedly as distance from the source increases, and generally follows the inverse square rule, assuming a point source. This allows a rapid falloff of intensity in a relatively short distance. In contrast, the laser process (sometimes referred to as *lasing*) can produce a highly coherent beam of optical radiation that concentrates its energy in a narrow beam over considerable distances. A typical laser emits a beam with little divergence (on the order of a milliradian), and the irradiance (energy per area) does not decrease appreciably over distances. As an example, there have been many reports of pilots of planes and helicopters being targeted by terrestrial-based low power laser pointers, creating an optical hazard (distraction or temporary flash blindness), some even resulting in arrests (Barat, 2009).

Ultraviolet Radiation

The UV radiation spectrum resides between the ionizing (gamma and X) radiation and the visible light region in the

TABLE 99.1 Divisions of the Optical Spectrum According to the International Commission on Illumination (CIE)

Region	Wavelength Range	Other Terminology
UV	100–400 nm	
UV-C	100–280 nm	Far UV
UV-B	280 to 315–320 nm	Middle UV
UV-A	315 to 380–400 nm	Near UV
Visible light	380–400 to 760–780 nm	Visible
IR	760–780 nm to 1 mm	
IR-A	760–780 to 1400 nm	Near IR
IR-B	1400–3000 nm	Middle IR
IR-C	3000 nm to 1 mm	Far IR

electromagnetic spectrum. The CIE defines UV wavelengths as 100–400 nanometers (nm), and divides it into three regions (UV-A, UV-B, and UV-C). The UV-C and UV-B wavelengths are collectively called the *actinic* region. These three regions vary widely with respect to the penetration and potential for causing biological effects. For example, the shorter UV wavelengths (below 200 nm) are highly attenuated by most materials (including the atmosphere), and are not considered an exposure problem because sources are uncommon. Prolonged exposure to other UV wavelengths (especially 270–320 nm) can cause deleterious bioeffects, as well as cause the degradation of many materials such as plastic and rubber (Sliney and Wolbarsht, 1980).

Visible/IR

It should be noted that, although the visible region of the spectrum is defined as the wavelengths between 400 and 700 nm, the actual range visible to the eye can range from 380 to 780 nm. Incoherent sources of visible light (400 to 760–780 nm) and IR (i.e., “heat”) radiation (760–780 nm to 1 mm) are common, and most do not present a hazard. This chapter addresses the relatively few sources of intense visible/IR radiation that should be handled with care, but does not cover conditions such as heat stress or conductive heat. Visible and IR sources are discussed together, because most (but not all) IR sources will also have a visible component.

Laser Radiation

A laser is a device that produces coherent electromagnetic radiant energy within the optical spectrum, from the far UV to the far IR region of the spectrum. The term laser is an acronym for *light amplification by stimulated emission of radiation*. Based on the theoretical work by Albert Einstein in 1916, and developed by Townes, Schawlow, and others in the late 1950s, the first laser was built by T. Maiman in 1960 (Henderson, 1997). At the time, it was considered a solution waiting for problems. And since then, lasers have been

developed into an essential tool, used in a multitude of diverse applications—medicine, technology, consumer items, industrial, defense, entertainment, communication, law enforcement, and a host of others.

Besides having the characteristic of coherence, lasers emit discrete wavelengths within the optical spectrum, and although most lasers are monochromatic (emitting one wavelength, or single color), many lasers emit several discrete wavelengths. For example, the argon laser emits radiation at several different wavelengths, but it is generally designed to emit only one green “line” (wavelength) at 514.5 nm or a blue line at 488 nm. When considering potential health hazards, it is crucial to establish the output wavelength or wavelengths. A list of common laser wavelengths is summarized in Table 99.2.

SOURCES OF EXPOSURE

Ultraviolet Radiation

Although the earth’s ozone (O_3) layer absorbs most of the UV produced by the sun, the remaining unattenuated solar UV reaching the earth is by far the largest source of exposure for the general population (Sliney and Wolbarsht, 1980). Exposure to UV varies and is dependent on the time of day, latitude, elevation, cloud cover, and presence of reflective surfaces. As an example, measurements of the daily variation in UV energy (erythema effective irradiance) were made in Denver, CO, on a clear summer day. The maximum value ($11.3 \mu\text{W/cm}^2$) was reached at approximately noon while low dense cloud cover somewhat reduced this intensity (Machta, 1975).

The UV-emitting equipment in the work/laboratory setting is common, and is used for a wide variety of purposes. The radiation emitted from UV sources is either deliberate (e.g., killing bacteria, ink curing), or incidental (unwanted UV from arc welding). Table 99.3 lists some processes and devices found in the workplace and other locations that emit non-coherent UV radiation (Cremonese et al., 1982; NRPB, 1977).

Visible/IR

Like UV radiation, the single largest source of visible/IR radiation is the sun. Occupational sources include lamps and lighting systems (flashbulbs, photocopiers, etc.), space heaters, welding, and industrial settings such as glass works and iron foundries. Some devices, such as remote control units and IR loops for the hearing impaired use IR signals, but the output power level is insignificant.

Lasers

As previously stated, lasers are used in a plethora of applications, and are on their way to becoming a ubiquitous

TABLE 99.2 Common Laser Wavelengths

Type	Wavelength (nm)	Optical Region
Krypton–fluoride excimer	249	UV
Xenon chloride excimer	308	UV
Helium–cadmium (“He–Cad”)	325, 442	UV, visible (blue)
Krypton	351, 356, 530, 647	UV, visible, IR
Nitrogen	337	UV
Argon	457, 476, 488, 514	Visible (blue-green)
Copper vapor	511, 578	Visible (green)
Helium neon (“HeNe”)	633	Visible (red)
Gold vapor	628	Visible (red)
Titanium sapphire (“Ti–Saph”)	660–1060 (tunable)	Visible, IR
Semiconductor (GaInP family)	670–680	Visible (red)
Ruby	694	Visible (red)
Alexandrite	700–830	IR
Semiconductor (GaAlAs family)	750–900	IR
Neodymium: YAG	266, 355, 532, 1064	UV, Visible (green), IR
Fiber—erbium, ytterbium, neodymium, and others	1060–1610	IR
Semiconductor (InGaAsP family)	1300–1600	IR
Hydrogen fluoride	2600–3000	IR
Carbon dioxide	10,600	IR

presence and technology as they become smaller, more powerful, and cheaper to manufacture. Essentially all segments of the laser market, including communication, materials processing, optical storage, medical and aesthetic, military, R&D, instrumentation, entertainment, and others are expected to continue to grow at a steady pace in coming years (Overton et al., 2014).

BIOEFFECTS

Ultraviolet Radiation

Effects from the exposure to UV radiation are very dependent on the wavelength. The organs that are most vulnerable are the eyes (especially the cornea and lens) and skin. In addition, photosensitization to UV can occur from various substances. It should be noted that a small amount

of UV exposure is beneficial, in that it promotes vitamin D production.

Effects on the skin can be divided into acute and chronic. The most common acute effect from overexposure to UV is erythema (sunburn), which is a photochemical response of the skin resulting from overexposure to the UV-C and UV-B regions (especially 200–315 nm). The severity of the effect depends on the duration and intensity of the exposure. Exposure to UV-A alone requires far greater levels to induce erythema; the UV-A dose required to produce erythema is 800–1000 times that of the UV-B dose. Maximum sensitivity of the skin occurs at 295 nm (ACGIH, 2010).

Chronic exposure to sunlight (especially wavelengths shorter than 315 nm) accelerates skin aging and increases the risk of developing skin cancer. These effects may not manifest themselves for years or even decades. Although the causal relationship of UV-B exposure and squamous cell and basal cell carcinoma seems to be well established (van der Leun, 1987; Sterenborg and van der Leun, 1987), the causal relationship for malignant melanoma is weaker (Koh et al., 1990).

The primary effect from UV-B and UV-C overexposure on the eye is keratoconjunctivitis (also known as welders flash, snow blindness, and arc eye), which involves the cornea. Symptoms include a “ground-glass” sensation in the eye, aversion to bright light, and pain/discomfort within hours of exposure. The cornea is considered as the “skin” of the eye, and the corneal cells have a very short lifespan—only about 48 h. Damage to this outermost layer, then, is usually repaired within 1–2 days by normal cell turnover (Sliney and Wolbarsht, 1980).

TABLE 99.3 Processes and Devices That Emit UV Radiation

Germicidal lamps	Tanning beds
Curing equipment	Welding equipment
Fluorescent lamps and equipment	Halogen lamps
Mercury lamps	Dermatology lamps (“Wood’s lamps”)
Carbon and xenon arcs	Scatter from UV lasers
Metal smelting	Solar lamps
Glass processing	Projection systems
“Black lights”	

Excessive UV exposure has been associated with cataractogenesis, especially in the case of brunescence (brown colored) cataract, a form of senile cataract (Hiller et al., 1977).

Photosensitivity, described as hypersensitivity to certain wavelengths in the optical spectrum, may be genetic, associated with various immune states, or induced. Certain creams, lotions, shampoos, and drugs (such as tetracycline) may induce hypersensitivity to UV radiation in many individuals. Fitzpatrick et al. lists many common photosensitizers (Fitzpatrick et al., 1974).

Visible/IR

Skin injury is usually not a concern from most conventional sources of IR radiation (such as industrial furnaces and open arcs) because the natural aversion response—moving away from the source of heat—will normally occur before injury can take place (Sliney and Wolbarsht, 1980). The eye does not have adequate thermal warning properties and is the organ most susceptible to visible/IR overexposure. Far-IR radiation (3000–1 mm) is absorbed in the cornea, and middle IR radiation (1400–3000 nm) is absorbed by the lens. Radiation between 400 and 1400 nm is focused onto the retina, and this wavelength range is referred to as the retinal hazard region (Youssef et al., 2011). It should be noted that glare can overwhelm adaptive capacity of the eye, causing visual fatigue and reduced visual perception, which can make a worker more prone to accidents.

Injury to the retina can be caused by two mechanisms—thermal injury (focusing thermal energy onto the retina), and blue-light hazard [$B(\lambda)$] photochemical reaction to chronic exposures to visible light (especially blue wavelengths between 400 and 500 nm). Figure 99.2 shows relative retinal irradiances for staring directly at various light sources, and includes exposure risks from retinal thermal injury and photochemical injury.

Although photokeratitis from welding arcs and other arc sources can be painful, it is transient. The principal risk of permanent injury from viewing bright light sources is photoretinitis, for example, solar retinitis with an accompanying

scotoma, which results from staring at the sun. Blue light retinal injury (photoretinitis) can result from either viewing an extremely bright light for a short time or viewing a less bright light for longer exposure periods; that is, reciprocity. Reciprocity helps to distinguish these effects from thermal burns, in which heat conduction requires a very intense exposure within seconds to cause a retinal coagulation; otherwise, surrounding tissue conducts the heat away from the retinal image. Injury thresholds for an acute injury in experimental animals for both corneal and retinal effects have been corroborated for the human eye from the accidental data. Occupational safety limits for exposure to UV radiation and bright light are based on this knowledge (ACGIH, 2010).

Lasers

Although skin injury may occur from higher powered lasers, the eye is the organ of greatest concern. For lower power lasers (<1 milliwatt), the natural aversion response or blink reflex, assumed to be up to 0.25 s, is sufficient to protect the eye. However, higher power lasers may produce damage to various structures of the eye in a much shorter time. Lasers in pulse mode can produce extremely high peak powers, and can have pulse durations in the femtosecond regime, which could result in numerous pulses to be absorbed into an unprotected eye before being aware of the exposure. Compared to a continuous wave laser with the same average power, or single pulse lasers with the same energy, more injury potential exists with repetitively pulsed lasers (Marshall, 2001).

The laser wavelength will determine the ocular absorption site, as shown in the Figure 99.1. Injury mechanisms are mostly either thermal, which are immediately apparent, or photochemical, which are manifested in approximately 24 h.

EXPOSURE GUIDELINES

The American Conference of Governmental Industrial Hygienists (ACGIH) annually publishes threshold limit values (TLVs[©]) for chemical and physical agents. Threshold

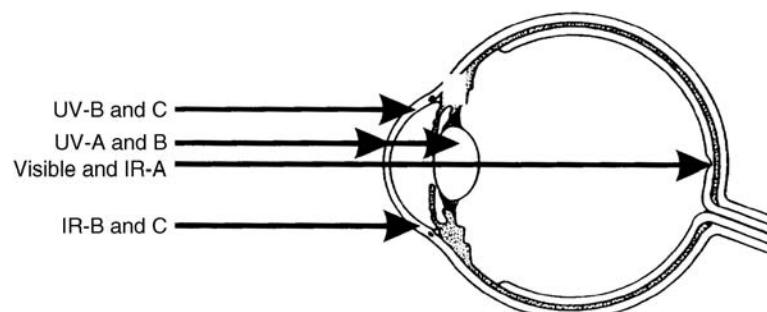

FIGURE 99.1 Locations in the eye where different bands of optical radiation deposit energy that may cause injury.

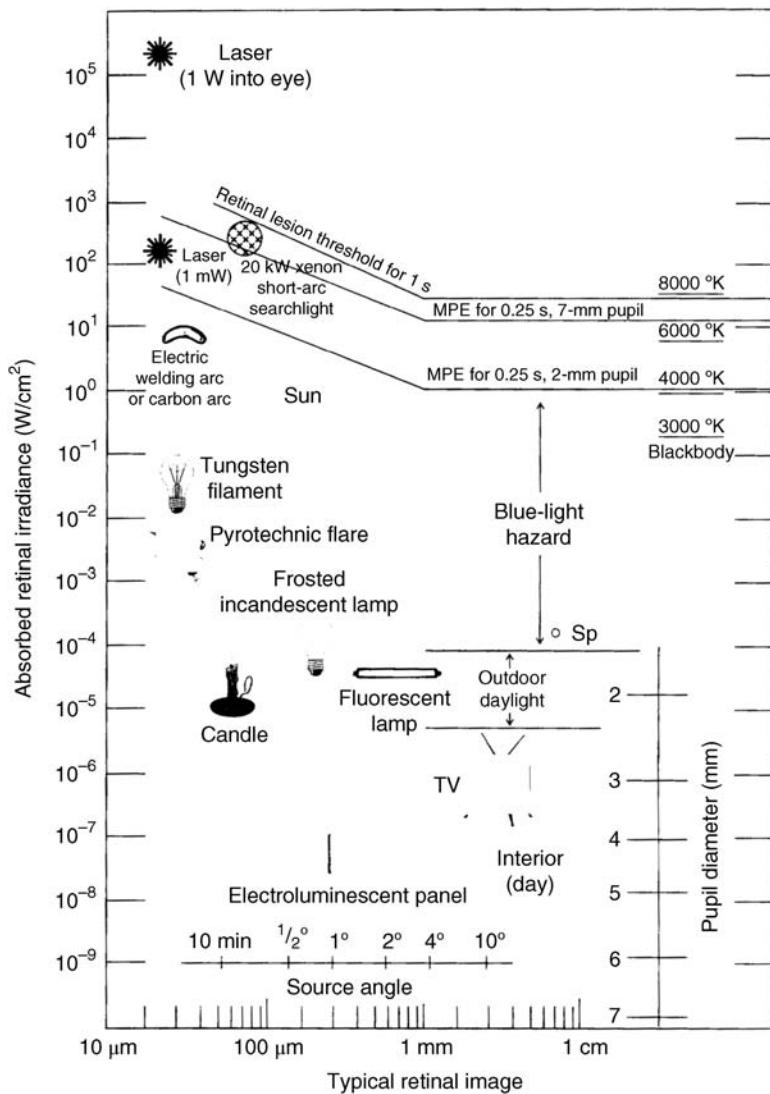

FIGURE 99.2 Relative retinal irradiances for staring directly at various light sources. Two retinal exposure risks are depicted: retinal thermal injury, which depends on the retinal image size, and photochemical injury, which depends on the degree of blue light in the source's spectrum. The horizontal scale indicates typical image sizes. Most intense sources are so small that eye movements and heat flow spread the incident energy over a larger retinal area. The range of photoretinitis ("blue-light hazard") is shown to extend from the normal outdoor light levels and above. The xenon arc lamp is clearly the most dangerous non-laser hazard. (Source: Sliney and Wolbarsht, 1980).

limit values are widely used for UV, visible, and IR radiation. For laser exposures, the American National Standards Institute (ANSI) Z136.1 standard is the most widely used for determining maximum permissible exposures (MPEs) for both skin and eyes (ANSI, 2014).

Ultraviolet Radiation

Threshold limit values "refer to UV radiation in the spectral region between 180 and 400 nm, and represent conditions

under which it is believed that nearly all workers may be repeatedly exposed without adverse health effects." The UV TLV is highly dependent upon the wavelength, and separate TLVs are provided for UV-A and UV-B regions.

For UV radiation in the *UV-A region*, the ACGIH suggests limiting long exposures (over 1000 s, about 16 min) to an irradiance of 1 mW/cm^2 . For shorter durations (up to 1000 s), the total energy should not exceed 1 J/cm^2 .

In the *UV-B region*, the total irradiance is determined by multiplying the irradiance in small wavelength bands ($\Delta\lambda$)

by the relative spectral effectiveness (S_λ), a weighting factor based on the action spectra for eyes and skin:

$$E_{\text{eff}} = \Sigma E_\lambda \cdot S_\lambda \cdot \Delta\lambda$$

The effective irradiance (E_{eff}), the weighted total in the UV-B range is limited to 3 mJ/cm² over an 8-h day. Some UV radiometer manufacturers manufacture detectors that respond to UV radiation according to the relative spectral effectiveness. Since the measurement result using this detector is in units of effective W/cm², comparison of the reading to the permissible UV exposure table will readily provide a determination of the allowable exposure duration per day.

Visible/IR

The ACGIH provides TLVs for visible and near IR radiation. Biological weighting factors for both the $B(\lambda)$ and retinal thermal hazard [$R(\lambda)$] are assigned to wavelengths between 305 and 1400 nm. Blue-light hazard has peak values at 435–440 nm while $R(\lambda)$ values rise sharply to the 435–700 nm region, then tail off to 1400.

Calculating TLVs for visible and IR wavelengths is multi-faceted. The ACGIH includes four conditions that may apply, and each requires one or more equations for calculating the appropriate TLV:

- Retinal thermal injury from a visible light source
- Retinal photochemical injury from chronic blue light exposure
- Thermal injury to cornea and lens from IR radiation
- Retinal thermal injury from near IR radiation

Due to the complexity and number of equations for calculating TLVs (over a dozen), the reader is referred directly to the ACGIH TLV booklet.

On a more empirical note, Whillock et al. measured the radiance levels at four industrial sites (a glass works, iron foundry, large-scale float glass facility, and a small food-preparation facility). They found that the radiance did not indicate potential photochemical or burn hazards to the retina from these operations. However, the authors did note that a potential for lenticular injury (cataracts) exists for long-term exposures (10–15 years) to IR radiation (Whillock, 1990).

Lasers

Although the ACGIH publishes TLVs for lasers, the ANSI Z136.1 standard, Safe Use of Lasers, is much more widely used. The ANSI standard employs the use of the MPE, which is defined as the level of laser radiation to which an unprotected person may be exposed without adverse biological changes to the eye or skin. The MPE is dependent upon a number of factors, including wavelength, duration of

exposure, whether the laser is continuous wave or pulsed, and others. The Z136.1 standard includes several pages of tables, charts, correction factors, rules, and other information to properly calculate the MPE. It is highly recommended that the MPE is calculated by a qualified individual, such as a Laser Safety Officer, due to the many possible pitfalls and caveats involved. It should be noted that several versions of software have been developed for these calculations. However, like any computations, if improper assumptions are entered, incorrect MPE values will result.

Since the early years of the ANSI Z136.1 standard, a classification scheme has been used to separate lasers into categories according to their potential for hazard. In 2007, the standard updated this classification system to harmonize with the international standards. Thus, there are a few classes that have changed only in name, but not intent. Table 99.4 shows the current and past terminology (from Rockwell Laser Industries, 2014).

INDUSTRIAL HYGIENE

For emitters in the optical spectrum, a comprehensive hazard evaluation requires precise instrumentation and complex measurements of spectral irradiance and radiance of the broad-band sources. This can often be done by an experienced industrial hygienist or health physicist. And for lasers, measurements of beam irradiance or other characteristics are rarely done for a safety evaluation. Instead, the ANSI classification will determine the types of controls needed for the protection. Class 4 lasers generally require the most stringent control measures. A qualified laser safety officer or professional is often consulted for a safety evaluation for high powered systems.

Engineering controls such as welding curtains, baffles, controlled areas, and doorway interlocks are used to control optical radiation hazards. Administrative controls, such as limiting the time of exposure, can be useful with regard to UV sources and welding arcs. Protective eye wear and face shields constitute a primary control measure in many operations such as welding or laser research.

Ultraviolet and IR Protection

Although many sources of UV radiation also emit some visible light, some do not. A germicidal lamp, for example, may only emit a faint visible glow while emitting intense UV radiation. Therefore, the amount of visible light should not be used as an indicator of the UV intensity. A combination of engineering/administrative controls and personal protection should be used to limit UV exposures. Engineering controls are preferred due to their broader effectiveness.

Shielding. UV leakage should be contained and shielded whenever possible. If viewing the process is required,

TABLE 99.4 ANSI Z136.1 Laser Classification System, Pre- and Post-2007

Class	Relative Hazard/Examples	ANSI Z136.1 (Post-2007)	ANSI Z136.1 (Pre-2007)
1	Minimal hazard. DVD player, laser printer are Class 1 laser systems (actual internal laser may be 3b)	Any laser or laser system containing a laser that cannot emit laser radiation at levels that are known to cause eye or skin injury during normal operation. Also, a <i>Class 1 system</i> may contain a Class 3 or 4 laser where the beam is fully enclosed	
1M	Safe for unprotected eye, potentially hazardous when collecting optics are used	Not known to cause eye or skin damage unless collecting optics are used	NA
2	Low hazard. Safe for unintended exposure, prolonged staring should be avoided Up to 1 mW power for visible, continuous wave (cw) lasers	Visible lasers are considered incapable of emitting laser radiation at levels that are known to cause eye injury within the time period of the human <i>eye aversion response</i> (0.25 s)	
2M	Visible low power lasers; either collimated with large beam diameter or highly divergent	Not known to cause eye injury within the aversion response time unless collecting optics are used	NA
3a	Can be hazardous. Power range for cw lasers: 1–5 mW	NA	Lasers similar to Class 2 with the exception that collecting optics cannot be used to directly view the beam
3R	Can be hazardous. Only small hazard potential for accidental exposure	Replaces Class 3a and has different limits. Up to five times the Class 2 limit for visible and five times the Class 1 limits for some invisible	NA
3b	Medium power lasers. Power range for cw lasers: 5–500 mW. Do not present a diffuse (scatter) hazard or significant skin hazard except for higher powered 3b lasers operating at certain wavelength regions	Medium powered lasers (visible or invisible) that present a potential eye hazard for intrabeam (direct) or specular (mirror-like) conditions. Class 3b lasers	
4	High power lasers. Greater than 500 mW for cw lasers. Industrial laser cutters, most R&D and surgical lasers. May be a fire hazard, and result in hazardous fumes	High powered lasers (visible or invisible) considered to present potential acute hazard to the eye and skin for both direct (intrabeam) and scatter (diffused) conditions	

Source: Rockwell Laser Industries (2014b).

observations should take place through materials such as polycarbonate plastics that attenuate UV-C and UV-B wavelengths while remaining transparent to visible light. Almost all glass and plastic lens materials block UV radiation below 300 nm and IR radiation at wavelengths above 3000 nm.

Interlocks. If access to equipment that houses UV radiation is required, the housing should be interlocked such that the UV source will be turned off when the housing or cover is removed. Interlocks should be tested regularly to ensure proper operation.

Non-reflective materials. If possible, reflective materials such as shiny metals (e.g., aluminum), glossy light-colored paint, and paint containing titanium should be avoided. It should also be noted that materials that appear dark and non-reflective in the visible portion of the spectrum may not be the same in the UV portion.

If UV radiation exposure cannot be avoided, the following will help to minimize the exposure.

Personal protection. All skin with potential for exposure (especially hands and face) should be protected. Gies et al. measured the effectiveness of various types of clothing and fabrics, and determined that clothing can provide significant protection against UV exposures (Gies et al., 1994). In general, dense, heavy fabrics with no direct transmission paths are recommended for UV protection during welding operations. Most gloves found in a laboratory environment will provide at least some protection for hands from UV exposure.

Safety eyewear with a UV-protective coating are available that will protect against UV wavelengths and still afford adequate visibility (they sometimes are light yellow in color). Moseley measured the UV and visible

light transmission properties of several types of protective eyewear used in medical, industrial, and welding applications (Moseley, 1985). Of paramount importance in these types of eye wear (and for industrial sunglasses) is the peripheral protection. Side shields or wraparound designs are important to protect against the Coroneo effect, which is the focus of temporal, oblique rays into the nasal equatorial area of the lens, where cortical cataracts frequently originate (Sliney, 1996).

Spectacles and goggles designed for ocular protection against IR radiation in foundries and glass manufacturing generally have a light greenish tint, although the tint may be darker if some comfort against visible radiation is desired. Such eye protectors should not be confused with the blue lenses used in the steel and foundry operations, for which the objective is to visually check the temperature of the melt; these blue spectacles do not provide protection and should be worn only briefly (Vinger and Sliney, 1995).

Ozone production. Ozone is a colorless, toxic gas, irritating to the lungs and mucous membranes, having a characteristic pungent odor. It is formed by the photochemical reaction between short wavelength UV radiation and oxygen molecules present in the air. In particular, wavelengths in the range of 185–300 nm (the UV-C and UV-B ranges), and especially with the 254 nm common in germicidal lamps, there is a distinct hazard of O_3 production. The threshold for odor detection ranges from 0.005 to 2 ppm. The TLV-time weighted average (TWA) (2001) for O_3 ranges from 0.05 to 0.1 ppm, depending on the workload (and resultant inhalation rate). Odor detection, therefore, may not provide adequate protection from occupational exposures. Diffey and Hughes provided a way to estimate the concentration of O_3 that may exist in the vicinity of UV-emitting lamps (Diffey and Hughes, 1980).

Welding Filters

Infrared and UV radiation filtration is readily achieved in glass filters with additives such as iron oxide, but the visible attenuation determines the shade number, which is a logarithmic expression of the attenuation (the shade number is equal to $\frac{7}{3}$ the optical density (OD) plus 1). Normally a shade of 3–4 is used for gas welding (goggles), and 10–14 for arc welding and plasma arc operations (helmet protection required). The thumb rule is that if the welder finds the arc comfortable to view, adequate attenuation has been provided against ocular hazards. Supervisors, welders' helpers, and other persons in the work area may require filters with a relatively low shade number (e.g., 3–4) to

protect against welder's photokeratitis ("arc eye") (ANSI, 1994).

The autodarkening filter/helmet has become a popular and effective solution. Regardless of the type of filter, it should meet the ANSI Z87.1 and Z-49.1 standards for fixed welding filters specified for the dark shade (ANSI, 1989, 1994). Considering the total welding process, the welders formerly had to lower and raise the helmet or filter each time an arc was started and quenched. The welder had to work "blind" just before striking the arc. Furthermore, the helmet frequently is lowered and raised with a sharp snap of the neck and head, which can lead to neck strain or more serious injuries. Faced with this uncomfortable and cumbersome procedure, some welders often initiate the arc with a conventional helmet in the raised position—leading to photokeratitis. Under normal ambient lighting conditions, a welder wearing a helmet fitted with an autodarkening filter can see well enough with the eye protection in place to perform tasks such as aligning and fixturing the parts to be welded, precisely positioning the welding equipment and striking the arc (Eriksen, 1985). Then, in the most typical helmet designs, light sensors detect the arc flash and direct an electronic drive unit to switch a liquid crystal filter from a light shade to a preselected dark shade. The aforementioned drawbacks of fixed shade filters are largely eliminated by autodarkening filters, which explain the widespread popularity of these systems.

Lasers

The ANSI Z136.1 standard includes a comprehensive list of requirements for addressing laser safety concerns, including engineering and administrative controls, eyewear requirements, signs, entryway controls, and others. Non-beam hazards should not be ignored—in fact, numerous accidents, some fatal, have occurred in the past from lack of proper controls for these hazards. Non-beam hazards include high voltage and capacitors, laser-generated air contaminants from laser cutting and welding operations, fires, injuries from robotic arms, and others. Rockwell Laser Industries keeps a listing of laser accidents (reported voluntarily) on their website, although it is estimated that only a small percentage of laser injuries are reported (Rockwell Laser Industries, 2014a).

Laser Eye Protectors

The ANSI Z136.1 standard calls for laser eye protection when working with Class 3b or 4 lasers. The objective of laser eye-protective filters is to transmit as much visible light for observing while blocking the laser wavelength or wavelengths of concern. The protective factor used for laser eye wear is called OD. The OD is a logarithmic expression

for attenuation factor, for example, a protection factor of 1000 (10^3) is equivalent to an OD of 3; a protection factor of 1 million (10^6) is equivalent to an OD of 6. The equation for determining OD is as follows:

$$\text{OD} = \log_{10}[\text{Irradiance}/\text{MPE}],$$

where irradiance = maximum power/area(W/cm²)

MPE = maximum permissible exposure(W/cm²)

Because most lasers emit powers or energies on the order of thousands to millions of times the MPE limit, optical densities of 3–6 are most typical. The ANSI standard Z136.1 provides detailed methods for determining the appropriate eye wear (ANSI, 2014). Polycarbonate has superior burn-through characteristics (Sliney et al., 1993) compared with other plastics and is also superior to all other lens materials for industrial impact protection.

MEDICAL MANAGEMENT

Photokeratitis

It is also called welder's flash, flash burn, arc eye, and snow-blindness. Ultraviolet photochemical injury of the cornea, occurring principally from 200 to 315 nm. This is a transient condition that lasts for 1–2 days and usually heals without leaving a scar. Symptoms include mild to severe pain, light sensitivity, blurry vision, eye irritation, bloodshot/watery eyes. Treatment may include dilation, padded dressing (cool) to immobilize the eyelids, and rest. Infection is a possibility and antibiotics may be considered.

Erythema

Ultraviolet photochemical injury of the skin occurring principally from 200 to 315 nm. This is also a transient condition that lasts for 1–2 days. Treatment may include cool wet cloths, lotions using aloe vera, topical steroids (e.g., 1% hydrocortisone cream) for more severe cases.

Laser Eye Injury

Thermal injury to the retina (occurring at 400–1400 nm); the local burn of the retina results in a blind spot (scotoma). Thermal injury of the cornea and conjunctiva (occurring at approximately 1400 nm to 1 mm). This type of injury is almost exclusively limited to laser radiation exposure. A visit to an ophthalmologist should be made immediately after a suspected laser injury.

IONIZING RADIATION

THOMAS A. LEWANDOWSKI, JUHI K. CHANDALIA, AND PETER A. VALBERG

IONIZING RADIATION

Ionizing radiation refers to subatomic particles or electromagnetic waves that have sufficient energy to break apart chemical bonds. Life on earth has always existed in a constant, low level stream of ionizing radiation from the radionuclides (elements emitting ionizing radiation) naturally present in the earth's crust, as well as cosmic rays from the sun and interstellar sources (UNSCEAR, 2000). Life has adapted to these conditions and, in fact, the low level of mutation attributable to these natural sources may have been instrumental in the evolution of life on earth. Modern technology allows for the production and exploitation of differing forms of ionizing radiation and with it, different types and intensities of exposure. This has in turn led to a greater study of exposures and the potential health effects of ionizing radiation.

Types of Ionizing Radiation

The two main forms of ionizing radiation are high energy subatomic particles (e.g., alpha and beta radiation) or high energy electromagnetic waves (gamma rays or X-rays). The energies of both types of radiation are measured in "electron-volts," or eV, where 1 eV corresponds to the energy of an electron accelerated through a potential of 1 V.

Subatomic particles are high energy fragments of atoms such as protons, neutrons, alpha particles, and beta particles (discussed below). High energy subatomic particles may originate from two sources: the decay of radioactive elements or generation by extraterrestrial sources (i.e., cosmic rays¹ and solar flare events). From an occupational standpoint, the

¹ Cosmic "rays" are actually high energy subatomic particles emitted by the sun and other stars. Their description as rays is an historical artifact.

former is of more importance. Radioactive elements are composed of inherently unstable nuclei that undergo decay, shedding energy and/or mass in the form of subatomic particles, in order to reach a stable state. Radioactive elements transform into other elements as they decay, some of which may also be unstable and emit ionizing radiation as part of a decay chain. The chain continues until a stable (i.e., non-radioactive) isotope is reached. Each radioactive isotope decays on a specific timescale called the half-life ($t_{1/2}$)—i.e., the time it takes for half of the existing material to be converted to a daughter product.

An alpha particle (α) is a highly energetic nucleus of a helium atom, ejected from a much larger nucleus during decay. It consists of two positively charged protons and two electrically neutral neutrons and is designated by the symbols ${}^2\text{He}_4^{++}$ or α . Alpha particles are emitted from the nuclei of certain radioactive isotopes (see Table 100.1). When an alpha particle is emitted, the alpha-emitting parent atom is transformed into a daughter isotope with an atomic number decreased by two, and an atomic mass decreased by four. For example, uranium-238 (${}^{238}\text{U}$, atomic number 92) is transformed by alpha emission to thorium-234 (${}^{234}\text{Th}$, atomic number 90).

A beta particle (β) is either an electron or a positron that is ejected from the nucleus in the process of nuclear decay. The β -particle is typically an electron formed by the decay of a neutron (yielding both an electron and proton). A beta particle can also be a positron (a positively charged electron), but the lifetime of the positron (which is essentially an "antielectron") is very short. Beta particles have very low mass (i.e., 1836 times less than the mass of a proton). Emission of a beta particle results in the transformation of the beta-emitting parent atom into a daughter, the atomic number of which is one greater (due to the gaining of one

TABLE 100.1 Examples of Isotopes That Undergo Alpha Decay

Isotope	Daughter	Half-life

²¹⁰ Po	²⁰⁶ Pb	138 days
²²² Rn	²¹⁸ Po	3.8 days

proton); the atomic mass remains unchanged (because a neutron and proton have nearly identical mass). For example, ⁹⁰Sr decays *via* beta particle emission to ⁹⁰Y, which has an atomic number one greater but the same atomic mass (see Table 100.2). Beta particles emitted by radioisotopes exhibit a range of energies that extends from near zero to a maximum, which is characteristic of that radioisotope. These maximum energies extend from several kiloelectron volts (keV) to several megaelectron volts (MeV).

A more unusual form of particulate radiation involves free neutrons. Having no net charge, these particles do not interact electromagnetically with atoms but, upon collision with an atom, may cause the atom to become ionized. Gamma radiation (see below) is typically produced by this interactive process. Other types of particle decay (e.g., electron capture, neutrino emission) are also possible but less common.

The other main class of ionizing radiation consists of high energy electromagnetic waves. Although the electromagnetic spectrum includes radio waves, microwaves, visible light, and ultraviolet (UV) rays, only the most energetic portion of the electromagnetic spectrum, X-rays, and gamma rays (γ), have the ability to ionize matter (i.e., adversely affect atomic structure). Some ambiguity exists concerning the distinction between gamma rays and X-rays. Historically, they were differentiated by the way in which they were produced (i.e., from decay of radioactive elements [γ -rays] *versus* the bombarding of targets with accelerated electrons [X-rays]), but this distinction has fallen out of use under current technologies and

the terms are used interchangeably (UNSCEAR, 2000). As with subatomic particles, the energy of the X-rays and gamma rays is quantified by eV. The “soft X-ray” spectrum ranges from electromagnetic waves with energies of 120 eV (0.12 keV) to 12 keV; the “hard X-ray” spectrum ranges from 12 to 120 keV.

Historical Background

In 1895, Wilhelm Röntgen discovered the phenomenon of penetrating radiation when high voltages were applied across electrodes contained in evacuated glass containers (Crookes tubes). Even when a Crookes tube was enclosed in a black box, the rays produced could penetrate the box and cause fluorescence of certain materials external to the box. Röntgen also found that photographic plates located outside the box became exposed and displayed images influenced by intervening objects (e.g., his wife’s hand) (Röntgen, 1896). He named the radiation associated with these effects “X-rays.” Röntgen was awarded the 1901 Nobel Prize in physics for his discovery. In the following year, Henri Becquerel reported that a similar phenomenon was associated with uranium ore. During the same period, Pierre and Marie Curie were investigating the properties of two new highly radioactive elements, polonium and radium, which they had painstakingly separated from a uranium ore (pitchblende). Becquerel and the Curies shared the 1903 Nobel Prize in physics for their work. In 1899 and 1900, scientists Ernest Rutherford and Paul Villard developed the nomenclature of alpha, beta, and gamma radiation based on the degree to which each penetrated various barriers (although they lacked a full understanding of the exact nature of each type of radiation).

In 1905, Einstein postulated the photon model of electromagnetic radiation. According to this model, electromagnetic radiation behaves as if it consists of particles of energy called photons, which travel at the speed of light. Each particle contains a discrete quantity, or “quantum,” of electromagnetic energy. The energy content of the photon (E) is proportional to the frequency of the radiation (ν), as described by $E = h\nu$, where h is called Planck’s constant ($6.62606957 \times 10^{-34} \text{ m}^2 \text{ kg/s}$). Concordant with the theory of electromagnetism, a general atomic theory was developed initially by Neils Bohr and completed by Erwin Schrödinger. Together, these two fundamental theories explain much of the phenomenon of ionizing radiation.

Concurrent with scientific discoveries of the properties of ionizing radiation and radioactive elements was the technologic exploitation of ionizing radiation. In medicine, the first cure of a cancer (a basal cell carcinoma) with X-rays was accomplished in 1899 (Williams, 1903). X-rays were widely used to treat various diseases (psoriasis, tuberculosis) and in imaging, including the imaging of developing fetuses (Williams, 1903). In addition, the first self-sustaining, nuclear-fission reactor was developed in 1942 by Enrico Fermi and Leo Szilard. This advance led to the Manhattan

Project and development of the atomic bomb, with the first detonation in 1945 during World War II. After the war, both military and peaceful uses of ionizing radiation continued.

After World War II, with the recognition of radiation-induced mortality and morbidity among bomb survivors, guidelines for exposure to radiation were put in place (although the levels of exposure tolerated by these guidelines were substantially higher than those considered acceptable today). Over succeeding decades, observations were made of occupationally exposed people, including scientists, medical personnel, radium dial painters, uranium miners, industrial radiographers, and nuclear energy workers. Coincident with the expansion of knowledge about the biological effects of radiation was the development of sensitive instruments that enabled accurate measurement of radiation levels as well as levels of exposures to individuals. Due to the extensive data collected on exposure and health effects of radiation, the risks of radiation exposure are better understood than those associated with most other environmental agents.

ASSESSING EXPOSURE TO IONIZING RADIATION

Dosimetry and Units

There are several ways to assess exposure to ionizing radiation. One important distinction is the difference between radioactive decay rate (or flux of decay products) *versus* tissue dose. Measures of radioactive decay can be measured as “counts per minute” (cpm) or number of radioactive events (alpha particle emissions, X-ray photons, etc.) per unit time. A small amount of a highly radioactive material could have the same radioactive decay rate as a large amount of a slightly radioactive material. Measurement units of radioactivity decay events per unit of time include curies (Ci) and becquerels (Bq). One Bq is equal to one disintegration per second, and one Ci is equal to 3.7×10^{10} disintegrations per second.²

Measures of radioactive decay rates are of limited relevance to evaluating potential effects on human health because they pertain only to the quantity—and not the form—of the radiation involved. To characterize the effect of ionizing radiation on tissues, a number of different measures are used: the absorbed dose, equivalent dose, effective dose, and committed dose. Each of these terms is described below.

The *absorbed dose* has units of absorbed energy per unit mass and can be calculated from the rate of radioactive emission, the specific properties of the material through which the radiation moves, and various geometric and conversion factors. Absorbed

² Another unit occasionally seen, the roentgen (R) can only be used to quantify the amount energy deposition from gamma and X-rays, and only in air. One R is equal to depositing in a kilogram of dry air enough energy to cause 0.000258 coulombs of electric charge. It is a measure of the number of ionized molecules in a mass of air.

dose can therefore account for the different penetrating properties of alpha-, beta-, and X-ray radiation in air, water, or biological tissue. Because it does not take into account potential tissue damage, the absorbed dose is not usually used as an indicator of long-term health risk in humans; however, it is often used to gauge the risk of acute radiation syndrome (ARS) (See below), which involves high level and acute exposures. The two main metrics for absorbed dose are the gray (Gy) and the rad. The Gy is the Système Internationale d’unités (SI) unit for absorbed dose and thus used increasingly relative to the more historical rad; 100 rads are equal to 1 Gy (NCRP, 1993).

The *equivalent dose* is based on absorbed dose, but is more closely related to biological and health effects of radiation than absorbed dose. It is important to realize that both absorbed and equivalent dose nominally measure the same quantity of energy deposited per mass (joules per kilogram). The equivalent dose differs from the absorbed dose in that it accounts for the relative biological effectiveness of the type of radiation to cause tissue damage (e.g., α -particles *versus* X-rays). Thus, the equivalent dose uses different units of measurement: the Sievert (Sv) and the rem (roentgen equivalent man). The Sv is the SI unit and is increasingly displacing the rem in most applications. To convert an absorbed dose to an equivalent dose, one needs to know the type of radiation involved and apply the appropriate radiation weighting factor (W_R , previously called the quality factor), which is a measure of linear energy transfer (LET) of different types of radiation. The LET is an indication of the potential of a given form of radiation to interact with matter as it passes through it. For example, for alpha particles, $W_R = 20$; for X-rays, $W_R = 1$. A summary of radiation weighting factors is provided in Table 100.3.

The *effective dose* is yet another dose metric that may be encountered and is used to account for the relative susceptibility of specific tissues to radiation-induced damage. To obtain an effective dose from the equivalent dose, tissue weighting factors are applied. These factors have been

TABLE 100.3 Radiation Weighting Factors

Radiation Weighting Factor	W_R

Body as a whole	1.0	1.0

officially tabulated by organizations such as the National Council on Radiation Protection (NCRP), International Commission on Radiological Protection (ICRP), and U.S. Nuclear Regulatory Commission (NRC) and are given in Table 100.4. Like the equivalent dose, the effective dose is expressed in either Sv or rem.

Finally, the term *committed dose* is used for cases where radionuclides are internalized by ingestion or inhalation and reflects the cumulative or chronic dose that will be received as the radionuclides decay over a period of 50 years. Thus, the committed dose encompasses the amount and activity of the internalized material as well as time the material remains within the body before being eliminated. The concept of committed dose is particularly important for bone-seeking radionuclides (e.g., calcium, strontium, radium, and plutonium) that undergo very slow turnover in the body.

Types of Exposure to Ionizing Radiation

People are exposed to both naturally occurring and anthropogenic ionizing radiation. Naturally occurring sources include cosmic rays and radioactive isotopes found everywhere (e.g., tritium, carbon-14, potassium-40, radium-226, radon-222). Examples of anthropogenic sources of radiation include medical devices such as X-ray machines, nuclear medicine, atomic-bomb fallout, and activities that generate radioactive waste.

Natural Sources Cosmic radiation, which consists of highly energetic subatomic particles, is a large ubiquitous source of naturally occurring ionizing radiation. Radiation from the sun, or solar radiation, is one source of cosmic radiation (ATSDR, 1999). Cosmic radiation creates additional ionizing radiation

(cosmogenic nuclides) when highly energetic cosmic particles collide with stable elements in the earth's atmosphere and on its surface. This is the mechanism of formation of ^{14}C and tritium (^3H), which can be incorporated into living matter as they cycle through the earth's ecosystem.

Primordial radionuclides are those that originate independent of cosmic rays and are primarily found in rocks and soil (NCRP, 1987a). Terrestrially derived radionuclides are also present in all organic matter, including food (Harley, 2008; NCRP, 1987a; Voelz, 1994) and the human body (NCRP, 1987a). For example, radioactive potassium (^{40}K) comprises about 0.012% of all terrestrial potassium, is found naturally in food, comprises the largest source of effective dose from the diet, and delivers a bone dose of approximately 0.15 mSv per year (Harley, 2008). When accounting for all radionuclides incorporated into the body tissues, as well as radionuclides in the diet that transit through the gastrointestinal (GI) tract without being absorbed/incorporated, the estimated effective dose is approximately 0.40 mSv per year (Harley, 2008).

One of the most significant sources of exposure to naturally occurring radionuclides involves inhalation of radon, a naturally occurring radioactive gas produced by the decay of uranium and thorium in soil and rock (NCRP, 1987a). The effective dose of radionuclide-containing atmospheric aerosols and gas-phase radionuclides (primarily due to radon) is estimated to be 2 mSv per year (Harley, 2000; Harley, 2008). Radon exposure varies depending on geography (e.g., radon exposures in California tend to be lower than those in the Midwest due to different soil composition; ATSDR, 1999) and housing type (e.g., radon exposure is typically lower in a house or apartment with no basement than in a house with a below-ground basement; NCRP, 1987a).

Anthropogenic Sources In 1987, the NCRP estimated that approximately 19% of all ionizing radiation exposures were due to medical devices, consumer products, and other man-made sources (NCRP, 1987b), but as noted above, present day radiation exposures to the population are about half from natural sources and half from medical procedures.

X-rays, in particular dental X-rays, are a common source of exposure to ionizing radiation. A patient's effective dose from dental X-rays can range from 0.005 to 0.39 mSv, depending on the type of X-ray and the film speed (Ludlow et al., 2008). Airline travel is another source of exposure to ionizing radiation. On average, airline passengers receive an effective dose of 0.005 mSv per year from air travel (Wallace and Sondhaus 1978). Although the use of back-scatter X-ray security scanners at airports has led to some public concerns, the typical dose associated with a normal 8-s scan is 0.03 microSv (0.00003 mSv); thus, even for frequent travelers, the cumulative dose will be well below typical background exposure levels (NCRP, 2003). People who smoke tobacco or regularly encounter secondhand smoke

can be exposed to increased levels of ionizing radiation from naturally occurring radionuclides present in tobacco; the average annual effective dose has been estimated at 0.25 mSv/year (Papastefanou, 2009). In addition, there are minor exposures related to nuclear applications and consumer products containing radioisotopes (e.g., televisions, tobacco products, smoke detectors, electric thermostats, and building materials) (CIWMB, 2005). Ionizing radiation from nuclear sources, such as residual atmospheric radiation from nuclear weapons testing, was a more significant source of exposure in the past than it is today (Ropeik and Gray, 2002). Current exposure to ionizing radiation from nuclear sources is very small, comprising an effective dose of less than 0.01 mSv per year (ATSDR, 1999; Ropeik and Gray, 2002). The 1986 nuclear accident at Chernobyl in the Ukraine resulted in a very slight increase in worldwide radiation exposures (estimated at an additional 21 days of world exposure to natural background radiation levels), although, on a regional level, exposures were substantially more (i.e., the estimated dose commitment was 1.2 mSv or 1/30th of a typical average lifetime dose) (Gonzales, 1996). The nuclear incident in Fukushima, Japan, is not expected to contribute appreciably to global radiation exposure levels (being less than 0.01 mSv) (WHO, 2012).

Overall, the typical cumulative dose for the United States population from all sources of ionizing radiation is approximately 6.2 mSv per year, with about half of this coming from natural sources and half from anthropogenic sources.³

Notable Sources of Occupational Exposure Exposure to ionizing radiation can occur in many different occupational settings and involve both natural and anthropogenic sources. Fields with widely recognized potential for ionizing radiation exposure include dentistry, medicine, nuclear power production, and the defense industry (in terms of nuclear weapons production). Other, less well-recognized fields include commercial aviation, academic research, veterinary care, construction, and mining. Table 100.5 summarizes the annual average exposure levels associated with various industries. As shown in this table, the typical annual exposure for nearly all occupations is less than the annual background radiation exposure due to nonoccupational sources (6.2 mSv).

HEALTH EFFECTS OF IONIZING RADIATION

Interactions Between Ionizing Radiation and Matter

Subatomic particles generally interact with atoms by transferring kinetic energy to the atom. The physical mechanisms by which charged, high speed particles such as alpha and beta

TABLE 100.5 Examples of Occupations Involving Exposures to Ionizing Radiation

Occupation	Average Annual Effective Dose, mSv
Uranium mining	4.5
Nuclear fuel production	1.0
Nuclear power generation (reactor personnel)	1.4
Medical radiology (e.g., X-ray technicians)	0.5
Dentistry (X-rays)	0.06
Heart catheterization laboratories (X-rays) ^a	4.8
Well logging (radioisotopes)	0.4
Coal mining (radon)	0.7
Metal mining (radioisotopes, including radon)	2.7
Space travel to the international space station (cosmic rays) ^b	4.1
Commercial aviation (cosmic rays)	3.0
Multiple indoor occupations (radon)	4.8
Backscatter X-ray security scanner operator ^c	"Indistinguishable from background"

radiation transfer their kinetic energy to matter are relatively well understood. The most likely occurrence is a collision between the charged particle and one of the orbital electrons. When the orbital electron is struck with sufficient force, it is ejected from the atom, and the atom is ionized. In air and soft tissue, alpha and beta particles lose about 35 eV of energy per ion pair produced.⁴

Because an alpha particle has a large mass and a double charge, it has a high rate of ionizing collisions and, consequently, a high rate of energy loss. The high rate of collision and energy loss explains the very low penetration of alpha radiation into matter (ANSI, 1983). As a result, it is fairly easy to protect tissue from external alpha radiation; a sheet of paper may be sufficient. However, alpha particles emitted adjacent to cells within the human body (e.g., after being ingested or injected) may be highly damaging; in this case, they deposit most of their energy in the cells and tissues lying within a millimeter or so of the emitting radionuclide.

Beta particles travel near the speed of light and have only a single charge. The depth of penetration increases as the energy of the radiation increases. In air, very low energy beta particles have a range of several centimeters, whereas high energy beta particles may travel up to several meters in

⁴ An ion pair refers to the positively and negatively charged particles (ions) that are produced when an electrically neutral atom is ionized by a source of external energy.

³ <http://www.nrc.gov/images/about-nrc/radiation/factoid2-lrg.gif>.

air. Being smaller in size and less massive than an alpha particle, they transfer relatively less energy per target encountered. This difference in rate of energy loss by beta radiation results in a lower relative biological effectiveness of the energy transferred to viable tissue, and it accounts for the higher penetrating power of beta radiation over that of alpha radiation. Beta particles can generally be stopped by thin barriers of low density materials such as aluminum, glass, or plastics such as polymethyl methacrylate (PlexiglasTM).

For very high energy beta particles, the production of X-rays when a charged particle undergoes a sudden change in velocity is an important source of ionizing radiation. This phenomenon, called *bremsstrahlung* (from the German meaning “braking radiation”), occurs when a beta particle collides with an atomic nucleus. There is an abrupt change in the particle’s velocity and some of the particle’s kinetic energy is converted into X-rays. This X-ray production is extremely small for low energy beta particles and low atomic-numbered target atoms, but it increases with increasing beta energy and atomic number for the target. For this reason, X-rays are associated with high energy electron beams hitting targets, as in electron microscopes, and some high energy beta-ray emitters, such as ⁶⁰Co.

X-rays are very penetrating compared to subatomic particles; they pass through matter fairly easily and can travel long distances in air. X-rays interact with absorbing media by several different competing mechanisms, depending on the photon energy and atomic number of the target. Two of these mechanisms, photoionizing electric absorption and Compton scattering, involve an interaction between an orbital electron and the photon that results in the ejection of the electron. For photons in which energy exceeds 1.02 MeV, a third mechanism, involving interaction with the target nucleus, results in the transformation of the photon’s energy into two particles: a negatively charged electron and a positively charged electron (positron). In each of these types of interactions, high speed electrons are produced. These energetic electrons, which are called primary ionizing particles, then transfer their energy by ionizing collisions with the orbital electrons of nearby atoms.

Effects at the Cellular Level

There are two primary ways that ionizing radiation may interact with biological structures, produce damage, and lead to adverse health outcomes. Direct interactions involve the transfer of energy from the radiation directly to the target tissue, producing ionization or breakage of chemical bonds, which in turn can result in a loss of molecular structure and function. For example, radiation may ionize lipids in the cell membrane or the membranes of organelles, leading to a loss of membrane function (Giusti et al., 1998). Radiation may also damage cells via indirect interactions. This involves ionization of an intermediate chemical (e.g., a water or oxygen molecule),

yielding a highly reactive by-product that can then interact with critical cellular components and produce damage. Because water comprises the largest component of cells, most of the indirect effects of radiation involve the generation of hydrogen and hydroxyl radicals (H^{\cdot} and OH^{\cdot}). Hydroxyl radicals may also combine to form hydrogen peroxide, H_2O_2 , a more long-lived oxidant that can also produce cellular damage (ATSDR, 1999). Finally, the degree of oxygenation of a tissue is correlated with susceptibility to radiation damage due to the generation of oxygen radicals (e.g., superoxide O_2^-). Thus, one of the treatments for individuals with high levels of radiation exposure is to administer chemicals that depress tissue levels of oxygen (ATSDR, 1999).

Both types of damage can be prevented or repaired at the cellular level. Because humans as a species have always had to contend with the threats of oxidative damage, various compensatory mechanisms exist. There are scavenger molecules (e.g., glutathione, tocopherol) that bind to free radicals and prevent them from damaging critical cell components, as well as various enzymes designed to break down oxidizing chemicals or repair the damage they cause (e.g., the enzyme catalase inactivates hydrogen peroxide, various glutathione reductases regenerate the antioxidant glutathione, and various enzymes are involved in repair of damaged DNA). Thus, it is only when damage occurs and is not repaired (either not repaired in time for critical cellular action or not repaired at all because the compensatory mechanisms are overwhelmed) that radiation exposure can lead to toxicity.

As noted previously, the degree of cell damage caused by radiation exposure depends on a number of factors: the energy of the radiation, form of the radiation (in terms of the LET), and sensitivity of the tissue involved. Radiation with a higher LET will produce more intense damage over a limited area than radiation with a lower LET, where the damage pattern may be more diffused (ICRP, 2007). The former case may pose a greater health risk if, on the local level, compensatory mechanisms become overwhelmed. At the lowest levels of exposure, single molecules may become ionized, leading to negligible effects on cell viability. As the level of damage increases, however, cell function will become increasingly compromised. In the case of the cell nucleus, sufficient damage to cellular DNA may trigger apoptosis or cell death.

Effects at the Tissue and Organism Level

Cells are most susceptible to the effects of radiation while undergoing division (Mettler and Moseley, 1985). Cell division involves a tightly coordinated series of events, many of which are susceptible to disruption by radiation or chemical insults. As a result, tissues composed of many rapidly dividing cells (e.g., skin, intestinal epithelium, bone marrow, and gonads) are more susceptible to radiation damage than tissues where cells divide very slowly or not at all. These tissues will show the greatest and earliest damage from

substantial radiation exposures (ATSDR, 1999). Damage to tissues with nondividing cells (e.g., the central nervous system, CNS) may also be significant, as there is no ability for the damaged cells to be replaced.

Cancer and Noncancer Effects Radiation toxicology has generally made a distinction between the noncancer and cancer health effects of radiation exposure. The reason is twofold. First, most noncancer effects of radiation exposure tend to occur over the short term, whereas cancer is likely to manifest itself only after a latency period of at least several years and generally several decades. In addition, the way that scientists conceive of the damage done to the cell is different in each case. Noncancer effects occur only when the damage from radiation exposure is large enough to overwhelm the cell's compensatory capacity, producing cell death and/or loss of cell function at such a scale that effects become apparent at the tissue level. Thus, a substantial number of "hits" are required to produce readily apparent symptoms. This obviously requires substantial exposures. In contrast, radiation-induced cancer (or heritable mutations) may only require a single "hit" if that particular lesion occurs in a critical part of the cell's DNA and the damage is not repaired before the cell divides. The initiation of the carcinogenic/mutagenic process, therefore, involves an aspect of probability (the likelihood that damage occurs at the necessary target and is not repaired in time), and it is feasible—although highly unlikely—that a single radiation "hit" may lead to tumor formation. Because there is an element of randomness in their occurrence, these types of effects are said to be stochastic events, whereas noncancer, non-mutagenic effects are said to be deterministic (the same level of exposure will always produce the same effect). Because they are associated with a threshold, the latter effects are only seen at higher levels of exposure.

General Noncancer Effects Acute, high level exposures to external radiation (several Gy or more) are associated with ARS, a constellation of serious symptoms that at higher

exposures can include death. The time and severity of symptom onset after exposure are determined by the dose. Symptoms primarily involve cells within rapidly dividing tissues such as the skin, hair, GI tract, bone marrow, and immune system (ATSDR, 1999). Very high acute exposures (around 10 Gy) may also result in CNS symptoms (Baum et al., 1984; ATSDR, 1999). Destruction of stem cells in the bone marrow leads to a sequential depletion of different blood cell types, with white cells (critical for immune response) depleted first and platelets (associated with clotting), appearing depleted several days later. Decreased production of red cells (erythrocytes) is generally not observed as a sign of acute radiation exposure due to the long life span of the existing red cell population (100–120 days). Monitoring of peripheral blood for differential cell counts is, therefore, one of the best indicators of radiation-induced damage. At somewhat higher doses, the rapidly dividing stem cells in the intestinal villi (responsible for producing the lining cells of the intestines) are also affected, leading to sloughing off of the intestinal epithelium and the loss of its absorptive and barrier functions. This in turn produces nausea, vomiting, diarrhea, hemorrhage, septicemia (due to gut bacteria entering the intestinal blood supply) and dehydration. The GI-related symptoms typically appear several days after the initial signs seen in the blood, although the latent period may be decreased at high levels of exposure (ATSDR, 1999). In terms of cutaneous effects, an acute dermal dose of about 2 Gy leads to an initial redness (erythema) of the skin; acute doses of 3 Gy or more may produce epilation (hair loss) (IAEA, 2013; CDC, 2005). Complete recovery of skin function is possible but may take several months and will confer a long-term increased risk of skin cancer (CDC, 2005). Dermal exposures in excess of 15 Gy will pose a greater challenge for recovery and may produce persistent or recurrent ulceration and tissue necrosis (CDC, 2005). The severity of symptoms and progress of deterioration is dose dependent (Table 100.6). If damage is not too severe and some stem cells are spared, survival is possible. Treatment is generally supportive and directed

TABLE 100.6 Acute Health Effects of Radiation Exposure

Dose Range, Gy	Effects	Survival Potential
0.15–0.5	Isolated chromosome breaks, possible slight changes in blood cell profiles in sensitive individuals	Certain
0.5–1 Gy	Mild changes in blood cell profiles	Virtually certain
5 Gy	Severe bone marrow damage, substantial intestinal damage, risk of infection	Without treatment, a substantial risk of dying within several weeks. With treatment, a fair chance of recovery
8–30 Gy	Severe GI damage, loss of GI stem cells, incapacitation, damage to major organs beyond GI tract and bone marrow	Minimal chances of survival, limited treatment other than palliative care
30 Gy and above	Massive and acute damage to CNS and all other tissues, rapid collapse and loss of autonomic functions	Death within several hours, if not sooner

Source: Modified from Baum et al., 1984, and updated based on ATSDR, 1999, and UNSCEAR, 2006.

toward the immune and GI symptoms. Individuals who die from ARS typically do so as a result of infection (due to the damaged immune system), dehydration, and blood loss (both due to the damage to the GI tract). At very high doses (10–30 Gy and above), the CNS may also be specifically affected, leading to rapid unconsciousness, loss of autonomic function, and rapid death (UNSCEAR, 1988; NCRP, 1980). Acute radiation syndrome is very rarely encountered and is seen in situations such as nuclear power plant disasters (e.g., Chernobyl) or accidental and unknowing exposures to high energy radioactive sources (e.g., in cases where X-ray sources were improperly disposed of and unknowingly used by the public) (Champlin et al., 1988).

Lower levels of acute radiation exposure (approximately 1 Gy) may lead to transient immune system depression (changes in blood cell counts) (UNSCEAR, 2006). Below 0.5 Gy, the primary concern involves chromosomal damage and its potential to produce cancer or birth defects. For example, Mettler and Moseley (1985) reported that the threshold for single-strand DNA breakage under acute exposure was 0.1 Gy. Chronic, low level exposure to ionizing radiation may also produce skin lesions and cataracts (a clouding of the lens of the eye). A cumulative ionizing radiation dose of approximately 0.5 Gy is considered to be the threshold for cataract formation (ICRP, 2011).

The foregoing discussion is relevant for external radiation doses. For exposures to radionuclides *via* ingestion, inhalation, or injection, the effects will depend in part on the ability of the material to move within the body (based on its form and chemical properties), its propensity to accumulate within particular tissues (e.g., radon decay products in the lungs, iodine accumulation in the thyroid, strontium, and radium accumulation in bone) and its LET. A significant issue with internally deposited radionuclides is that exposure continues even when the individual moves away from the actual source of the material (the concept behind the notion of committed dose). Individuals with substantial internal exposures to radionuclides require long-term monitoring to assess changes in body burden and cumulative radiological dose.

Reproductive and Developmental Effects Radiation exposure poses particular risks for both reproduction and development *in utero*. For example, as with other tissues with rapidly dividing cells, the testes are sensitive to the effects of ionizing radiation. Reduced sperm counts or sperm abnormalities have been observed with external radiation doses as low as 1 Gy (Birioukov et al., 1993), and “temporary sterility” has been associated with doses as low as 0.15 Sv (Upton, 2005). At these lower exposure levels, sperm production can rebound to normal levels after cessation of exposure; however, permanent sterility (due to the death of spermatogonial stem cells) can result from doses to the testes in excess of about 6 Gy (Adams and Wilson, 1993). The ovaries do not undergo the same degree of rapid cell division as is

observed in the testes. However, because half of the DNA in all of the future child’s cells is attributable to the maternal contribution, damage to the DNA contained in the egg still represents a substantially more significant event than damage to a single cell elsewhere in the body. Temporary impaired fertility in women may be seen after a dose to the ovaries of 1.5–2.0 Sv (Upton, 2005). Permanent sterility may occur with acute ovarian doses in the range of 2.5–6 Sv (Upton, 1991).

Because it is undergoing rapid growth, cell division, and cell differentiation, the developing embryo and fetus is also susceptible to radiation damage (CDC, 2011). Timing of exposure is critical; early exposures (when the population of cells that will go on to form the adult is limited) may have more significant consequences than those later in pregnancy (ATSDR, 1999). The form of radiation is also an important consideration; external alpha and beta radiation would be unable to reach the developing child, but X-ray radiation or exposure to internalized radionuclides could be of concern. Small doses of external radiation (0.05 Gy, equivalent to several full-body positron emission tomography scans) at any time during pregnancy are not believed to result in an increased risk of birth defects (McCollough et al., 2007). Much larger doses, if experienced between weeks 2 and 18 of pregnancy (the most sensitive period) can result in birth defects. For example, children exposed *in utero* during the atomic bombs dropped on Hiroshima and Nagasaki were found to have a high rate of brain damage, which resulted in lower IQs and even severe mental retardation. They also suffered an increased risk of other birth defects (NRC, 1990). The no observable effect level for these individuals was reported to be 0.2–0.4 Gy (NRC, 1990). After about week 18 of pregnancy, the fetus is much more resistant to the effects of ionizing radiation and only large doses (3 Gy or more, a dose producing acute radiation sickness in the mother) will result in birth defects seen at 0.3 Gy earlier on (CDC, 2011). In addition to birth defects, exposure to radiation *in utero* may result in a higher chance of developing cancer later in life. Thus, the nuclear accident at Chernobyl (which released large amounts of radioactive iodine) is now believed to have produced an increased incidence of thyroid cancers in persons exposed *in utero* (Bromet et al., 2009; Hatch et al., 2009). However, the increased risk of cancer from *in utero* exposure is believed to be small, except at exceptionally high doses. For example, it is estimated that the probability of developing childhood cancer from *in utero* external radiation exposure is less than 1% at doses of 0.1 Gy and less than 0.1% at 0.025 Gy (McCollough et al., 2007). Note that the exposure to the fetus from a single mammography X-ray is approximately 0.001 Gy (Behrman et al., 2007).

Radiation and Cancer For most cases, the primary concern regarding exposure to radiation is its potential to cause cancer. The carcinogenic potential of radiation exposure is

in fact likely to be the greatest concern of workers who are involved with technologies with a potential for radiation exposure.

There are three major dose-response models that are used to predict biological damage that may result from exposure to ionizing radiation. The “linear no-threshold” (LNT) theory postulates a linear relationship between a response, such as cellular damage, and any concomitant increase in the dose of ionizing radiation (NRC, 2006). Under this LNT theory, any exposure to radiation is presumed to cause biological harm. An alternative model, the “threshold” model, is that disease (e.g., cancer) occurs only above a defined dose or “threshold” of ionizing radiation exposure (Cohen, 2008; Calabrese, 2012). A third dose-response model is the hormetic response (Calabrese and Baldwin, 2000). This “radiation hormesis” model is characterized as a “U-shaped” dose response (or inverted U for some response measures) that shows an opposite response at low *versus* high doses. In terms of radiation risk, this usually means that while high doses are damaging (similar to the previous two models), low level exposures may actually be more beneficial than zero exposure. Currently, both the NRC and U.S. Environmental Protection Agency (EPA) have, as a matter of policy, adopted the linear dose-response model for assessing radiation dose (NRC) and radiation risk (U.S. EPA). The NRC, however, recognizes “practical” thresholds for a safe dose that are incorporated in their exposure guidelines.

The carcinogenic properties of radiation are somewhat unique in that estimates regarding the potency of radiation to produce cancer are largely derived from studies conducted in human populations. This is quite different from cancer assessments of most chemical agents, where estimates of the carcinogenic potency have to be inferred from studies conducted in laboratory animals. The key studies that have allowed for a greater understanding of radiation-induced cancer include those of the following populations (Harley, 2008):

- *Miners with radon exposure.* Several cohorts of miners (e.g., uranium miners in Bohemia) have experienced chronic exposures to radon gas released as a by-product of the decay of naturally occurring radium found in uranium-containing ores. Comprehensive analyses and modeling of the data collected in these cohorts (e.g., NIH, 1994; NRC, 1998) have shown a statistically increased risk of lung cancer relative to control populations.
- *Radium dial painters.* In the early part of the twentieth century, female workers at the United States Radium factory in New Jersey applied radium-containing paints to watch dials and other electronic equipment to create fluorescent indicators. In order to obtain fine brush marks, the workers would use their tongue to create a

fine brush point and consequently ingested considerable quantities of radium over the course of their careers. Some individuals ingested as much as several thousand Ci of radium. Consistent with the bone-seeking nature of radium, these workers developed osteogenic sarcoma, as well as symptoms of acute radiation poisoning (Rowland et al., 1978).

- *Survivors of the atomic bombs dropped on Hiroshima and Nagasaki, Japan.* Large cohorts of atomic bomb survivors were enrolled in monitoring programs beginning in the 1950s that collected cancer and other health statistics over time. Considerable modeling has been done to estimate the exposures of these individuals based on their location during the bombing. Whole-body doses varied with distance from the bomb epicenter, but a substantial number of individuals who survived the acute effects of the exposure and were enrolled in the study had experienced doses as high as 0.24 Gy. Increased risks for various types of cancer have been observed, including those of the lung, breast, thyroid, and lymphatic system (RERF, 1987; Pierce and Preston, 1993).
- *Ankylosing spondylitis patients treated with X-rays.* In the middle part of the last century, individuals with ankylosing spondylitis (a painful inflammation of the spinal joints) were treated with ^{224}Ra , which was able to relieve the debilitating pain. The average dose received during a single treatment has been estimated to be 2.6 Gy (NRC, 2006). Studies of this cohort have indicated increased risks of leukemia and lung and other solid tumors (Darby et al., 1987).
- *Children treated with radiation for ringworm.* Between 1905 and 1960, approximately 200,000 children worldwide were treated with radiation to induce hair loss and facilitate treatment for ringworm (*Tinea capitis*). The use of standard treatment protocols has allowed for derivation of reasonably good estimates of radiation exposure. Studies have included a group of 11,000 children treated in New York (Shore, 1990). Exposures to the scalp in this cohort were in the range of 0.2–0.5 Gy; doses to the thyroid were in the range of 0.06 Gy. Increased incidences of skin and thyroid cancers have been reported in these studies.

Because radiation-induced cancer cannot be distinguished from cancer arising from other causes, it is impossible to say with certainty that cancer observed in a specific individual enrolled in these studies was due to radiation exposure. One can only compare the incidence of cancer in the exposed group to that in a suitable control population to examine the possible excess risk. For example, analysis of cancer data by the Radiation Effects Research Foundation (RERF) on the survivors of the atomic bomb found no increased probability of dying from leukemia for individuals whose radiation dose did

not exceed 0.1 Gy (ATSDR, 1999). Among the various types of cancer, some leukemia subtypes are most commonly associated with elevated exposures to ionizing radiation (IARC, 2000). Other cancers commonly associated with elevated doses of ionizing radiation include cancers of the thyroid, breast, lung, and pleural tissues (IARC, 2000; Ron, 1998).

In addition to the large cohorts involving historical high level exposures, a number of studies have been conducted with occupational cohorts with lower level exposures to ionizing radiation. For example, some studies of radiology technicians have suggested an increased risk of developing leukemia for technicians with cumulative whole-body doses of ionizing radiation in the range of 470 mSv (Yoshinaga et al., 1999). Individuals with lower levels of cumulative exposure, in the range of 132 mSv (primarily those who entered the workforce after the 1950s), did not evidence an increased risk of leukemia (Yoshinaga et al., 1999). Similar conclusions were drawn from an in-depth review of the epidemiology literature concerning cancer risks in medical radiation workers by Linet et al. (2010). A study of Canadian dental workers (dentists, dental assistants, and hygienists) indicated no increased risks for any cancer except skin melanoma, where the increase was modest [standardized incidence ratio (SIR) = 1.46, 90% confidence interval (CI): 1.14–1.85] (Zielinski et al., 2005). The cohort in this study included nearly 200,000 workers whose employment spanned 1951–1987. The authors noted that average annual radiation exposures in this group peaked in 1963 (at approximately 1.1 mSv per year) and declined dramatically to less than 0.1 mSv per year in 1970–1987 (Zielinski et al., 2005).

Concerns have been raised about exposures of interventional cardiologists exposed to radiation scatter while conducting cardiac catheterizations, specifically increased risks for cataracts and brain cancer (Kuon et al., 2003). The available information, however, is limited to isolated case reports, so no definitive conclusions can be drawn regarding these possible risks; cardiologists are urged to employ appropriate protection to address these concerns (Kuon et al., 2003). Studies have also investigated the effects of ionizing radiation on cohorts of pilots and/or cockpit crew members, who experience increased levels of naturally occurring radiation while flying at high altitudes. For example, Band et al. (1996) reported an increase in one type of leukemia (acute myelogenous leukemia) in a cohort of 2680 Canadian pilots (SIR = 4.72; 90% CI: 2.05–9.31) who had been employed as pilots more than 20 years and experienced estimated mean annual radiation exposures of 6 mSv. However, a review of multiple studies has concluded that the data supporting an increased risk of cancer among commercial airline personnel are equivocal and suggestive of, at most, a very low level of increased risk (Bagshaw, 2008).

RADIATION EXPOSURE LIMITS AND GUIDELINES

Some of the agencies that have established and continue to monitor acceptable limits for ionizing radiation include the ICRP, NCRP, National Academy of Sciences Committee on the Biological Effects of Ionizing Radiation (the BEIR Committee), U.S. EPA, United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR), and U.S. NRC.

Exposure Limits and Guidelines for the General Population

According to both the ICRP and NRC, general population exposures to ionizing radiation should be kept as low as reasonably achievable (ALARA) to protect against the stochastic effects of radiation. More generally, the ICRP and U.S. NRC have recommended dose limits for exposure to specific, nonnatural sources of radiation of 1 mSv per year, or roughly one sixth of the normal background exposure due to anthropogenic and naturally occurring radiation. In the United States, the NRC imposes more stringent exposure limits for the public from nuclear power plants (0.25 mSv/year) and waste disposal facilities (0.15 mSv/year) (CPEP, 2003). The U.S. EPA has established an “action level” for indoor radon exposure of 4 pCi/l of air (approximately 8 mSv/year) at which it recommends activities to reduce exposure be taken (CPEP, 2003). In addition to whole-body dose limits, the ICRP recommendations also indicate tissue-specific doses of 50 mSv for the skin and 15 mSv per year for the lens of the eye (and an average equivalent dose of 20 mSv averaged over 5 years) (ICRP, 2007).

Occupational Exposure Limits

Consistent with the concept of a zero threshold for stochastic effects, the ALARA principle also applies to occupational exposures to ionizing radiation. Thus, use of appropriate personal protective equipment and good hygiene practices are required in workplaces using radiological materials even when measured exposures are below established workplace limits. In terms of specific limits, the U.S. NRC has set a total effective dose limit of 50 mSv per year for whole-body occupational exposures. Specific dose limits have also been established for the lens of the eye (150 mSv per year) and the skin and extremities (500 mSv per year). The sum of the deep dose (non-skin), non-eye equivalent and committed dose equivalents cannot exceed 500 mSv for any given organ (U.S. Code of Federal Regulations, Title 10, Part 20). The dose that can be experienced by a pregnant woman is limited to 5 mSv (as the dose to the fetus) summed over the gestation period. The analogous ICRP limits allow for averaging over a 5-year time period (i.e., a maximum

5-year average total-body dose of 20 mSv, with exposure in any individual year not to exceed 50 mSv). The allowable doses to the skin and extremities are identical to those adopted by the NRC (Boice, 2012). Regarding the lens of the eye, in 2011, the IRCP recommended reducing the exposure limit to 20 mSv averaged over 5 years, with exposure to the lens in any individual year not to exceed 50 mSv (Boice, 2012).

101

ELECTROMAGNETIC WAVES (EMF AND RF) AND HEALTH EFFECTS

PETER A. VALBERG

First aid: Remove from RF or ELF-EMF exposure by increasing distance from the emissions source or by de-energizing the source (e.g., transmitting antenna).

Target organ(s): For high level RF: skin, cornea, inner ear. For high level power-line EMF, none known other than non-adverse “magneto-phosphenes” stimulated in retinal receptor cells. Other, putative organs: lymphocyte stem cells in the bone marrow, neurons and neural support cells in the brain, peripheral nervous system.

Occupational exposure limits: ACGIH TLV: For power-line (60 Hz) fields: 1 mT (10,000 mG); for workers with implanted cardiac pacemakers: 0.1 mT (1000 mG). For RF fields, see values tabulated in TLV handbook, which range from 10 to 100 W/m². For FCC and ICNIRP values, see Tables 101.4 and 101.5 in this chapter.

Reference values: No RfC derived for either RF or ELF-EMF exposure. Radio frequencies specific absorption limit (SAR) is 0.08 W/kg for the general public, and 0.40 W/kg for RF workers.

Risk/Safety Phrases: IARC Group 2B Carcinogen; ACGIH, A4; ACGIH has Threshold Limit Values (TLVs) for EMF exposure that are protective of worker health and are listed by frequency. There are currently no OSHA standards for worker exposure to extremely low frequency (ELF) fields. Likewise, there are no OSHA-specific standards for radiofrequency and microwave radiation exposure. The Federal Communications Commission (FCC) is the U.S. federal regulatory agency as to radiofrequency exposure limits.

BACKGROUND: THE ELECTROMAGNETIC WAVE SPECTRUM, NONIONIZING VERSUS IONIZING RADIATION

As illustrated in Table 101.1 below, the electromagnetic spectrum encompasses wave energy with a vast range in frequency from very low (e.g., power lines at 60 Hz), through the kilo- and megahertz radio frequencies (RF) (e.g., radio and television signals), to microwaves (gigahertz), and on up into waves of infrared, light, ultraviolet, X-rays, and gamma rays. The last three categories (from UV and higher in frequency) are considered “ionizing radiation,” and this chapter focuses on electromagnetic waves with wavelengths longer, and frequencies below those of ultraviolet, namely, waves that fall into the “nonionizing” portion of the electromagnetic spectrum. Ionizing radiation is discussed in Chapter 100 of this book, and ionizing radiation is distinguished by the fact that those electromagnetic waves have sufficient energy to break apart chemical bonds in biological molecules, whereas nonionizing waves do not.

The International Agency on Research in Cancer (IARC) has classified ultraviolet light and ionizing radiation as “Group 1” or “known” carcinogens, meaning epidemiology of exposed populations is sufficiently strong to establish that elevated exposure increases cancer risk in humans. For nonionizing radiation, IARC has classified power-line (extremely low frequency) electric and magnetic fields (ELF-EMF) and RF as “Group 2B” or “possibly carcinogenic to humans,” which, in the RF and EMF circumstances, refers to limited-to-inadequate evidence of cancer risk in humans

TABLE 101.1 The Electromagnetic Spectrum: The Columns Illustrate How Wave Properties Change as You Go Up in the Spectrum (The Second Row Gives Median Values for Wavelength, Frequency, and Photon Energy)

Power Lines	Navigation, AM Radio, Ham Radio	FM Radio, UHF TV, Cell Phones	Microwave Beacons and Radar	Radiant Heating, Infrared	Sunlight, e.g., yellow light	Medical and Dental x-Rays	α -, β -, γ -Rays
5000 km	300 m	30 cm	3 mm	6 μ m	600 nm	0.3 nm	0.0003 nm
50–60 Hz	0.001 GHz	1 GHz	100 GHz	50 THz	500 THz	10^{18} Hz	10^{21} Hz
0.24 peV	4 neV	4 μ eV	0.0004 eV	0.2 eV	2 eV	4,000 eV	4 MeV
		◆		◆	◆		◆
		Cell phones, ~1–2 GHz		Body heat	Vision		cosmic rays
–	–	–	–	←←Nonionizing←←		→Ionizing→→→→	
				(RF heating currents)	(Photochemistry)		(molecular damage)

nm = nanometers = 10^{-9} meter = one-billionth of a meter.

GHz = gigahertz = 10^9 Hz = one thousand million cycles per second.

THz = terahertz = 10^{12} Hz = 10^{12} cycles per second = one million cycles per second.

eV = electron volt = energy gained by electron accelerated through 1 volt potential difference.

and limited-to-inadequate evidence of carcinogenicity in experimental animals.

The Physical Properties of Electromagnetic Waves are Frequency and Intensity

All matter contains electrically charged particles. Most objects are electrically neutral because positive and negative charges are present in equal numbers. When the balance of electric charges is altered, we experience electrical effects caused by the force between electric charges, such as the static electricity attraction between a comb and our hair, or the force between current carrying wires in an electric motor. Electric charges that accelerate back and forth ("oscillate") can lose their energy into electromagnetic radiation that propagates away at the speed of light.

Electric and magnetic fields (EMF) are essentially constructs created by scientists to help understand how electrically charged particles interact with each other. Scientists explain the forces exerted by charges by saying that each electric charge generates an electric field that exerts force on other nearby charges. That is, an electric field is a measure of force per unit charge (newtons per coulomb), but is usually expressed in units of volts per meter (V/m) or kilovolts per meter (kV/m). When electric charges move, an electric current exists, and a current generates a magnetic field. Units of electric current are amperes (A), and current measures the flow of electricity, somewhat like the flow of water in a plumbing system. The current of moving electric charges produces a magnetic field that exerts force on other moving charges. That is, a magnetic field expresses the force per unit length of current-carrying wire (newtons per ampere-meter), but is usually expressed in units of gauss (G) or milligauss (mG). Another magnetic field unit is the tesla (T), where 1 T = 10,000 G, and thus, 1 μ T = 10 mG.

Oscillation Frequencies for Electromagnetic Waves

Oscillating, electrically charged particles create "waves" in the EMF lines associated with them, and these waves move outward at the speed of light. That is, electromagnetic waves have a time period or frequency equal to the rate at which the electric charges creating them are being shaken back and forth. The overall result is called an "electromagnetic wave," with the frequency given in "Hertz" (Hz), which is the same as "cycles per second." Table 101.1 (above) shows the vast range in frequencies of electromagnetic waves. The energy contained in the electromagnetic waves increases in proportion to their frequency.

The science of electromagnetic waves has been studied and tested over a very long period of time. James Clerk Maxwell described the basic interactions between electromagnetic waves and matter in the 1860s, and he showed that electromagnetic waves travel at the speed of light. In 1887, Heinrich Hertz experimentally demonstrated the existence of electromagnetic waves, and, in 1909, Guglielmo Marconi was awarded the Nobel Prize in physics for inventing the radio, i.e., showing how electromagnetic waves could be used to transmit information without wires. Notably, Maxwell's 1867 equations (with the addition of quantum mechanics) have been verified time and time again as valid predictors of how electromagnetic waves and matter interact. No exceptions to Maxwell's equations have been found, and no unexplained electromagnetic phenomena have been encountered.

Radio-wave frequencies cover the range from about 300,000 Hz (i.e., 0.3 megahertz, or 0.3 MHz) to 30,000,000,000 Hz (i.e., 30 gigahertz, or 30 GHz), and beyond. Communications signals rely on a "carrier frequency," which is different for each communication signal, and the difference in frequencies allows many RF signals to

be present simultaneously, because the information carried at each frequency can be extracted by frequency-selective electronic tuners. For example, for cellular telephone technology, the carrier frequencies range from about 900 MHz up to about 2200 MHz.

By itself, an RF carrier wave is an unchanging continuous electromagnetic wave, and it carries no information. Information is imposed on the carrier wave by a modulation process that alters it by changing its amplitude, frequency, or phase in step, with the voice frequency (or other information) being imposed (amplitude modulation, AM; or frequency modulation, FM). Alternatively, information can be coded into computer bits, and the carrier wave can be modulated by changing its amplitude or frequency in discrete steps (digital modulation). The interaction of RF waves with cells and molecules depends on the frequency of the carrier wave, but not on the type information being transmitted, e.g., "voice," or "music," or "computer bits." This is because the physical energy of the RF waves depends only on the power of the carrier wave, and studies have provided no evidence that the biological impact (or lack of impact) of RF depends on the information content carried by the radio waves.

Visible light is the major source of electromagnetic energy in our daylight environment. Also, the human body, by virtue of being alive and warm, generates heat energy (electromagnetic energy in the infrared portion [IR] of the spectrum), which can be seen by a "night vision" camera, in the absence of visible light.

Absorption of Energy from Electromagnetic Waves

In considering potential health effects of EMF or RF, it is important to recognize that electromagnetic radiation, although "wave-like" in nature, can also act like "particles" when being absorbed or emitted by matter. That is, absorption and emission of radiation occurs in discrete energy units, photons or quanta, with energy content $E = h\nu$, where h is Plank's constant and ν is the frequency. Table 101.1 lists photon energies, and these energies can be compared to chemical bond energies, which are typically 3–12 electron-volts (eV) per bond. Thus, high frequency radiation, e.g., X-ray photons have high enough energy content to ionize (disrupt) biological molecules held together by covalent bonds. Photons in the visible and UV range can excite molecules and initiate molecular shape changes or chemical reactions. Photon energies of electromagnetic radiation in the microwave region and above can excite vibrational energy levels of molecules. Lower frequencies, including microwaves and down to 50/60-Hz EMF have small photon energies, and in fact, 50/60-Hz EMF are not considered to "radiate."

For EMF or RF exposures to cause or exacerbate disease in humans, such exposures would have to trigger a series of sequential steps that lead to a disease outcome. The causal

chain would begin with human exposure to some particular frequency/intensity/duration of EMF or RF. To complete the first step, the fields would interact with biological molecules (or structures) in such a way as to alter their size, shape, charge, chemical state, function, or energy (by a mechanism currently unknown). In this energy "transduction" step, some absorption of electromagnetic energy must occur or there can be no effect. For observable biological (and possibly health adverse) effects to follow transduction, a cascade of sequential events at the molecular, cellular, and tissue level would be required, leading without interruption to the final outcome. Identifying a plausible, mechanistic or transduction step, in this multistep pathway has been one of the most challenging and elusive puzzles, despite considerable effort by biologists, chemists, and physicists.

Identifying how electromagnetic waves alter biological systems is crucial to determine the correct exposure metric. Since the health and viability of the human body depends in a fundamental way on the normal structure and function of large molecules (e.g., proteins, nucleic acids, carbohydrates, and lipids), a theory on how EMF or RF mechanisms act must predict how weak electromagnetic energy could interfere with or modify the normal synthesis, function, or degradation of these molecules. For example, a viable mechanism would predict thresholds of exposure effectiveness in terms of electromagnetic wave amplitude, frequency, time of onset, intermittency, coherence, exposure duration, polarization, etc.

ELECTRIC POWER: 60 Hz ELECTRIC AND MAGNETIC FIELDS (EMF)

Electrical effects can occur through the generation and use of electric power. The power grid creates EMF varying in time at 50 or 60 Hz (cycles per second), which are considered "extremely low frequency" (ELF) fields.

The electrical tension on utility power lines is expressed in V or kilovolts (kV; 1 kV = 1000 V). Voltage can be thought of as the pressure driving the flow of electricity. The existence of a voltage difference between power lines and ground results in an electric field, which is usually expressed in units of kV/m. The size of the electric field depends on the voltage, the separation between lines and ground, and other factors.

Power lines also carry an electric current that creates a magnetic field. The units for electric current are A and are a measure of the flow of electricity. Electric current can be envisioned as analogous to the flow of water in a plumbing system. The magnetic field produced by an electric current is usually expressed in units of G or mG, where 1 G = 1000 mG. As noted earlier, another unit for magnetic field levels is the microtesla (μ T), where 1 μ T = 10 mG. The size of the magnetic field depends on the electric current, the distance to the current-carrying conductor, and other factors. The units of measure are basically the same as those for static fields.

For example the steady magnetic field from the earth is 570 mG (57 µT).

Properties of Power-Line EMF

When EMF derives from different sources (e.g., adjacent wires), the size of the net EMF produced will be somewhere in the range between the sum of EMF from the individual sources and the difference of the EMF from the individual sources. Thus, EMF may partially add, or partially cancel, but generally, because adjacent wires are often carrying current in opposite directions, the EMF produced tends to be cancelled. Inside residences, typical baseline 60-Hz magnetic fields (far away from appliances) range from 0.5 to 5.0 mG. Electric and magnetic fields in the home arise from electric appliances, indoor wiring, grounding currents on pipes and ground wires, and outdoor distribution or transmission circuits.

Larger 60-Hz magnetic field levels are found near operating appliances. For example, can openers, mixers, blenders, refrigerators, fluorescent lamps, electric ranges, clothes washers, toasters, portable heaters, vacuum cleaners, electric tools, and many other appliances generate magnetic fields of size 40–300 mG at distances of 1 ft (NIEHS, 2002). Magnetic fields from personal care appliances held within ½ ft (e.g., shavers, hair dryers, massagers) can produce 600–700 mG. At school and in the workplace, lights, motors, copy machines, vending machines, video-display terminals, pencil sharpeners, electric tools, and electric heaters are all sources of 60-Hz magnetic fields.

Although the steady geomagnetic field does not have the 60-Hz time variation characteristic of power line EMF, people's movements in its presence can cause it to be experienced as a changing magnetic field. Also, moving magnets generate time-varying magnetic fields. For example, a magnet spinning at 60 times a second will produce a 60-Hz magnetic field indistinguishable from that found near electric power lines carrying the appropriate level of electric current. Even the rotating steel-belted radial tires on a car produce time-varying magnetic fields. Magnetic resonance imaging (MRI) is a diagnostic procedure that puts humans in large steady and changing magnetic fields (e.g., static fields of size 20,000,000 mG). In contrast to medical X-rays, MRIs have no known health risks (other than the large forces exerted on nearby steel objects).

Review of Power-Line EMF Bioeffects

Power-line EMF has been the focus of considerable research for more than three decades. Over this period of time, the focus has been primarily on the magnetic field component. The three major lines of investigation have involved epidemiology, laboratory animal studies, and biological mechanism studies. The scientific evidence currently accumulated does not

support a clear and coherent picture whereby environmental levels of power-line EMF constitute a hazard to human health, primarily because animal studies and mechanistic investigations have not shown a consistent, deleterious effect of typical ambient power-line magnetic fields on biology.

EMF epidemiology studies focused on childhood leukemia have received considerable attention. An observational epidemiologic study published by Wertheimer and Leeper (1979) suggested that living near electric power distribution lines was linked to an increased risk of childhood cancer. In this and subsequent epidemiology studies, the actual EMF levels that children had been exposed to were unknown, so researchers developed surrogates for past EMF exposures based, for example, on the proximity, number, and size of electric-utility distribution (or transmission) lines near the homes. In the initial 1979 study, the electric utility distribution line configuration near a home was called its "wire code," and homes with high wire codes (and presumably higher EMF levels) were found to be represented in a greater proportion of the leukemia cases as compared to the control children.

During the 35 years since this first study, a large number of epidemiological studies have examined associations between disease and various proxies of power line field strength (e.g., the "wire code" classification of homes, the distance to power-line corridors, present-day EMF measurements, the field strength calculated from power-line loading). If a correlation was detected, it was generally interpreted as linking power-line EMF to increased risk for the disease being studied, but consistency of the findings was poor. Often, the associations became weaker or disappeared when actual personal-monitor measured magnetic fields were substituted in place of other surrogate measures. It was found that some surrogates used for ranking EMF exposure also correlated with non-EMF factors such as traffic density, age of the home, rental vs. ownership, and assessed value of the home. Such potential confounders made it problematic to interpret the associations as an effect of EMF exposure per se. That is, the statistical correlations did not establish that power-line EMF exposure was the "causal" factor.

Hundreds of EMF epidemiology and laboratory research studies have been published in the 35 years since the initial 1979 study reported a statistical correlation between residential "wire codes" and childhood leukemia. Generally, each study focused on a particular hypothesis, and the range of possible investigations has been immense. Some of the most important work was done under the auspices of the National Institute of Environmental Health Sciences (NIEHS). The NIEHS had a program called "EMF RAPID,"¹ which funded laboratory research to determine what, if any, aspects of power-line magnetic fields (ELF-EMF) interaction with

¹ RAPID = "research and public information dissemination."

biological systems had the potential to trigger adverse disease outcomes. The conclusion of this extensive laboratory research program was summarized by NIEHS (1999).

The scientific evidence suggesting that ELF-EMF exposures pose any health risk is weak. . . . No indication of increased leukemias in experimental animals has been observed. . . . Virtually all of the laboratory evidence in animals and humans, and most of the mechanistic studies in cells fail to support a causal relationship between exposure to ELF-EMF at environmental levels and changes in biological function or disease status.

For the proposition that power-line EMF exposure leads to health effects, there continues to be a lack of supporting laboratory-animal evidence, or support as to a plausible biological mechanism (Wood, 1993; Valberg et al., 1997; Boorman et al., 1999, 2000; McCormick et al., 1999; Swanson and Kheifets, 2006; Brain et al., 2003; Foster, 2003; WHO, 2007; SCENIHR, 2009).

Epidemiologic analyses have continued over the years, and some associations continue to be reported. The following list provides examples of prominent analyses, reviews, and/or summaries of the more recent power-line EMF literature. Notably, the epidemiological associations have not become stronger over the years, i.e., following the advent of larger, more in-depth studies. There still remains considerable inconsistency among the epidemiology results, the levels of incremental risk are low, and often do not reach statistical significance. Although the listing below (15 articles, 2000–2014) is not intended as a comprehensive review, it provides a sampling of some of the more recent and more significant epidemiological results. The reader is encouraged to read some of the individual studies in more detail.

- Ahlbom et al. (2000): “When [we] pooled nine epidemiology studies, . . . [we] found a relative risk of 2.0 (1.27–3.13) for childhood leukemia in the children with average exposures of 4 mG or greater. For children with lower average exposures, no significant elevation of childhood leukemia was found in the pooled studies. . . . The explanation for the elevated risk is unknown, but selection bias may have accounted for some of the increase.”
- Greenland et al. (2000): “Summary estimates from 12 studies that supplied magnetic field measures exhibited little or no association of magnetic fields with leukemia when comparing 0.1–0.2 and 0.2–0.3 microtesla (μ T) categories with the 0–0.1 μ T category, but the Mantel-Haenszel summary odds ratio comparing $>0.3 \mu$ T versus 0–0.1 μ T was 1.7.” “Based on a survey of household magnetic fields, an estimate of the U.S. population attributable fraction of childhood leukemia associated with residential exposure is 3%.”
- Hatch et al. (2000): “Our recent large case-control study [638 cases, 620 controls] found little association between childhood acute lymphoblastic leukemia (ALL) and electric-power-line wire codes.”
- Kleinerman et al. (2000): “Neither distance nor exposure index was related to risk of childhood acute lymphoblastic leukemia, although both were associated with in-home magnetic field measurements. Residence near high-voltage lines did not increase risk.”
- UKCC (2000): “Our results provide no evidence that proximity to electricity supply equipment or exposure to magnetic fields associated with such equipment is associated with an increased risk for the development of childhood leukemia nor any other childhood cancer.”
- Rubin et al. (2005): “The symptoms described by “electromagnetic hypersensitivity” sufferers can be severe and are sometimes disabling. However, it has proved difficult to show under blind conditions that exposure to EMF can trigger these symptoms. This suggests that “electromagnetic hypersensitivity” is unrelated to the presence of EMF, although more research into this phenomenon is required.”
- Kabuto et al. (2006): “We analyzed 312 children newly diagnosed with ALL or AML in 1999–2001. [. . .] Weekly mean MF level was determined for the child’s bedroom. [. . .] The odds ratios for children whose bedrooms had MF levels $\geq 0.4 \mu$ T compared with the reference category ($MF < 0.1 \mu$ T) was 2.6 (n.s., 95% CI = 0.76–8.6) for AML + ALL and 4.7 (1.15–19.0) for ALL only.”
- Mezei and Kheifets (2006): “The International Agency for Research on Cancer [has] classified ELF-MF as a possible human carcinogen. Since clear supportive laboratory evidence is lacking and biophysical plausibility of carcinogenicity of MFs is questioned, a causal relationship between childhood leukaemia and magnetic field exposure is not established. Among the alternative explanations, selection bias in epidemiological studies of MFs seems to be the most plausible hypothesis. In reviewing the epidemiological literature on ELF-MF exposure and childhood leukaemia, we found evidence both for and against the existence of selection bias.”
- Kavet et al. (2008): “Limits on exposures to extremely low-frequency electric fields, magnetic fields and contact currents, designated as voluntary guidelines or standards by several organizations worldwide, are specified so as to minimize the possibility of neural stimulation.” “[We describe] neurostimulation thresholds and the relevance of magnetophosphenes to setting guideline levels.”
- Kheifets et al. (2010): “10,865 cases and 12,853 controls were pooled from 7 studies; 24-hr meas. or calculated MF; >3 mG, compared to MF <1 mG: OR = 1.44 (n.s.,

95% CI 0.88–2.36), “the results are compatible with no effect [of EMF]. Overall, the association is weaker in the most recently conducted studies, but these studies are small and lack the methodological improvements needed to resolve the apparent association.”

- Kroll et al. (2010): “For children born in England and Wales during 1962–1995; there were 28,968 complete matched case–control pairs [calculated fields for 58,162 total].” “We found no statistically significant associations between childhood-cancer risks and estimated magnetic fields from high-voltage power lines near the child’s home address at birth.”
- Keegan et al. (2012): In a case-control study of paternal occupation and childhood leukaemia, “results showed some support for a positive association between childhood leukaemia risk and paternal occupation involving social contact.” Of the 16,764 cases of childhood leukemia, 93% were either acute myeloid leukemia or lymphoid leukemia, and neither showed an association with parents’ occupational EMF exposure. Of the 7% “other leukemias,” EMF exposure showed an increased odds ratio (OR = 1.6), but it was based on small numbers.
- Elliott et al. (2013): “[Our] study included 7,823 leukemia, 6,781 brain/central nervous system cancers, 9,153 malignant melanoma, 29,202 female breast cancer cases, and 79,507 controls [. . .] 15–74 years of age living within 1000 m of a high-voltage overhead power line.” “We observed no meaningful excess risks and no trends of risk with magnetic field strength for the four cancers examined.” “Our results do not support an epidemiologic association of adult cancers with residential magnetic fields in proximity to high-voltage overhead power lines.”
- Pedersen et al. (2014): “1,698 childhood leukemia cases were compared to 3,396 controls; exposure assessment used the distance between residence at birth and the nearest 132–400 kV overhead power line; children who lived 0–199 m from the nearest power line had OR = 0.76 [0.40–1.45] when compared to children >600 m away. Overall distance to the nearest power line was not associated with a higher risk of childhood leukemia. We did not observe any association with close distance or further away.”
- Bunch et al. (2014): “16,630 leukemia cases 1962–2008 compared to 20,429 matched controls; calculated distances of mother’s address at child’s birth to power lines used as exposure metric. Odds ratio for leukemia, 0–200 m compared with >1,000 m over the whole period OR = 1.12 (0.90–1.38) – not statistically significant. Over the whole period, there is no evidence of a distance effect for any of the three cancer groups.”

As can be seen, the power line magnetic-field epidemiology studies have yielded some statistical associations, and

scientists have struggled with whether such associations can really be interpreted as having a causal basis. Over the years, EMF epidemiology studies have stimulated numerous laboratory experiments where scientists examined the adverse health effect hypothesis, i.e., can environmental power-line EMF affect biology, alter processes in living cells, or change molecules in such a way as to increase the risk of cancer or other diseases?

To date, there is neither an accepted mechanism by which power line EMF can cause disease, nor is there any animal model in which lifetime exposure to even considerably elevated 60-Hz magnetic fields has reliably produced a disease or a pre-disease condition (Valberg et al., 1997). That is, the research work has not been able to identify what aspect of EMF is the one we should potentially avoid or regulate. If adverse health effects are to be expected, would they be due specifically to the frequency of oscillation, the electric fields, the magnetic fields, continuous exposure, intermittent exposure, peak fields, transients? Despite considerable effort and many years of work, no firm evidence of adverse EMF effects has been found in the laboratory for any of the measures of EMF exposure that have been experimentally examined. Because the laboratory evidence and mechanistic analyses have not supported a causal link for the increments in risk suggested by the epidemiology studies, most scientists give less weight to the statistical correlations.

Public Health Agency Views on EMF Causing Health Effects

In 2002, the IARC classified power-line-frequency EMF as “possibly carcinogenic to humans” which refers to the circumstances where there is limited-to-inadequate evidence of carcinogenicity in humans and limited-to-inadequate evidence in experimental animals. As noted, a biological mechanism to support this carcinogenic effect has not been found, because 60-Hz EMF interact weakly with the human body, because a 60-Hz wavelength is much larger than body size, and EMF exposure results in extremely low levels of energy deposition in the body. One must also consider the many years of human experience with EMF, i.e., use of electricity at an increasing rate for more than 100 years with no indication of increasing disease at the national, population level (Jackson, 1992).

The scientific data on EMF and health have been assembled and reviewed by many independent consensus groups of research and health scientists. These groups and agencies include (among many others) the European Union (EU), International Commission on Nonionizing Radiation Protection (ICNIRP), World Health Organization (WHO), the National Academy of Sciences, (NAS) the American Cancer Society (ACS), and the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR). As illustrated by the examples listed below,

these “blue-ribbon” panels do not conclude that ambient levels of EMF are unsafe. The reports of these groups are voluminous, thorough, and evenhanded. Some of their conclusions are illustrated below, but many of the documents extend to many hundreds of pages, so a more complete view of their analyses and opinions requires going to the reports themselves.

- American Cancer Society (ACS) (2014a): “The possible link between electromagnetic fields and cancer has been a subject of controversy for several decades. It’s not clear exactly how electromagnetic fields, a form of low-energy, non-ionizing radiation, could increase cancer risk. Plus, because we are all exposed to different amounts of these fields at different times, the issue has been difficult to study.”
- European Union (EU) (2009): “Animal studies do not provide evidence that ELF magnetic field exposure alone causes tumors or enhances the growth of implanted tumors. Some inconsistent evidence has suggested that ELF magnetic fields might be co-carcinogenic (enhance the effects of known carcinogens) and that they may cause cancer-relevant biological changes in short-term animal studies. However, it was concluded that the data were not sufficient to challenge IARC’s evaluation that the experimental evidence for carcinogenicity of ELF magnetic fields is inadequate.”
- Institute of Electrical & Electronics Engineers (IEEE) (2002): “Protection is to be afforded to individuals in the general population by limiting maximum permissible exposure to magnetic field levels of 9,040 mG at 60-Hz power-line frequencies.”
- International Agency for Research on Cancer (IARC) (2002): “The association between childhood leukemia and high levels of magnetic fields is unlikely to be due to chance, but it may be affected by bias. In particular, selection bias may account for part of the association.” (p. 332) [Thus] there is limited evidence in humans for the carcinogenicity of extremely low-frequency magnetic fields in relation to childhood leukemia. There is inadequate evidence in humans for the carcinogenicity of extremely low-frequency magnetic fields in relation to all other cancers.” (p. 338)²
- International Commission on Non-Ionizing Radiation Protection (ICNIRP) (2010): “[Two pooled epidemiological analyses] indicated that long-term exposure to 50–60 Hz magnetic fields might be associated with an increased risk of leukemia. . . . However, a combination of selection bias, some degree of confounding, and chance could possibly explain the results. In addition, no biophysical mechanism has been identified and the experimental results from animal and cellular laboratory studies do not support the notion that exposure to 50–60 Hz magnetic fields is a cause of childhood leukemia.”
- National Academy of Sciences (NAS) (1999): “Results of the EMF-RAPID program do not support the contention that the use of electricity poses a major unrecognized public-health danger.”
- National Cancer Institute (NCI) ((2005)): “Currently, researchers conclude that there is limited evidence that magnetic fields from power lines cause childhood leukemia, and that there is inadequate evidence that these magnetic fields cause other cancers in children. Researchers have not found a consistent relationship between magnetic fields from power lines or appliances and childhood brain tumors.”
- Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR) (2013): “Some epidemiological studies are consistent with earlier findings of an increased risk of childhood leukemia with long-term average exposure to magnetic fields above 0.3 to 0.4 µT [3 to 4 mG]. However, as stated in [SCENIHR’s] previous opinions, no mechanisms have been identified that could explain these findings. The lack of experimental support and shortcomings identified for the epidemiological studies prevent a causal interpretation.”
- World Health Organization (WHO) (2007): “Uncertainties in the hazard assessment [of epidemiological studies] include the role that control selection bias and exposure misclassification might have on the observed relationship between magnetic fields and childhood leukemia. In addition, virtually all of the laboratory evidence and the mechanistic evidence fail to support a relationship between low-level ELF magnetic fields and changes in biological function or disease status. Thus, on balance, the evidence is not strong enough to be considered causal, but sufficiently strong to remain a concern.”

² In 2002, the IARC classified ELF magnetic fields as Group 2B (possibly carcinogenic) on the IARC scale of carcinogenic risk to humans. IARC uses the “possibly carcinogenic” category when talking about both cell phone RF fields and power-line magnetic fields (“EMF”), and the IARC category 2B includes many ordinary exposures as “possible carcinogens,” e.g., coconut oil, gasoline, diesel fuel, fuel oil, mobile phones, “carpentry and joinery,” coffee, carbon black (car tires), car-engine exhaust, surgical implants, talc-based body powder, iron supplement pills, mothballs, nickels, pickled vegetables, safrole tea, titanium dioxide, chloroform, for a total of 285 substances.

Regulatory Guidelines for Electric and Magnetic Fields

The US has no federal standards limiting occupational or residential exposure to 60-Hz EMF. Table 101.2 shows guidelines for power-line EMF suggested by national and

TABLE 101.2 60-Hz EMF Guidelines Established by Health and Safety Organizations

Organization	Magnetic Field	Electric Field
American Conference of Governmental and Industrial Hygienists (ACGIH) (occupational)	10,000 mG ^a 1000 mG ^b	25 kV/m ^a 1 kV/m ^b

and have been typically adopted to maintain the status quo for EMF on and near transmission line rights-of-way (ROWs).

RADIOFREQUENCY (RF) WAVES AND COMMUNICATIONS TECHNOLOGIES

The RF portion of the electromagnetic spectrum lies at much higher frequencies than the ELF-EMF frequency range, but at a lower frequency range than radiation in the infrared (heat) or visible (light) portion of the spectrum (see Table 101.1). In the RF range, some sources of radio-wave energy include the following:

- Commercial radio (AM, FM), television (VHF, UHF, digital), amateur (ham) radio
- Marine and aviation radio services, military and weather radar, satellite TV/radio, GPS
- Hospital (EMS), fire, police dispatch services
- Wireless paging, routers, remote-control, baby monitors, walkie-talkies, etc.
- Cordless telephones, cell phones, smart phones, smart meters, base station antennas
- Microwave ovens (RF leakage); microwave computer links
- RF in medicine: ablation, cautery, diathermy, MRI

As can be appreciated from this list, our society has used RF communication for more than 100 years, and RF energy has been used in medical treatments for over 75 years (Hunt, 1982). The health effects of RF have been vigorously investigated from the 1950s, when military uses of RF, and radar in particular, were greatly expanded, on up to the present day (Schwan, 1954; Guy, 1975; Adair, 1983; Lin and Michaelson, 1987; Valberg, 1997; Valberg et al., 2007; Lin and Michaelson, 2010; Foster and Moulder, 2013).

In 2011, IARC classified RF as a “possible carcinogen,” which IARC describes circumstances where there is limited-to-inadequate evidence of carcinogenicity in humans and limited-to-inadequate evidence in experimental animals (IARC, 2011). But, as in the case of ELF-EMF, laboratory animal and biological mechanism evidence fail to support adverse health effects from low levels of RF exposure. Notably, MRI uses radio frequency waves to generate images of all parts of the human body, and MRI scans are not considered to pose health risks, in contrast to imaging techniques that use ionizing radiation (X-rays, CAT scans, PET scans, etc.).

Properties of Radiofrequency (RF) Electromagnetic Waves

In the above list of communications technologies, the total amount of RF energy transmitted by these sources varies

widely, and it's helpful to compare the RF emissions to a “100 watt light bulb.” Most commercial radio and television broadcast stations are licensed to operate at power outputs of tens of kilowatts to millions of watts; cell telephone base antennas range in power from 100 to 1000 W; a cell-phone handset typically produces less than 2–4 W of RF energy. For any antenna, the energy emitted is spread across a wide angle (in different directions), and the RF energy level decreases rapidly with distance. At the closest publicly accessible point, all transmitters must comply with the RF safety standards and guidelines for the general public, which in the United States are set by the Federal Communications Commission (FCC), and which are overall similar world-wide (ICNIRP, 2009). Below is a list of some sources of electromagnetic energy, listed according to the power they emit into the electromagnetic spectrum (mostly in the RF spectrum, but, for perspective, including some with emissions in the “heat” and “light” part of the electromagnetic spectrum).

Electric utility “smart meters”---	<1 W
Handheld cell phones, cordless phones---	<2–4 W
Remote control toys and nursery monitors---	~3 W
Typical flashlight---	~5 W (light + heat)
“Walkie-talkies”---	~10 W
Cellular telephone base stations---	~100–1000 W
Incandescent light bulb---	~100 W (light + heat)
The living human body---	~100 W (heat [IR waves])
Inside a microwave oven---	~1500 W (some RF leaks out)
Electric space heater---	~1500 W (light + heat)
Radio and television antennas---	~50,000 to 1,000,000 W

Typical measurements of the intensity of RF waves provide “energy per unit area,” and the results are given in “microwatts per square centimeter” or $\mu\text{W}/\text{cm}^2$. A microwatt is a millionth of a watt. Sometimes the units are “watts per square meter” of W/m^2 ($1 \text{ W}/\text{m}^2 = 100 \mu\text{W}/\text{cm}^2$). The Safety-standard allowable RF exposure levels vary with the frequency of the radio waves, being lowest (most restrictive) level in the frequency range 30–300 MHz (FM radio). The RF safety standard for public exposure in the AM-radio frequency band is $20,000 \mu\text{W}/\text{cm}^2$, in the FM-radio frequency band is $200 \mu\text{W}/\text{cm}^2$, at cellular telephone frequencies of 910 MHz is $610 \mu\text{W}/\text{cm}^2$, and at cellular telephone frequencies of 2000 MHz and above is $1000 \mu\text{W}/\text{cm}^2$. (Refer also to Tables 101.4 and 101.5 at the end of the chapter.) By comparison, summertime sunlight at noon bathes us with about $150,000 \mu\text{W}/\text{cm}^2$ of electromagnetic energy in the visible light portion of the spectrum.

When considering biological effects, another useful comparison to consider is the whole-body specific absorption rate (SAR) guideline used by the FCC, ICNIRP, and IEEE for the

TABLE 101.4 FCC Limits for Maximum Permissible Exposure (MPE), 300 kHz to 100 GHz

Frequency Range (MHz)	Electric Strength (E) (V/m)	Magnetic Field (H) (A/m)	Power Density (S) (mW/cm ²)	Averaging Time E ² , H ² or S (minutes)
(A) Limits for Occupational/Controlled Exposure ^a				
0.3–3.0	614	1.63	(100)*	6
3.0–30	1842/f	4.89/f	(900/f ²)*	6
30–300	61.4	0.163	1.0	6
300–1500	—	—	f/300	6
1500–100,000	—	—	5	6
(B) Limits for General Population/Uncontrolled Exposure ^b				
0.3–1.34	614	1.63	(100)*	30
1.34–30	824/f	2.19/f	(180/f ²)*	30
30–300	27.5	0.073	0.2	30
300–1500	—	—	f/1500	30
1500–100,000	—	—	1.0	30

f = frequency in MHz.

*Plane-wave equivalent power density.

^aOccupational/controlled limits apply in situations in which persons are exposed as a consequence of their employment provided those persons are fully aware of the potential for exposure and can exercise control over their exposure. Limits for occupational/controlled exposure also apply in situations when an individual is transient through a location where occupational/controlled limits apply, provided he or she is made aware of the potential for exposure.

^bGeneral population/uncontrolled exposures apply in situations in which the general public may be exposed, or in which persons that are exposed as a consequence of their employment may not be fully aware of the potential for exposure or cannot exercise control over their exposure.

TABLE 101.5 IEEE Basic Restrictions (BRs) for Frequencies Between 100 kHz and 3 GHz

		Action level ^a (W/kg)	Persons in Controlled Environments SAR ^b (W/kg)	SAR ^c (W/kg)
Whole-body exposure	Whole-body Average (WBA)	0.08	0.4	
Localized exposure	Localized (peak spatial-average)	2 ^c	10 ^c	
Localized exposure	Extremities ^d and Prinnae	4 ^c	20 ^c	

^aThese are basic restrictions (BR) for the general public when an RF safety program is unavailable.

^bSAR is averaged over 30 min for the general public and over 6 min for controlled (worker) environments.

^cAveraged over any 10 g of tissue (defined as a tissue volume in the shape of a cube [the volume of the cube is approximately 10 cm³]).

^dThe “extremities” are the arms and legs distal from the elbows and knees, respectively.

general public, which is 0.08 W/kg, and which is the basis of the RF “maximum permissible exposure” guidelines.³ How much would this amount of continuous energy input (0.08 W) heat up a kilogram of water (11 of water) over 1 h of exposure? The answer is that, absorbing 0.08 W for a whole hour would raise the water temperature by 0.07 °C, assuming all of the heat input from the RF remained with the water, and did not get conducted, convected, or radiated away.⁴ By way of comparison, the human body generates energy constantly at about 100 W, in the process of “burning” ingested food and staying warm at about 37 °C. When exercising, the energy generation rate of the human body goes up many-fold. The IR radiation from the warm human body (37 °C, or 310 K) has an intensity of about 50 mW/cm², and the IR wavelength ranges from 6 to 14 μm (Rogalski, 2010). Thus, if our bodies, organs, cells, and molecules typically function well in a 100 W bath of IR electromagnetic energy (with IR photons having much more energy than RF photons), it is hard to explain why absorbing less than a watt of RF power would disrupt physiological function.

Research Studies on Health Effects of RF

The absorption of RF energy by living organisms is well understood to cause some degree of heating, in an amount dependent upon the RF intensity and RF frequency (or wavelength). This well established effect of RF exposure (thermal effects) forms the basis of guidelines protective against adverse effects via this mechanistic pathway, for both occupational and general-public RF exposure standards (IEEE, 2006; ICNIRP, 2009). Although “nonthermal” effects of RF are regularly reported in the research literature, the consistency, reproducibility, and usefulness of the “non-thermal” results have not achieved a reliability to the point where they can form the basis of RF exposure standards.

Epidemiologic analyses have continued over the years, and more recent studies have primarily focused on cellular telephone exposures, because this technology has become so ubiquitous. The 15 articles listed below (2002–2014) provide examples of prominent analyses, reviews, and/or summaries of the more recent RF literature. Although not a comprehensive review, the summary conclusions provide a sampling of some of the more recent and more significant epidemiological results. Even though very brief, quoted conclusions are presented, the reader is of course, encouraged to consult the complete article for a more complete presentation.

- Groves et al. (2002): “This study reports on over 40 years of mortality follow-up of 40,581 Navy veterans of the

³ Federal Communications Commission: http://www.fcc.gov/Bureaus/Engineering_Technology/Documents/bulletins/oet56/oet56e4.pdf

⁴ 0.08 W = 0.08 joules/sec, so for 1 h, energy going in = 288 joules = 69 calories, which would raise the temperature of 1000 g of water by 0.069 °C.

Korean War.” For these radar technicians, “Deaths from all diseases and all cancers were significantly below expectation overall, and [in particular] for the 20,021 sailors with high radar exposure potential. There was no evidence of increased brain cancer in the entire cohort or in high-exposure occupations.” “No significant excesses were seen for lymphoid malignancies.”

- Johansen (2004): “At present, there is little, if any, evidence that the use of mobile phones is associated with cancer in adults, including brain tumors, acoustic neuroma, cancer of the salivary glands, leukemia, or malignant melanoma of the eye.”
- Takebayashi et al. (2008): In this study of exposure to radiofrequency electromagnetic fields from mobile phone use, and brain tumor risk: “the adjusted odds ratios (ORs) for regular mobile phone users [was] 1.22 (95% confidence interval (CI): 0.63–2.37) for glioma and 0.70 (0.42–1.16) for meningioma. When the maximal SAR value inside the tumour tissue was accounted for in the exposure indices, the overall OR was again not increased and there was no significant trend towards an increasing OR in relation to SAR-derived exposure indices. A non-significant increase in OR among glioma patients in the heavily exposed group may reflect recall bias.”
- Ahlbom et al. (2009): p. 642. Glioma: “The pooled analysis of Nordic and UK Interphone studies, which to date includes the largest number of glioma cases, found an OR of 1.0 (0.7–1.2) based on 143 exposed cases, among persons who started to use a mobile phone 10 or more years before diagnosis.” p. 646. Meningioma: “The largest study so far—the pooled analysis of the Nordic and UK Interphone studies— found an OR of 0.9 (0.7–1.3) for long-term use. Pooling all original studies gave risk estimates close to or below unity.” p. 647. Acoustic neuroma: “For long durations of exposure (10 years or more), the Nordic-UK pooled analysis included the largest number of cases, and reported an OR of 1.0 (0.7–1.5).” “Pooling all studies gave summary risk estimates of 1.2 (0.8–2.0) for long-term use, and 1.1 (0.8–1.4) for ever-use.” p. 650. Salivary gland tumors: “There is no consistent evidence of an increased risk of salivary gland tumors among mobile phone users”
- Aydin et al. (2011, 2012): “There is no plausible explanation of how a notably increased risk from use of wireless phones would correspond to the relatively stable incidence time trends for brain tumors among children and adolescents observed in the Nordic countries.” “Regular users of mobile phones were not statistically significantly more likely to have been diagnosed with brain tumors compared with nonusers.” “Almost 90% of the [Swedish] population had been using mobile phones for at least seven years in 2009, and the

proportion that had been using them for 10 years or even 15 years must have been substantial. Hence, the absence of a trend in the incidence of brain tumors in national statistics is reassuring [as to mobile phones not increasing risk of brain cancer].”

- de Vocht et al. (2011): “Given the widespread use and nearly two decades elapsing since mobile phones were introduced, an association should have produced a noticeable increase in the incidence of brain cancer by now. Trends in rates of newly diagnosed brain cancer cases in England between 1998 and 2007 were examined. There were no time trends in overall incidence of brain cancers for either gender, or any specific age group.” “The increased use of mobile phones between 1985 and 2003 has not led to a noticeable change in the incidence of brain cancer in England between 1998 and 2007.”
- INTERPHONE Study Group (2011): “There was no increase in risk of acoustic neuroma with ever regular use of a mobile phone or for users who began regular use 10 years or more before the reference date,”
- Swerdlow et al. (2011): “Although there remains some uncertainty, the trend in the accumulating evidence is increasingly against the hypothesis that mobile phone use can cause brain tumors in adults.”
- Larjavaara et al. (2011): “The study included 888 gliomas from 7 European countries (2000–2004), with tumor midpoints defined on a 3-dimensional grid based on radiologic images.” “[Our] results do not suggest that gliomas in mobile phone users are preferentially located in the parts of the brain with the highest radio-frequency fields from mobile phones.”
- Schiøtz et al. (2011): “In this study including 2.9 million subjects, a long-term mobile phone subscription of ≥ 11 years was not related to an increased vestibular schwannoma risk in men ($RR = 0.87$, 95% CI: 0.52, 1.46), and no vestibular schwannoma cases among long-term subscribers occurred in women versus 1.6 expected. Vestibular schwannomas did not occur more often on the right side of the head, although the majority of Danes reported holding their mobile phone to the right ear.”
- Deltour et al. (2012) and Little et al. (2012): Time trends in brain cancer rates do not reflect increases in mobile phone use, suggesting that there is no effect of low-level RF on brain cancer risk. “Age specific incidence rates of glioma remained generally constant in 1992–2008 (-0.02% change per year, 95% CI -0.28% to 0.25%), a period coinciding with a substantial increase in mobile phone use from close to 0% to almost 100% of the US population. If phone use [were] associated with glioma risk, we expected glioma incidence rates to be higher than those observed, even with a latency period of 10 years and low relative risks (1.5).”

- Mohler et al. (2012): “The results of [our] large cross-sectional study did not indicate an impairment of subjective sleep quality due to exposure from various sources of RF EMFs in everyday life.” “We did not find evidence for adverse effects on sleep quality from RF-EMF exposure in our everyday environment.” “individuals who claim to be able to detect low level RF-EMF are not able to do so under double-blind conditions”
- Barchana et al. (2012): “We found a statistically significant decrease in [gliomas] over 30-years period that correlates with introducing of mobile phones technology” “[This] is in-line with other observations and does not support the assumption that mobile phone use is a causative factor for brain gliomas.”
- Kwon et al. (2012): [people with self-reported electromagnetic hypersensitivity (EHS)] “In this double-blind study, two volunteer groups of 17 EHS and 20 non-EHS subjects were simultaneously investigated for physiological changes (heart rate, heart rate variability, and respiration rate), eight subjective symptoms, and perception of RF-EMFs during real and sham exposure sessions.” . . . “There was no evidence that EHS subjects perceived RF-EMFs better than non-EHS subjects.” “32 min of RF radiation emitted by WCDMA mobile phones demonstrated no effects in either EHS or non-EHS subjects.”
- Lagorio and Röösli (2014): “A meta-analysis of [29] studies on intracranial tumors and mobile phone use published by the end of 2012 was performed.” “High heterogeneity was detected across estimates of glioma and acoustic neuroma risk in long term users, with cRRs ranging between 1.19 (95% CI 0.86–1.64) and 1.40 (0.96–2.04), and from 1.14 (0.65–1.99) to 1.33 (0.65–2.73), respectively.” “Overall, the results of our study detract from the hypothesis that mobile phone use affects the occurrence of intracranial tumors.”

Public Health Agency Views on RF Causing Health Effects

As with guidelines and standards, generally RF exposure standards have been developed by interdisciplinary, consensus groups, based on the scientific knowledge accumulated from many years of laboratory work and of human experience with RF waves (e.g., radio, television, navigation, telemetry, cell telephones, radar). As is the case with power-line EMF, research findings on potential health effects of RF waves have been assembled and periodically reviewed by numerous independent scientific professional groups composed of research, engineering, medical, and public health scientists. The reports of these groups, written by researchers, medical doctors, biologists, engineers, and toxicologists, are voluminous, thorough, and evenhanded.

To account for uncertainties in the data and increase confidence that adverse health effects will not occur at exposure levels below the RF standards, the established threshold of actual biological effects is generally divided by a factor of 10 to provide a margin of safety for occupational environments. For general public environments, an additional factor of 5 is applied, meaning that the RF guidelines are typically 50-fold lower than the empirically observed threshold for RF effects that might be considered adverse to health. The public health groups looking at RF health effects include the ACS, ICNIRP, WHO, and SCENIHR. As illustrated by the examples listed below, a consistent finding is that, by limiting RF exposures according to the current RF guidelines, we can expect to be protective of health.

- American Cancer Society (ACS) (2014b). “Most animal and laboratory studies have found no evidence of an increased risk of cancer with exposure to RF radiation. A few studies have reported evidence of biological effects that could be linked to cancer. Studies of people who may have been exposed to RF radiation at their jobs (such as people who work around or with radar equipment, those who service communication antennae, and radio operators) have found no clear increase in cancer risk.”
- Advisory Group on Non-Ionizing Radiation (AGNIR) (2012). “Exposure of the general public to low level RF fields from mobile phones, wireless networking, TV and radio broadcasting, and other communications technologies is now almost universal and continuous.” “In summary, although a substantial amount of research has been conducted in this area, there is not convincing evidence that RF exposure below internationally accepted guidance levels causes health effects in adults or children.”
- Australian Radiation Protection and Nuclear Safety Agency (ARPANSA) (2012). “Laboratory studies do not provide evidence to support the notion that RF fields cause cancer. Review groups evaluating the state of knowledge about possible links between RF exposure and excess risk of cancer have concluded that there is no clear evidence for any links.”
- Federal Communications Commission (FCC) (2014). “Some health and safety interest groups have interpreted certain reports to suggest that wireless device use may be linked to cancer and other illnesses, posing potentially greater risks for children than adults. While these assertions have gained increased public attention, currently no scientific evidence establishes a causal link between wireless device use and cancer or other illnesses. Those evaluating the potential risks of using wireless devices agree that more and longer-term

studies should explore whether there is a better basis for RF safety standards than is currently used. The FCC closely monitors all of these study results. However, at this time, there is no basis on which to establish a different safety threshold than our current requirements.”

- Food and Drug Administration (FDA) (2012) “Many people are concerned that cell phone radiation will cause cancer or other serious health hazards. The weight of scientific evidence has not linked cell phones with any health problems.”
- Health Canada, Royal Society of Canada (RSC) (2003) “All of the authoritative reviews completed within the last two years have concluded that there is no clear evidence of adverse health effects associated with RF fields”
- Health Council of the Netherlands (NHC) (2011) “Available data do not indicate that exposure to radiofrequency electromagnetic fields affect brain development or health in children.”
- Institute for Electrical and Electronics Engineers (IEEE) (2006) “[RF standards] protect against harmful effects in human beings exposed to electromagnetic fields in the frequency range from 3 kHz to 300 GHz.”
- International Agency for Research on Cancer (IARC) ((2013). In May of 2011, the IARC Working Group determined that “There is *limited* evidence in humans for the carcinogenicity of radiofrequency radiation. Positive associations have been observed between exposure to radiofrequency radiation from wireless phones and glioma, and acoustic neuroma.” “Radiofrequency electromagnetic fields are *possibly* carcinogenic to humans (Group 2B).” “There was, however, a minority opinion that current evidence in humans was *inadequate*, therefore permitting no conclusion about a causal association.”⁵ However, IARC’s classification, because it did not include a quantitative analysis, has not led to the modification of RF guidelines and standards for safe exposure levels.
- International Commission on Non-Ionizing Radiation Protection (ICNIRP) (2009) “With regard to [RF and] non-thermal interactions, it is in principle impossible to disprove their possible existence but the plausibility of the various non-thermal mechanisms that have been proposed is very low. In addition, the recent *in vitro* and animal genotoxicity and carcinogenicity studies are

⁵ IARC uses the “possibly carcinogenic” category when talking about both cell phones and power-line magnetic fields (“EMF”), and the IARC category 2B includes “possible carcinogens” such as coconut oil, gasoline, diesel fuel, fuel oil, power-line EMF, “carpentry and joinery,” coffee, carbon black (car tires), car-engine exhaust, surgical implants, talc-based body powder, iron supplement pills, mothballs, nickels, pickled vegetables, safrole tea, titanium dioxide (sunscreen), chloroform, and many other substances. <http://monographs.iarc.fr/ENG/Classification/ClassificationsGroupOrder.pdf>

rather consistent overall and indicate that such effects are unlikely at low levels of exposure.”

- National Cancer Institute (NCI) (2013). “Cell Phones and Cancer Risk.” “Studies thus far have not shown a consistent link between cell phone use and cancers of the brain, nerves, or other tissues of the head or neck. More research is needed because cell phone technology and how people use cell phones have been changing rapidly.”
- National Council on Radiation Protection & Measurements (NCRP) (2003). “[NCRP] concludes that the scientific literature related to modulation-dependence of biological effects of RF energy is not sufficient to draw any conclusions about possible modulation-dependent health hazards of RF fields, nor is there any apparent biophysical basis from which to anticipate such hazards apart from exposure to very intense RF pulses produced by some specialized military equipment.”
- National Radiological Protection Board (NRPB) (2013) “The [Interphone] study provides no clear, or even strongly suggestive, evidence of a hazard. Moreover, it indicates that if there is any hazard of brain cancer or meningioma from use of mobile phones then the risk during the initial 10–15 years of use must be small. This conclusion is consistent with the findings of most other epidemiological studies that have examined the relation of brain tumours to use of mobile phones, and also with the absence of demonstrable effects on cancer incidence when laboratory animals have been exposed to radio-frequency radiation experimentally.”
- New Zealand Ministry for the Environment (NZME) (2012). “The Ministry of Health considers there are no established adverse effects from exposures to radio-frequency fields which comply with the ICNIRP guidelines and the New Zealand Standard.”
- Norwegian Institute of Public Health (2012-3) “With the exception of some case-control studies, the majority of the case-control studies and cohort studies have reported no increased risk of cancer. The results of the incidence studies show no evidence of increasing incidence of these cancers over time.” “A number of studies of cancer in animals have been performed, and relevant mechanisms have also been studied using micro-organisms and cells. Overall, these studies provide further evidence that exposure to weak RF fields does not lead to cancer.” Electromagnetic Hypersensitivity: “Blind trials show that symptoms also occur when subjects are not exposed. This means that electromagnetic fields do not need to be present for health problems attributed to electromagnetic fields to occur.”
- Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR) (2013): “Overall, there is evidence that exposure to RF fields does not cause

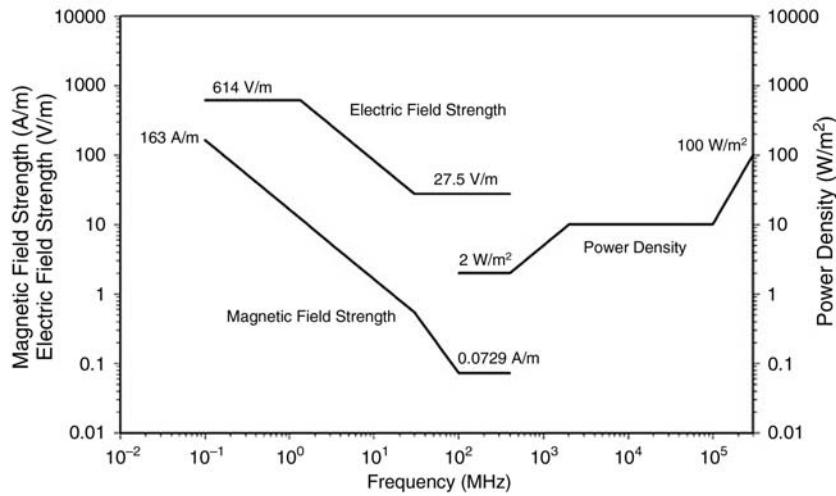

FIGURE 101.1 Graphic Representation of MPEs. Reprinted with permission from IEEE (2006), p. 27, Figure 4.

symptoms or affect cognitive function in humans. The previous SCENIHR opinion concluded that there were no adverse effects on reproduction and development from RF fields at exposure levels below existing limits. The inclusion of more recent human and animal data does not change that assessment.” (p. 5) “The results [. . .] have typically not found any effect of exposure to radiofrequency fields on self-reported symptoms, are supported by a series of meta-analyses conducted by Augner, Gnambs, Winker and Barth (2012). These authors identified nine single- or double-blind provocation studies which assessed the effects of [RF] exposure on five self-reported symptoms (headache, nausea, dizziness, fatigue and skin irritation) and which were suitable for inclusion in a meta-analysis. No evidence was found in the meta-analyses that any of these endpoints were affected by exposure.” (p. 109)

- World Health Organization (WHO) (2011) “A large number of studies have been performed over the last two decades to assess whether mobile phones pose a potential health risk. To date, no adverse health effects have been established as being caused by mobile phone use.”

In summary, there is general agreement among a wide range of “blue ribbon” scientific review panels that the current standards used to prevent overexposure to RF levels can be expected to be health protective.

RF Electromagnetic Wave Exposure Limits and Guidelines

A number of scientific consensus groups have developed quantitative RF exposure guidelines, both for the occupational and general public environment. The groups that have

produced numerical values include the following, and the standards are generally in agreement with each other.

- American Conference of Governmental Industrial Hygienists (ACGIH, 2014)
- Federal Communications Commission (FCC, 1997)
- Health Canada, Safety Code 6 (Canada, 2010)
- Institute of Electrical & Electronics Engineers/American National Standards Institute (IEEE, 2006)
- International Commission for Non-Ionizing Radiation Protection (ICNIRP, 2009)

Rather than display all of the possible standards, the FCC and IEEE standards are tabulated above to show the general manner in which these RF standards are presented.

The FCC standards were finalized in 1997 (FCC, 1997), and the agency has periodically reviewed the literature to ascertain that the standards remain current and health protective.⁶

The IEEE/ANSI standards for RF were finalized in 2005, and published in 2006, and in the table below, basic restrictions on human exposure to RF are given in terms of a SAR (energy absorbed per unit mass of tissue), over either a 6 min (occupational) or 30 min (general public) averaging time. The units of energy absorption are “watts per kilogram.” The “Action Level” is the value applied for the general public, and the “Controlled Environment” figure is applied to occupational environments where workers are fully aware of the potential for exposure and can exercise control of their RF exposure levels.

Because the amount of energy absorbed from RF waves by the human body varies with frequency, the IEEE graph above (Figure 101.1) illustrates how these limitations in SAR

⁶ <http://www.fcc.gov/encyclopedia/faqs-wireless-phones>

play out in terms of maximum permissible exposure (MPS's) limits for RF as a function of RF frequency (IEEE, 2006).

TRAUMATOGENS ASSOCIATED WITH CARPAL TUNNEL SYNDROME

JOAN M. WATKINS

BACKGROUND

Dorland's Illustrated Medical Dictionary defines "Traumato" as a combining form denoting relativity to trauma or injury. Traumatogenic is defined as capable of causing trauma. Thus, traumatogen is an excellent description of forces or motions that can cause injury depending on their amount of exposure or dose."

The "worker disease" was first documented in 1717 by Ramazinni:

Various and manifold is the harvest of diseases reaped by certain workers from the crafts and trades they pursue. All the profit that they get is fatal injury to their health. . . . That . . . I ascribe to certain violent and irregular motions and unnatural postures of the body, by reasons of which, the natural structure of the vital machine is so impaired that serious diseases gradually develop therefrom.

Although Ramazinni recognized the influences of forces on worker's muscular skeletal health, it was many years before the Science of Ergonomics was developed and contributed to the relationship of design and disease. Ergonomics also works to determine permissible levels of work load that do not lead to injury. (P. Van Wely). Cumulative trauma disorders (CTDs) are now termed work related musculoskeletal disorders (WRMSD). The WRMSDs are physiological illnesses that may develop over a period of weeks, months, or even years as a result of prolonged mechanical stresses imposed on the musculoskeletal system, resulting in injuries recognized as physical ailments or abnormal conditions. These disorders may also

be referred to as *repetitive strain injuries* (RSIs) (Kiesler and Finholt, 1988), *overuse injuries* (Green and Briggs, 1989), or *repetitive motion injuries*.

Cumulative trauma disorders (WRMSDs) are considered to be work related because they are more prevalent among the working population than the general public. Because of slow onset, both management and employees often ignore the microtrauma until the symptoms become chronic and permanent injury occurs (Putz-Anderson, 1988).

The development of such occupational illnesses in high risk industries has been recognized and monitored for some time. Although slight when compared with manual handling injuries, the RSI problem has been increasing consistently since the early 1980s (Green and Briggs, 1989) so that CTDs (WRMSDs) now represent a significant proportion of all workers' compensation claims (Brogmus and Marko, 1990; Brogmus et al., 1994). Several theories to substantiate this upward trend have been suggested, not least of which is a rise in symptomatic reporting as a result of increased public awareness.

CLASSIFICATION OF MUSCULOSKELETAL DISORDERS

Three basic types of cumulative illnesses or musculoskeletal disorders to the upper extremity musculoskeletal system are classified according to the anatomical source of irritation: tendon disorders, nerve disorders, and neurovascular disorders. Tendon disorders are those ailments associated with

overuse or unaccustomed use of a specific body part, examples of which include tendinitis, tenosynovitis, de Quervain's disease, and ganglionic cysts. Neurovascular disorders involve the compression of nerves and neighboring blood vessels. Thoracic outlet syndrome and vibration syndrome are commonly classified as neurovascular disorders.

Nerve disorders are attributable to repeated or sustained work activities that cause partial or complete loss of sensory, motor, or autonomic nerve function as a result of pressure against the nerve. Common examples of nerve compression disorders include neuritis, nerve entrapment syndrome, and carpal tunnel syndrome (CTS).

Carpal Tunnel Syndrome

First described by Sir James Paget in 1865, CTS is the most common example of a nerve compression disorder. Other terms used to describe this disorder include *writer's cramp*, *occupational neuritis*, *partial thenar atrophy*, and *median neuritis*.

It is caused by restriction of the median nerve as it passes through the carpal tunnel, an anatomical space in the wrist bound on the palmar side by the inelastic transverse carpal ligament and on the dorsal aspect by the carpal bones. The 10 structures that transverse the carpal tunnel include the four tendons of the flexor digitorum superficialis, the four tendons of the flexor digitorum profundus, the flexor pollicis longus, and the median nerve.

Robbins (1963) suggests three possible alternatives by which the cross-sectional area of the carpal tunnel may be compromised, thus reducing the available volume through which soft tissue structures pass: (1) increase of volume of the contents of the carpal canal, (2) an alteration of the osseous trough, and (3) thickening of the transverse carpal ligament.

The tendons that form a bridge between metacarpals in the hand and the flexor muscles of the forearm are lubricated along their path by tenosynovium, which allows the tendons to glide against each other. Personal factors or occupational conditions that cause irritation to, or inflammation of, the tendons can result in swelling and thickening of the tenosynovium. Because the median nerve is fragile compared to the surrounding structures, it compresses as the tendons swell, producing symptomatic experience of CTS.

Symptoms of CTS are usually experienced in the region of the hand served by the median nerve. This encompasses the second to fourth fingers, the base of the thumb on the palmar side, and the backs of the first four fingers on the dorsal side.

Acute CTS is often associated with nocturnal pain and tingling, episodic tingling during the workday, and gradual numbness, all of which may be encouraged by certain activities such as abnormal postures or repetitive or forceful hand motions. Symptoms usually diffuse shortly after the activity is changed.

As severity increases, the patient may experience aching, tingling, and what has been described as "painful numbness" in the fingers of the median distribution and deep in the palm. Perceptually, the patient may recall subjective feelings of uselessness related to the affected hand and wrist, mental sensation of swelling (although not apparent on inspection), clumsiness, and difficulty performing everyday tasks, such as unscrewing a bottle cap.

At the most severe level, patients with CTS may experience dull aching throughout the limb, which radiates not only distal to the site of compression, but also proximally. Patients may report pain throughout the forearm, upper arm, shoulder, and even the neck. Changes in coloration of the skin become more apparent, especially with exposure to cold. There may be excessive sweating in the palm and a possible mild degree of edema, which has been related to vasomotor imbalance. Wasting of the thenar muscles and mild weakness of the abductor pollicis brevis or opponens pollicis muscle may also be observed in severe cases.

Incidence of Work-Related CTS

The Bureau of Labor Statistics, a division of the US DOL, has defined repetitive trauma disorders for the purpose of classifying work-related incidence of these occupational illnesses:

Disorders associated with repeated trauma include conditions due to repeated motion, vibration, or pressure, such as CTS, noise-induced hearing loss, synovitis, tenosynovitis and bursitis, and Raynaud's phenomenon.

Although repetitive motion disorders represent only a small, but growing percentage of total occupational injuries and illnesses involving lost work time in the United States (1994 = 4.9%), group classification has limited the analysis of incidence for individual disorders. Because of the increasing prevalence of musculoskeletal disorders, and in particular, debilitating nerve disorders such as CTS, the Bureau of Labor Statistics redesigned their survey in 1992 to report for the first time the diagnosis of specific repetitive motion disorders that commonly affect the shoulders, arms, and other upper extremity parts.

The limited data from 1992 to 1994 suggest that incidence of CTS involving lost workdays was between 36.0% (1992) and 40.8% (1994) of the total occupational illnesses. (Note: Back injuries are excluded from these data because the US DOL considers them as accidents rather than cumulative injuries.)

From 1981 to 1990, there has been a steady increase in reporting of WRMSD, with a brief accelerated increase in 1987 and 1988. Several theories on the escalating occurrence include increased employee awareness through media attention and employer training programs; increased reliance on computer terminals in the workplace without appropriate ergonomic education and application. In addition increased

female populations in the workforce (females reporting CTS is approximately twice than that of male counterparts), and aging of the U.S. worker population may have also influenced the increase. The increased incidence of reporting is likely to be a result of a combination of these reasons. The whole picture will only truly be painted as more information becomes available from the Bureau of Labor Statistics' refined survey.

More than half of all incidents of CTS involving lost work days are attributable to the manufacturing industry. Massive downsizing of the manufacturing industries in favor of semi-automated processes during the 1980s is likely to continue in the foreseeable future; therefore, only through appropriate ergonomic intervention in the workplace to minimize known occupational factors will this problem be solved.

The recent slowing of occupational reporting of repetitive motion disorders has been further supported by the Bureau of Labor Statistics' 1996 announcement, which encouragingly revealed a decline in the number of occupational CTS cases for the first time in 15 years. It is speculated that the reduced incidence is in part a result of successful ergonomic interventions within specific high risk trades, including the meat industry, where incidence rates had fallen by 15.9%.

The Bureau of Labor Statistics reissued a table in 2009 that detailed the Incidence Rate for nonfatal occupational injuries and illnesses involving days away from work per 10,000 full-time workers by selected worker occupation and selected nature of injury or illnesses. The highest incidence rate was food servers, non-restaurant at 8.9. The next highest 4.6 and 4.4 for cooks, institution and cafeteria, and welders, cutters, solderers, and refrigeration, respectively. Those occupations with incidence rates between 2.4 and 2.9 in ascending order were: Butchers and meat cutters, roofers, labor and freights stock and material movers, hand, industrial machinery mechanic and automotive service technicians and mechanics. Those occupations with incidence rates between 1 and 2 were bus and truck mechanics and diesel engine specialists, maids and housekeeping cleaners, truck drivers heavy and tractor trailer and truck drivers light and delivery services. Those occupations with incidence rates below 1 were nursing aids, orderlies and attendants, construction laborers, carpenters, janitors and cleaners, except maids, and house-keeping cleaners (Bureau of Labor Statistics, 2008). In July 1997, National Institute for Occupational Safety and Health (NIOSH) published Musculoskeletal Disorders and Work Place Factors—A Critical Review of Epidemiologic evidence for WRMSD of the neck, upper extremity, and lower back. This publication is a comprehensive review of the relationship between musculoskeletal disorders and exposures to physical factors at work. Evidence for work relatedness of carpal tunnel is reviewed in Chapter 5. The thirty epidemiologic studies reviewed involved studies of populations exposed to a

combination of work factors. There was evidence of positive association between highly repetitive work alone and in combination with other factors and CTS. There was evidence of a positive association and forceful work in CTS. There was insufficient evidence between CTS and extreme postures. However, there was strong evidence of a positive association between exposure to a combination of risk factors such as force and repetitiveness or force and posture. One of the important aspects of this review is that it begins to quantify the risk factors associated with CTS.

Another important aspect of the developing research is CTS case definitions. The CTS case definition in Prevalence and Incidence of CTS in the United States working populations: Polled analysis of six prospective studies (Dale) was that both CTS hand diagrams and electrodiagnostic study results consistent with median nerve mononeuropathy of the wrist. More specifically; the carpal tunnel symptoms case definition required that subjects report symptoms of tingling, numbness, burning, or pain in one or greater than one of the first three digits (thumb, index, and long finger) on a hand symptom diagram. In addition, electrodiagnostic study results consistent with median nerve mononeuropathy at the wrist were required.

Social and Economic Costs

It is estimated that the economic burden of CTS on the U.S. industry presently exceeds \$2 billion per year (Palmer and Hanrahan, 1995). A significant share of this expense is attributable to CTS surgery, which is estimated to cost between \$400 and \$500 million a year. A proportion of these surgeries are performed because of symptomatic recurrence in which a patient's recovery may be encumbered as a result of deficient procedures (Kern et al., 1993).

Cases of CTS also have the longest recuperation period for any reported occupational injury or illness category. More than 36% of work-related CTS cases involve more than 1 month of lost work time, with a median recovery period of 18 days, compared to the overall median for all occupational injuries and illnesses of 6 days (Box 102.1).

When determining the cost of worker injuries, it is usual to add the expenses associated with medical intervention and workers' compensation insurance premiums. However, the total costs might be as high as five times the actual direct costs (Box 102.1).

With cost-effective surveillance, workers at risk may be identified and the incidence of CTS prevented or reduced; thus the social and economic impact would be significantly lessened.

Occupational Factors Associated with CTS Prevalence

It is often difficult to identify a specific cause of CTS because many risk factors may interact simultaneously to bring about

BOX 102.1 DIRECT AND INDIRECT COSTS ASSOCIATED WITH CTD INCIDENCE

Direct Costs (20%)

Medical expenses
Workers' compensation premiums
Lost and light duty workdays

Indirect Costs (80%)

Loss of injured worker's production
Time lost of employee paid by employer
Time lost by uninjured employees
Temporary help
Reporting and retraining
Reporting and claims
Management time
Worker/management discussions
Litigation costs

the condition. It is also difficult to isolate occupational factors from leisure activities, and individual susceptibility further compounds the problem. Studies identified the following factors as being contributory to the development of musculoskeletal disorders:

1. *High task repetition.* Silverstein et al. (1986) classified a job as highly repetitive if the cycle time is <30 s or if more than 50% of the time involves performing the same kind of fundamental cycle. The more repetitive the task, the more rapid and frequent are the muscle contractions, which become less efficient and hence require increased effort, therefore, demanding greater time for recovery.
2. *Forceful exertions.* As muscle effort increases in response to high task load, circulation to the muscle decreases, causing more rapid muscle fatigue.
3. *Posture.* Awkward postures overload muscles and tendons, load joints in an asymmetrical manner, and impose a static load on the musculature (Van Wely, 1970).
4. *Mechanical pressure.* Frequent or continuous use of tools with hard or sharp edges or short handles can cause compressional ischemia, impeding nerve conduction.
5. *Vibration.* Vibrating tool operation also affects myelinated nerve fiber activity and parasympathetic activity, which depresses peripheral nerve conduction (Murata et al., 1990; Murata et al., 1991).

6. *Exposure to cold.* Working in a cold environment or handling cold tools affects circulation to the digits, reducing tactile sensitivity, thereby increasing hand force.
7. *Gloves.* Use of gloves reduces tactility, thereby increasing the amount of force exerted to hold or manipulate a given object.
8. *Insufficient recovery time.* Recovery time can exceed work time for jobs where physical demands are high. Deprived of sufficient recovery time, soft tissue injuries may occur.
9. *Lead.* Constant contact or exposure to lead has been shown to impair maximal motor and sensory nerve conduction velocities of the median nerve (Araki et al., 1986).
10. *Organic solvents.* Chronic exposure to n-hexane, xylene, and toluene correlates with suppressing activity of myelinated fibers in the peripheral nervous system (Murata et al., 1994).
11. *Underreporting.* A selective loss of symptomatic employees may occur in high risk jobs, a form of healthy worker effect (Morgenstern et al., 1991).
12. *Psychosocial factors.* Kiesler and Finholt (1988) suggest that job dissatisfaction leads to increased reporting of WRMSD.

When two or more of the preceding risk factors are present, the risk of trauma is dramatically increased. Odds ratios of developing WRMSDs appear to be multiplicative. Jobs that combine high force and high repetition may pose the greatest risk (Silverstein et al., 1986).

Personal Factors Associated with CTS Prevalence

It is widely recognized that several medical and post-operative conditions can predispose a patient to CTDs. For reasons that are unclear, hypothyroid and hyperthyroid patients, postmenopausal women, and posthysterectomy patients are more susceptible to musculoskeletal disorders. Increased incidence among these patients may be because of altered hormonal balances causing connective tissue changes similar to an inflammatory response. Other medical conditions associated with an increased incidence of WRMSDs include rheumatoid arthritis, hypertension, diabetes mellitus, kidney disorders, lipoma, amyloid disease, myxedema, acromegaly, gout, cystic fibrosis, body mass index, pregnancy, use of oral contraceptives, alcoholism, and a variety of endocrine problems.*

*Robbins, 1963; Chabon, 1985; Pascual et al., 1991; Nathan et al., 1994; Osorio et al., 1994; Werner et al., 1994; Chammas et al., 1995; O'Riordan et al., 1995.

Nonmedical personal factors have also been positively correlated with increased reporting, which might be indicative of CTS prevalence among the general population. Tanaka et al. (1995) determined, based on self-reported CTS findings, that race (odds ratio=4.2, whites higher than nonwhites), gender (odds ratio=2.2, females higher than males), and age (odds ratio=1.03, risk increasing per year) might predispose individuals to musculoskeletal disorders of the hand and wrist. Furthermore, Radecki (1994) discovered 75% of female and 40% of male CTS patients had a positive family history suggestive of hereditary traits.

Traumatic and Nontraumatic Causes of CTS

Median palsy can be produced as a result of traumatic compression of the median nerve resulting in CTS symptoms. Based on the in-depth anatomical studies of the carpal tunnel (Robbins, 1963), the following identifiable sources of traumatic and nontraumatic causes of CTS were developed. This has helped establish a foundation as to potential causes of hand–wrist musculoskeletal disorders.

Traumatic causes are as follows:

1. Hematoma caused by hemorrhage in the palm
2. Carpal dislocation: forward dislocation of the lunate bone
3. Recent fracture of the distal end of the radius
4. Immobilization of a Colles fracture in the position of the acute volar flexion and ulnar deviation (Cotton-Loder position)
5. Healed fracture of the distal end of the radius with excessive new bone formation or with an unreduced bone fragment, resulting in tardy median nerve palsy
6. Deformities of the carpal bones caused by recent or old fractures or gross traumatic arthritis of the wrist

Nontraumatic causes are as follows:

1. Tenosynovitis
2. Calcium deposit
3. Ganglion
4. Leri's pleonosteosis
5. Neuromass of the median nerve at the wrist
6. Pseudoneurosis of attrition of the median nerve in the carpal tunnel
7. Aberrant artery closely accompanying the median nerve in the carpal tunnel, beating against the nerve
8. Abnormally low muscle belly of the sublimis of the long finger contracting against the nerve
9. Accessory bundle of the flexor brevis minimi digiti originating proximally from the antebrachial fascia and passing as a bridge over the nerve

MEDICAL DIAGNOSIS OF UPPER EXTREMITY MUSCULOSKELETAL DISORDERS

Conservative surveillance techniques report that the occupational incidence of disorders associated with repeated trauma increased by 1500% between 1983 and 1996 (US DOL). This increase equates to an average annual increase of 24%, based on previous year's data. Such dramatic growth prompted attention by the research and medical communities. As a result, a repertoire of clinical and quantitative diagnostic utilities for upper extremity musculoskeletal disorders was developed.

Because of the nature of nerve disorders, such as CTS, two patients for whom symptomatic experience is similar may be suffering from two quite different disorders or from neurological irritation at two different sites along a nerve path. Therefore, the clinician must be confident in findings of the diagnostic tests before prescribing an appropriate course of treatment, surgical, or otherwise. A full diagnosis contains several parts.

History

The first and most important information is the patient's experience: how the problem started, how it progressed, and what activities encourage symptomatic trauma. The patient can offer a level of insight not found in any quantitative measures, the benefits of which should be fully utilized. Their perspective may be solicited through structured questionnaire or informal interview techniques. This history should include symptoms of numbness, tingling, burning, or pain in the distribution of the median nerve occurring more than 3 times or lasting 7 days or longer in the previous 12 months (Burt et al., 2011). Having the patient fill in a hand diagram is most likely the best way to illustrate or define these symptoms.

Physical Examination

A correct diagnosis requires specific examination of the affected body part. Many rapid assessment tools have been developed to aid the clinician in this process, including Phalen's test, Tinel's test, Flick test, reverse Phalen's maneuver, range of motion, strength, sensory, reflex, and circulation/pulse testing, the details of which are offered in more extensive texts. Carpal tunnel compression test adds to the clinical examination methods that can be used to determine the likelihood that CTS is the diagnosis or part of the diagnosis. In a prospective study on 200 hands diagnosed as having CTS a control group of 100 volunteers with no symptoms of CTS were also assessed. This study was done to evaluate the effectiveness of the compression test in the physical exam to determine if CTS was present. Essentially, the carpal tunnel compression test reproduces the disease itself.

because it increases the pressure within the canal by external manipulation. It can also be used on wrists with limited range of motion (Gonzalez Del Pina et al., 2003).

Electrodiagnostic Studies

Compression of a nerve has been shown to produce slow conduction, entirely block nerve conduction, or cause axonal destruction. Electrodiagnostic studies are used as a tool to measure the time required for an impulse to travel from a proximal stimulus to a more distal site at which a response is evoked. This measure is called nerve latency.

Both medial and ulnar nerve latencies may be recorded and then compared. If median latency is significantly greater than ulnar latency, this is suggestive of CTS. If median and ulnar nerve latencies are both slow compared with normal values, low hand temperature, or peripheral neuropathy may be suggested (Bleeker and Agnew, 1987) (Figure 72.4).

Electrodiagnostic utilities have become widely instituted and are the primary means of detecting mild nerve disorders such as CTS. Early diagnosis can facilitate dramatic reductions in pain and suffering, associated costs, and lost time.

Kirschberg et al. (1994) demonstrated the effectiveness of combining clinical and electrodiagnostic diagnostic utilities to improve the reliability of findings. In a reevaluation of 112 patients who performed similar repetitive motion tasks and had reported pain, tingling, numbness, or all three in the hand, wrist, and forearm, only 35% presented positive clinical symptoms or positive electrodiagnostic findings. Only 17% overall actually had positive diagnostic results for both tests. This is also illustrated when a patient presents with consistent symptoms of numbness and/or pain but has negative electrodiagnostic findings. The hand surgeon makes the clinical decision to release the carpal tunnel and finds that the patient's symptoms are relieved following the release.

As noted in Burte et al's cross-sectional study the nerve conduction study must show electrodiagnostic criteria for median mononeuropathy. That is criteria A and B or C.

Criteria A. Slowed latency in median nerve

- Wrist to index finger sensory latency >3.7 ms or
- Mid-palm to wrist sensory latency >2.2 ms or
- Motor latency >4.4 ms

Criteria B. Normal distal ulnar nerve latency

- Wrist to little finger sensory latency ≤ 3.7 ms

Criteria C. Distal median nerve latency > distal ulnar latency

- Median wrist to index finger—ulnar wrist to little finger latency difference >1.0 ms or

- Median mid-palm to wrist—ulnar mid-palm to wrist latency difference >0.5 ms

Treatment of CTS

If CTS is detected during the early stages of development, conservative treatment is recommended. This can be significantly less disruptive to the patient and less costly than surgical approaches. The patient may also be able to return to normal duties within a relatively short time and with minimal pain and suffering.

Conservative treatment of CTS combines four types of therapies: restricting motion and splinting to immobilize the affected area; applying heat or cold to facilitate the repair process; medications and injections to reduce inflammation and pain; and special exercises that promote circulation to speed recovery and increase the range of motion. A simple wrist brace will sometimes lessen symptoms of mild CTS, especially if the patient is instructed to refrain from activities that require working against the brace, which could accelerate the onset of more severe symptomatology. The brace might be most effectively worn at night during sleeping to prevent awkward wrist postures, which are thought to foster nocturnal exacerbation. Anti-inflammatory medications are used as the second line of treatment to help control swelling of soft tissue structures. An injection of cortisone into the carpal tunnel may be prescribed to decrease swelling within the carpal tunnel, thereby permitting time for recovery. Giannini et al. (1991) showed use of local steroid injection facilitated improvement in median nerve function long after the pharmacological effects of the agents ceased.

Only if the symptoms are extreme and the preceding medical treatments are ineffective should surgical means of rehabilitation be considered. Boniface et al. (1994) reported that symptomatology for 86% of CTS nerve disorder patients may be resolved without surgical intervention.

Traditional release surgery involves the making of a small incision, usually <2 inches, along the palm of the hand. This incision is continued through the palmar fascia to reveal the transverse carpal ligament, the constricting element. The transverse carpal ligament is then cut to relieve pressure from the median nerve. Only the skin incision is sutured, leaving the gap in the transverse carpal ligament open to slowly heal as scar tissue.

Improvements in surgical techniques now permit the operating physician to use endoscopic tools for this procedure. Either one or two ports may be cut, depending on the preferred variation, through which both monitoring and incision are accomplished. Although endoscopic surgeries tend to be more expensive and less successful than the traditional approach, the reported benefits include decreased surgical time, decreased postoperative attention, early return to duty, decreased pain, and increased thenar strength (Bernstein, 1994).

Several studies support aggressive postoperative rehabilitation therapy and early return to work. One cost-effective approach might be to teach self-stretching techniques to patients undergoing myofascial release surgery, which have been shown to reduce symptoms and improve electromyographic results (Sucher, 1993). In a comparative evaluation, Goodman (1992) demonstrated that 14% of a traditional treatment group, whereas only 2% of an aggressive return-to-work group failed to resume their normal duties following carpal tunnel release surgery. Furthermore, tangible costs computed were found to be 50% lower in the aggressively treated group.

If a complete and permanent recovery is expected, it is important that the worker not be returned to the same job or task that precipitated the musculoskeletal disorder unless that job or task has been appropriately modified.

Recurrence of CTS

Recurrences of CTS following surgery are predominantly the result of inadequacies of the first procedure, such as incomplete splitting of the transverse carpal ligament or compression of the median nerve caused by excessive and improperly formed scar tissue. Additionally, up to 50% of recurrent CTS patients have medical conditions such as insulin-dependent diabetes mellitus, terminal renal insufficiency, or acromegaly that increase their susceptibility to nerve disorders (Kern et al., 1993). These reported statistics suggest that the number of operations for recurrent CTS can be dramatically reduced if the first operation is performed with greater care and attention. Patients with CTS secondary to a systemic disease are particularly at risk.

ERGONOMIC EVALUATION OF WORKPLACE HAZARDS

Health and risk factor surveillance provides a means of systematic identification of patterns or trends of work-related musculoskeletal symptoms and disorders, and their risk factors. Through ongoing methodical collection, analysis, and interpretation of health and exposure data, surveillance systems often identify the effects of workplace hazards before individual employees would normally feel compelled to report them. When performing an ergonomic workplace evaluation, the following three steps should be followed:

Phase I: Passive surveillance of available records. Surveillance tools are characterized by their practicality and speed with which data collection may be conducted, rather than their accuracy. Passive surveillance relies on the analysis of information from existing databases, such as those listed in Table 102.1, and is generally accepted as a means of rapid assessment.

By calculating incidence rates and comparing them with company or industry norms, it is relatively easy to identify specific areas within a facility that warrant further investigation.

Phase II: Active surveillance of workers. Questionnaire and informal interviewing techniques are useful for identifying new or incipient problems as well as for assessing the effectiveness of medical interventions and ergonomic controls. Specifically designed active surveillance tools can also be used to determine employee perceptions about aggravating factors and job improvement ideas.

Once the problem areas have been identified through passive and active surveillance, the proactive administration of physical examinations may prove to be a cost-effective approach for the early detection of WRMSD among operators in that area.

Phase III: Workplace risk factor analysis. Worksite assessments are usually performed by experienced ergonomists or other health specialists who have received specialized training in the identification of ergonomic hazards. Workstations, posture, tools and materials, as well as organizational and environmental factors should all be considered.

Circumstances that may raise concern include awkward postures, relatively short cycle time or high task repetition, high force demands, awkward or improperly designed tools, and employee-initiated task or tool redesigns. The ergonomist will likely use a variety of techniques to record and document these circumstances for further examination.

Once an ergonomic job analysis has established the presence of potential contributors to cumulative trauma, a plan for control and prevention should be devised. The principal technique for preventing musculoskeletal disorders is to reduce exposure to associated risk factors, although the specific amount of acceptable exposure has not been determined. To this end, a combination of administrative and engineering approaches may be considered. Hand activity level (HAL) and wrist strain index (SI), parameters may also be considered.

Engineering Controls

Engineering controls focus on the job or work environment. The aim is to redesign the job or tool to achieve control over those job factors associated with the onset of CTDs. Examples of engineering controls include the following:

1. Design jobs to reduce hand force and frequency of repetition.
2. Position the work and worker to eliminate awkward postures.

TABLE 102.1 Tools for Work-Related Musculoskeletal Disorder and Associated Risk Factor Surveillance

Surveillance Level	Method of Surveillance	
	Passive	Active
Level I (low)	Company dispensary logs Insurance records Workers' compensation records Accident reports Transfer requests Absentee records Grievances and complaints	Checklists Questionnaires
Level II (high)		Interviews Physical examinations Checklists Questionnaires Job analysis
Workplace risk factor		

Source: From *Traumatogens Associated with Carpal Tunnel Syndrome in Hamilton and Hardy's Industrial Toxicology 5th Edition*, Mosby, 1988.

3. Provide adjustable workstations and seating that permit postural changes.
4. Design workstations to minimize biomechanical loading.
5. Eliminate wrist deviations by angling the work toward the operator.
6. Use fixtures and jigs to support and position work pieces.
7. Provide parts bins below elbow height to avoid bent wrists.
8. Locate tools and components within easy reach.
9. Design or select hand tools using ergonomic principles to eliminate risk factors.
10. Use power tools to reduce exertion and repetition, but be sure to follow ergonomic tool selection guidelines.
4. Reduce repetitive body motion through task automation.
5. Avoid machine pacing.
6. Avoid incentive pay scales (i.e., piece work).
7. Provide and enforce the use of adequate protective equipment.
8. Control environment to prevent extreme conditions.
9. Gradually introduce new and returning employees.
10. Train workers in correct methods.
11. Educate management and supervisory personnel about the problem.
12. Employee selection; seek medical advice about job placement.

Administrative Controls

Administrative controls refer to actions taken by management or medical staff to limit the potentially harmful effects of a stressful job, which is usually achieved by modifying existing personnel functions. Appropriate administrative interventions for a given situation might include several of the following control measures:

1. Job rotation to less hand-intensive tasks.
2. Integrate work breaks to permit physiological recovery from biomechanically demanding tasks.
3. Alternate hands so that the task is not performed primarily by one hand.

STANDARDS AND LEGISLATION

The late 1990s was a time when American industries were grappling with significant incidence of musculoskeletal disorders and, in particular, CTS in many workplaces. Unfortunately, market forces seem to have provided insufficient incentive for top management to grasp the economic potential of workplace ergonomic investments.

During the mid-1980s, in response to the beginnings of increased CTD incidence, the NIOSH investigated appropriate strategies for the prevention and control of musculoskeletal injuries and illnesses. The following is an excerpt from their report that presently serves as the basis for the Occupational Safety and Health Administration's (OSHA's) legislative intervention endeavors.

When job demands repeatedly exceed the biomechanical capacity of the worker, the activities become trauma inducing. Hence, traumatogens are workplace sources of biomechanical strain that contribute to the onset of injuries affecting the musculoskeletal system.

In the absence of a general industry standard, OSHA continues to rely on the general safety clause 5 (a)(i) of their Health and Safety Act of 1970 to pursue legislative correction for ergonomic infringements. This approach has been successful in several well-publicized cases, including the John Morrell meatpacking facility in South Dakota (NIOSH, 1988). However, OSHA's goals lie not in seeking monetary compensation through citation, but in the prevention of occupational injuries and illnesses that can be debilitating to the employee and employer alike.

The original OSHA enactment of 1970, currently standing, is outdated as a legislative means of preventing occupational illnesses of ergonomic source. A more contemporary mandate may be required to reflect industry changes during the past two decades.

In light of the Morrell case, a guideline was set forth for the meatpacking industry (OSHA, 1990), which proved to be the most effective testing ground (see the case study). OSHA has since pursued a general industry enactment of their workplace ergonomics protection standard (EPS), the first draft of which was released in March 1995 (OSHA, 1995). Neither the profession of ergonomics nor manufacturing industries supported the first draft of the EPS because of potential financial ramifications. Efforts to refine the standard into a suitable format continue.

The OSHA again published an ergonomics program standard on 11/14/2000 that went into effect on 01/16/01. Congress overturned the rule in 2001. A major factor in defeating this standard was again the economic impact on industry. In addition, it was felt that there was a multiple factorial etiology for CTS that is the worker's outside of work activities also significantly contributed to the CTS and the industry will not have to pay for the cost of care.

Progress has been made in research and assessment tools for the effect of exertion on upper extremity muscles and structures. The American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV) for hand activity is a method for evaluation of job risk factors due to musculoskeletal disorders of the hand and wrist. The TLV for HAL is aimed for monotask jobs with 4 or more hours of repetitive handwork (www.ttl.fi/workloadexposuremethods June2009).

The level of hand activity is identified by using a scale of 0–10, where zero is virtually no activity to a level of 10 (highest imaginable hand activity) The normalized peak flow (NPF) is the relative level of effort on a scale of 0–10 that a person of average strength would exert in the same posture required by the task (v1.52/17/02 2002 Thomas E Bernard and ACGIH).

Hand Activity Level (HAL) TLV Scoring Sheet

HAL/TLV Scoring Graft Tiffany Cash described in her Thesis and Dissertations "Using the Strain Index and TLV for HAL to Predict Incidence of Aggregate Distal Upper Extremity Disorders in a Prospective Cohort" 2012 that if the job falls above the TLV line on the graph, it is said to be hazardous to most workers. If the plotted line falls below the AL (action level) line it is said to be safe for most workers.

The wrist SI includes six putative risk factors (force, repetition, percent, duration of exertion, postural, speed of work, and shift duration and was derived from epidemiology of (Moore and Garg, 1995). Garg et al. (2012) studied a cohort of 536 workers monthly for a period of 6 years to determine if the TLV for HAL and the SI were useful metrics for estimating exposure to biomechanical stressors. "Both the TLV for HAL and the SI were found to predict risk of CTS when adjusted for relevant covariates."

Workplace and industrial risk factors for CTS was a cross-sectional study published in 2011. This study concluded that the quantitative and rating space job exposure measures were each associated with CTS and that obesity increased the association between frequency and exertion and CTS (Burt et al., 2011).

The value of these entities is that they allow not only the ability to design research tools to investigate the relationship of these factors, but also the ability to assess the safety of workplace tasks. Thus, jobs can be modified to prevent the development of CTS. These research and measurement methods allow industry to design systems that are less likely to contribute to the development of CTS. The concept of action level in TLV certainly placed traumatogens in the realm of industrial toxicology.

CASE STUDY

In 1990 OSHA published its Ergonomics Guidelines for the Meatpacking Industry (OSHA, 1990). This directive was developed in cooperation with the meat industry and the American Meat Institute (AMI) trade association in an attempt to combat the extraordinarily high and ever increasing incidence of CTDs among industry employees.

It is speculated that the meat industry has the highest rates of CTS because of the high percentage of the workforce that performs hand-intensive tasks. Further, the meat industry faced severe engineering constraints on equipment development as a result of the random shapes of their products and strict sanitation requirements. Although the financial benefits of an ergonomic risk management program are understood among health and safety specialists, it was believed that direct legislation would provide the necessary impetus to initiate proactive intervention programs and keep them

going. Thus, OSHA and AMI developed the first industry-specific ergonomic guidelines in an attempt to control CTD incidence.

The meatpacking ergonomics guidelines encourage management commitment as evidenced by a written company program, employee involvement, and regular program review and evaluation. The guidelines, while being flexible enough to be adapted to the needs and resources of each employer, provided policy on the following four program elements: (1) worksite analysis, (2) hazard prevention and control, (3) medical management, and (4) training.

The results of 4 years' postguideline experience are encouraging. Although still 30 times greater than the general industry norm, CTD incidence in the meat industry has demonstrated a promising trend since 1991, during which time rates have declined by almost 16%. These data support the notion that employer ergonomics programs in the meat industry are working and that OSHA's Ergonomics Guidelines for the Meatpacking Industry are having a positive impact.

CONCLUSIONS

Carpal tunnel syndrome, a compression neuropathy affecting the median nerve, may develop whenever task demands habitually exceed a worker's capacity to respond to those demands. Personal or medical factors might predispose certain individuals to the development of CTS such that, in the absence of sufficient physiological recovery, relatively inconsiderable occupational demands may impose mechanical stresses on the musculoskeletal system.

Hand activity level and wrist SI through ongoing passive and active surveillance of health and exposure data, the effects of workplace hazards may be identified before employees would normally feel compelled to report them. The solution is to balance task demands with worker capacity through the appropriate implementation of engineering and administrative controls.

VIBRATION

DONALD E. WASSERMAN

DESCRIPTION OF THE HAZARD

Vibration is mechanical motion that is defined as a vector, which simply means that it describes motion as consisting of both a magnitude/intensity and a direction; vibration at any point contains six direction vectors, three linear directions, and three rotational directions. (For a complete description of vibration see: Tse et al., 1963; Wasserman, 1987) In the linear direction [i.e., moving along a line, or axis], the total linear motion is described as movement along three mutually perpendicular (orthogonal) "triaxial" directional axes: front-to-rear motion, side-to-side motion, up-down motion (designated as: x -, y -, and z -axes, respectively). Similarly, total rotational motion is described as motion around these same orthogonal axes called: pitch, roll, and yaw. However, as a practical matter, the vast majority of human and/or occupational medical and epidemiology studies and their respective data bases, and its effects on humans are virtually supported only by human vibration linear axes triaxial vibration measurements, predominantly performed as part of these biological studies. Thus, only linear vibration is discussed herein, neither rotational motion nor its measurement, because of this lack of supporting medical and epidemiology effects data to date.

How is the vibration magnitude described and expressed for each of these three axes? To answer that question, a few more vibration basics are needed: When we speak of vibratory motion we usually refer to motion of an object starting at some reference [or neutral] point and then moving off to another position along the same axis. The linear distance the object has traversed is called *displacement*. The units of displacement are given as distances in meters, millimeters, centimeters, inches, feet, miles, etc. It obviously took some

time for that object to move from its initial position to its new position. If we in effect divide the distance traversed by its travel time, we obtain the object's "*speed*" or *velocity* (more precisely mathematically: velocity is the time rate of change of displacement). The units of velocity are a ratio of distance to time, for example, ft/s, inch/s, m/s, cm/s, mm/s, miles/h, etc.

In many instances the speed of a moving object changes over time. The time rate of change of speed or velocity is called *acceleration*. The units of acceleration are distance/time/time, or m/s/s, or ft./sec/sec. It is convenient to compare vibration acceleration to gravitational or "g" units, where $1\text{ g} = 9.81\text{ m/s/s}$. Thus displacement, velocity, and acceleration are three different descriptors of motion magnitude or "intensity" which are all mathematically linked; if you know either one of these three descriptors, the remaining two can be calculated. To answer the original question above: *acceleration* is the measurement of choice to quantify the vibration magnitude/intensity for human exposure to vibration; expressed as either "g" or " m/s^2 ." When performing triaxial vibration measurements we simultaneously measure all three linear axes and obtain three independent measurements for each of these axes. What is eventually sought from these triaxial acceleration measurements is a "vector sum" of the acceleration values for all three x , y , z directions; representing the overall total linear vibration exposure for the moving point.

In addition to direction and acceleration, the *frequency* of vibration must also be known. Vibration frequency is expressed in hertz (Hz). The elemental or simplest form of vibratory motion is sinusoidal (like a pure single frequency sound emanating from a vibrating tuning fork). The frequency is defined as the number of times in 1 s that a cycle is completed; 10 complete cycles/s = 10 Hz; 1000 complete

cycles/s = 1 kHz; 1,000,000 cycles/s = 1 mHz, etc. However, in reality most power tool or vehicle vibration is complex, that is, it is composed of a mixture of multiple varying frequency sinusoids appearing together forming a complex mixture. This vibration mixture can be decomposed into a display called a "vibration spectrum." This method is called Fourier analysis and is capable of analyzing and decomposing a complex vibration time mixture into all of its elemental (sinusoidal) frequencies and corresponding acceleration/intensity amounts which composed the original complex mixture. This analysis technique can be likened to a familiar technique used in chemistry for many years called "spectroscopy" wherein an unknown compound is similarly analyzed (mathematically decomposed) into all its elements, including the calculation of their corresponding concentrations for each element composing the original compound and then visually displaying all as the total composition spectrum of the original compound. Know that sinusoidal vibration is usually periodic and thus repeats its motion over and over again, but all vibration need not be periodic, it could be impulsive (bursts) and/or random depending on the characteristics of the vibrating source.

Finally, there is a unique vibration characteristic and parameter that particularly concerns both health professionals and engineers; it is called "resonant" frequency or natural frequency vibration. Resonant frequency vibration is an aberrant and undesirable condition whereby a small amount of input vibration impinging on a system or structure produces an uncontrolled, exaggerated, and undesirable amplified response. This occurs when the input vibration mechanically excites the natural frequency within a structure. For instance, soldiers marching in cadence across a bridge induce in-phase vibration into the bridge structure, which in turn mechanically excites the bridge structure by naturally tuning to this pounding vibration and then the structure actually makes things worse by internally amplifying this vibration causing the bridge to sway and collapse. To avoid bridge damage, soldiers *never* march across a bridge. Instead, they will break the unified rhythm of marching cadence and simply walk normally when crossing. At resonance the vibration energy transfer from the source to the structure is very efficient and is easily tuned and amplified and therefore most likely to cause damage. Unfortunately, like mechanical structures, the whole human body and individual organs have resonant vibration frequencies too which respond similarly to the structure just described and must be avoided when subjected to vibration; for example, whole-body vibration (WBV) resonances occur: 4–8 Hz vertical up-down "z"-axis; 1–2 Hz for either, front-back "x"- or side-to-side "y"-axes. It becomes increasingly obvious that human resonances usually represent the Achilles heel of human vulnerability to impinging exposure to vibration, mainly because it takes only a small amount of vibration energy at any of those resonant frequencies to trigger an exacerbated

human response to this input vibration, as compared to nonresonant vibration frequencies impinging on the human body, at the same point, exposure time, and axis, which requires much more vibration exposure to elicit the same response.

WHOLE-BODY AND HAND-ARM VIBRATION

Human vibration exposure is customarily subdivided into ubiquitous WBV and (segmental or hand transmitted or) hand-arm vibration (HAV). Whole-body vibration affects the entire person; typical sources include cars, highway and off-highway trucks, forklift trucks, buses, trains, heavy equipment and farm vehicles, subways, aircraft, hovercraft, and fixed machinery in buildings, etc. Hand-arm vibration exposures come primarily from vibrating hand operated power tools such as gasoline-powered chain saws and brush cutters; pneumatic, hydraulic, and electrically powered tools such as chippers, grinders, drills, scalers, rivet guns, nailers, sanders, impact hammers, jackhammers, jackleg type mining tools, etc. Occasionally there are crossover situations between WBV and HAV, for example, a worker using a jackhammer ripping up a road: if the hammer is operated with the hands extended away from the workers body, it is a HAV problem; but if the worker operates the hammer where both the hands and tool are drawn in touching the body at the abdomen, chest, pelvis then it becomes a WBV problem; since vibration now can enter the body via multiple pathways. In order to cause damage to the body, vibration *must* come into physical contact with the body; where physical contact occurs defines its potential damage entrance and route.

All human triaxial vibration measurements are obtained using three, light-weight [i.e., <15 g each] accelerometers, each mounted perpendicular to each other on a small metal cube. This method allows all three perpendicular [triaxial] vibration axes to be measured simultaneously. The location and orientation of the cube are specified by internationally agreed upon methods and directions: *biodynamic coordinate systems* (Figures 103.1 and 103.2).

The biodynamic coordinate system shown in Figure 103.1 is used for WBV measurements, where the *z*-axis is vertical vibration defined as up-down motion from head-to-toe, the *y*-axis is motion across the shoulders, and the *x*-axis is motion from front-to-back. In practice, for example, a driving situation, all three axes (triaxial) measurements are obtained simultaneously using a special pie-plate size hard rubber disk placed between the top of the driver's seat cushion and the buttocks. Buried in the center of this disk are three tiny accelerometers and their preamplifiers each mounted orthogonal (perpendicular) to each other on a common small metal cube. For triaxial measurements each of the accelerometer output signals is simultaneously conditioned, amplified, digitized, and stored for later computer analysis.

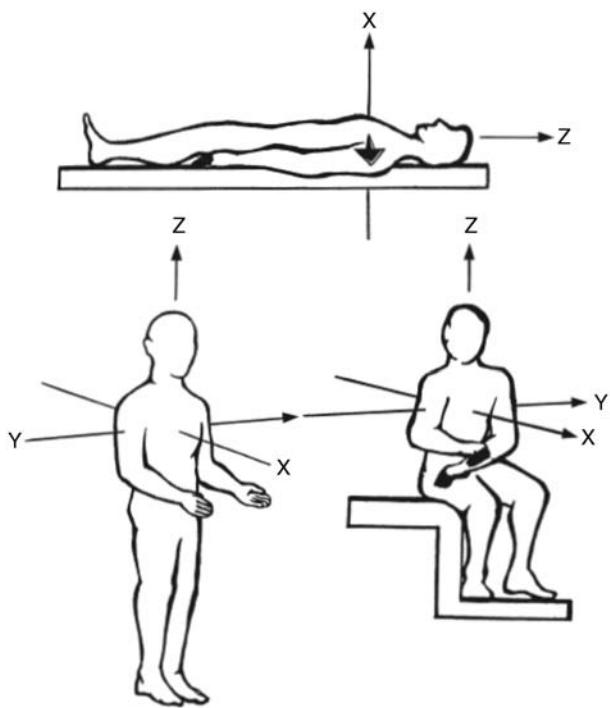

FIGURE 103.1 Biodynamic coordinate system used to assess whole-body vibration.

The biodynamic/basicentric coordinate system shown in Figure 103.2 is used for HAV measurements, where the z -axis defines motion along the long bones of the HAV, the y -axis defines motion across the knuckles, and the x -axis defines motion through the palm of the hand. Although the point for HAV measurements is defined at the third knuckle or metacarpal, as a practical matter HAV measurements are usually obtained on the actual tool handle(s) near where the hand(s) grasps the tool using only the basicentric coordinate system. In practice, three small accelerometers each with built in preamplifiers are perpendicularly orientated to each

other and all are mounted to a single small metal cube, which in turn is mounted to a hose clamp. This entire clamp assembly is then oriented and clamped snugly around the vibrating tool handle, and [as before] each of the accelerometers output signals is electronically conditioned, amplified, digitized, and stored for later computer analysis. Dual handle tools usually require a second independent triaxial accelerometer clamp assembly.

In both WBV and HAV triaxial measurements, each axis of acceleration is recorded over time; as early as the 1970s it took a very sophisticated and expensive computer system to perform a Fourier spectrum analysis, which identified and separated the vibration signal into its component sinusoidal frequencies and performed other needed calculations. Today with the advent of modern solid state electronics and special software a Fourier analysis is no longer needed when performing an initial vibration survey; because this initial survey simply asks the question: is this device being vibration tested in compliance with or has it exceeded the recommended vibration exposure standard[s] criteria, programmed into the measurement computer? If the answer is that the tested device HAS met all exposure criteria then the initial survey has been successful. If the answer is that the device has exceeded the exposure criteria, then if the problem is to be solved, usually much more data analysis is required where a Fourier spectrum computer analysis, etc. is then needed as well as other engineering techniques beyond the scope of this presentation. Today several hand-held and portable basic vibration survey instrumentation, some with portable printer and/or PC interfaces, have been developed which collect data and perform these basic calculations; all are commercially available.

Finally, there are two more important critical vibration measurement concepts, briefly presented next, which the reader needs to know before a meaningful discussion of HAV and WBV standards can be given—here is our *problem*—in order for vibration workplace exposure measurements to be meaningful, these measurements must

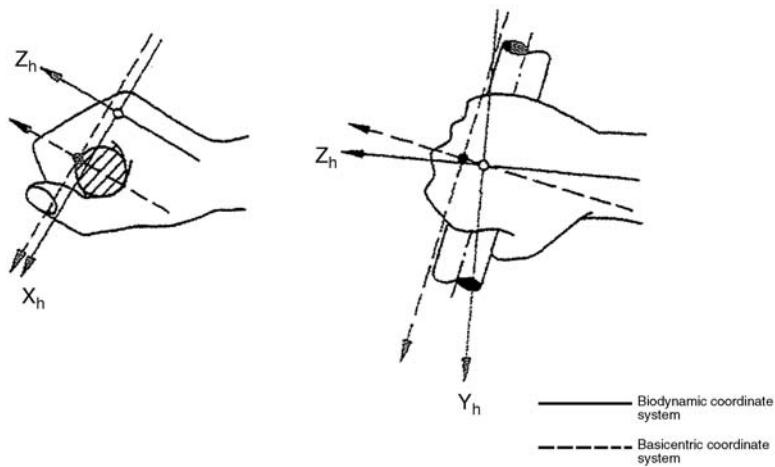

FIGURE 103.2 Biodynamic and basicentric coordinate systems used to assess hand-arm vibration.

attempt to exemplify, characterize, and quantify the [overall] typical daily vibration exposure dose impinging on a tool operators hands for HAV, or in the case of WBV the entire human body, for say a truck driver. *Answer:* Since it is neither practical, nor economically feasible to return multiple times to obtain more measurements over time, since *vibration conditions commonly change daily!* How can this practical dilemma be solved? *Answer:*

First, we must average the triaxial acceleration data collected, specifically, when triaxial acceleration data is originally collected, digitized and stored, for each of the three axes, separately we must mathematically calculate the so-called *root-mean-squared* (rms) acceleration values of the data, because the resulting rms value of acceleration is proportional to the energy impinging on the human body and in our case these rms values are a form of averaging the vibration exposure over time, namely, over a daily work shift, and small variations of daily exposure data are also averaged; the process gathers all the “raw” vibration, including peak vibration data and then calculates its [average] rms values; a rms example: in the case of a sinusoidal vibration its rms value is 0.707 of the peak or largest amplitude value.

Second, a *weighting function* is needed, because of resonance and that human response for either HAV or WBV is “*not linear*,” rather it is frequency, axis, acceleration, and exposure time dependent. Thus, for example, one unit of vibration acceleration in a given direction/axis, time, and frequency impinging on a human, does not necessarily produce the same biological damage as compared to the same unit of acceleration, same axis, same exposure time, but at a different frequency. So what has been developed over the years, each for HAV and WBV, are mathematical curves and expressions called “*weighting functions*,” whose purpose is to attempt to mimic and characterize human HAV response by axis, exposure time, for frequency and acceleration; and similarly human WBV response by axis, exposure time, for frequency and acceleration. All HAV standards try to use the same HAV weighting function; similarly so do all WBV standards try to use the same WBV weighting function too.

Third, know that both human HAV and WBV exposure standards use the following nomenclature to express acceleration values as:

“Weighted rms acceleration, m/s/s” or “weighted rms acceleration, g.” For each linear triaxial direction or axis; or as an overall expression of total “X, Y, Z overall weighted rms acceleration vector sum.” In either m/s/s or “g” [where 1 g = 9.81 m/s/s].

To permit vibration measurements to be compared worldwide

All WBV standards use the same triaxial directions or axes [Figure 103.1].

All HAV standards use the same [basicentric] triaxial directions or axes [Figure 103.2].

OCCUPATIONAL VIBRATION STANDARDS

Standards of good practice for the evaluation and control of occupational exposures to vibration used in the United States and elsewhere are customarily divided into separate WBV standards and separate HAV standards:

Whole-body vibration *standards* used in the United States as follows:

International Standards Organization (Geneva), ISO 2631-1, “Guide to the Evaluation of Human Exposure to WBV” [1974 to present; use latest release version].

American Conference of Government Industrial Hygienists (ACGIH, Cincinnati), standard for: WBV [1997 to present].

EU Vibration Directive. European Communities (Brussels), 2002/44/EC, [2005].

HAV *standards* used in the United States as follows:

ACGIH (Cincinnati), standard for HAV [1984 to present]

International Standards Organization (Geneva) ISO 5349, Parts 1 and 2 “Guide to the Measurement & Evaluation of Human Exposure to Vibration transmitted to the Hand,” [1984 to present; use latest release version].

National Institute for Occupational Safety and Health (NIOSH, Cincinnati), Document #89-106, “criteria for a recommended standard for HAV,” [1989].

EU Vibration Directive, European Communities (Brussels), 2002/44/EC, [2005].

American National Standards Institute (New York), ANSI S2.70-[2006], “Guide for the Measurement & Evaluation of Human Exposure to Vibration Transmitted to the Hand.”

Standards Notes

1. Before attempting vibration data measurements, it is imperative that the user obtain a complete, up-to-date latest version of the standard to be used and thoroughly understand it before collecting and analyzing vibration data. To do less is folly!
2. From 1971 to the present this author has actively worked and significantly contributed to this area of occupational vibration for more than four decades. Much of this time has been spent with national and international colleagues on the development and promulgation of virtually all HAV and WBV: ISO, ANSI, ACGIH, and NIOSH vibration exposure standards used in the United States and elsewhere. Please be aware herein. I will briefly discuss each of the above listed standards and try to provide insight into these standards, but the final choice of their usage is simply yours—the reader or user to make—thank you.

3. Currently in the United States there are *no* mandatory occupational protective standard; as in many other fields related to worker health and safety, all HAV and WBV standards in the United States are voluntary “consensus standards.” The U.S. Occupational Safety & Health Administration [OSHA] have issued *no* standards for exposure to vibration to date. It is known that OSHA is well aware of occupational vibration issues and has been known to cite and fine employers regarding vibration using the legal provisions known as the General Duty Clause of the OSHA Law passed in 1971. The OSHA’s sister organization NIOSH created under the same law, has been actively involved and working on occupational vibration problems since 1971 [when I was the NIOSH vibration group’s first Chief] and continues through the present day. By contrast, the 28 nation European Union in 2005 issued and enforces a law [called a “EU Directive”] regarding [separate] exposures and rules regarding HAV and WBV.
4. ISO and ANSI each regularly review their standards every 5 years and determine if and what revisions are necessary; if needed their standards are so modified. Thus it is imperative that you use the latest version of the standard for best results.
5. For HAV: the total weighted triaxial rms acceleration vector sum is:

$$A_{TH(rms)} = \sqrt{A_x^2(rms) + A_y^2(rms) + A_z^2(rms)}.$$

6. For WBV: the total weighted triaxial acceleration vector sum for each of the three orthogonal directions (as seen in Figure 103.1) in either a supine, seated or standing operator posture is: A total = the square root of the sum of the individual squares[i.e., A_x , A_y , A_z] as modified in the following:

$$A_{T(rms)} = \sqrt{1.4A_x^2(rms) + 1.4A_y^2(rms) + A_z^2(rms)}.$$

Whole-Body Vibration Standards Used in the United States

ISO 2631[1974-to present]: Is the first, oldest, and well-known occupational vibration exposure standard in the world. Original development by ISO/technical committee 108 experts began in the late 1960s and it was publically issued and promulgated worldwide in 1974. At that time, much of the initial research data which contributed to the formulation of ISO 2631’s development arose first primarily from many diverse military situations where WBV was a serious factor determining the outcome of missions involving: high speed fighter aircraft; the effects of buffeting on bombers and air tanker crews; helicopter piloting operations

in military situations, crews operating ground vehicles such as military tanks and troop carriers; and maintaining the ability of naval gunners to accurately firing warship guns in rough seas. The civilian sector also contributed to the WBV knowledge base: data came from the auto industry describing WBV resonance research; data also was contributed by some heavy equipment and farm tractor manufacturers too. Because of the military aspects of the data, initially the main focus of this document was on human “mission critical performance proficiency” under vibratory environments, later called “fatigue decreased proficiency” or FDP. Unfortunately in the early 1970s, supporting WBV exposure chronic occupational health epidemiology and clinical data was sparse and was needed; the medical effects of WBV on the lumbar spine was discovered and elucidated after the first standard was published.

The heart of the early ISO 2631 standard [1974–1996] was the development of “weighting function curves” shown in Figure 103.3 [vertical z-axis] and Figure 103.4 [both x- and y-axes]; the frequency range of 1–80 Hz is designated as the WBV bandwidth as shown in both Figures. The “flat trough” of each weighting function is the resonance range for each respective axis; because humans are of different physical weights, there is a narrow resonant frequency spread of 4–8 Hz in Figure 103.3 looking at the “U”-shaped exposure time-dependent weighting curve for the vertical “z”-axis; similarly in Figure 103.4 from 1 to 2 Hz resonance band looking at the “hockey stick”-shaped exposure time-dependent weighting curve for either or both “x- and y”-axes. These “flat resonant frequency troughs” in both Figures 103.3 and 103.4 represents the smallest permissible allowable vibration intensity [rms acceleration] for any daily WBV exposure time; all because of the internal amplification of impinging vibration at resonance and the body’s extreme sensitivity to WBV. Notice, in Figure 103.3 for example, frequencies on either side of the resonance band [i.e., <4 Hz or >8 Hz] which shows that there is increasing tolerance and thus more allowable exposure time for nonresonant vibration impinging on the body. This same description and logic applies to Figure 103.4 where resonance is 1–2 Hz, when looking at nonresonant frequencies >2 Hz.

The major downsides of this original standard are essentially as follows: When using these graphical curves, unfortunately, a Fourier spectrum analysis must be used and it is highly technical and laborious; three spectra must be generated, each separately for the x-, y-, z-axes. Once these spectra have been determined, each must be separately compared to their respective curves by overlaying each spectra over the appropriate curves with a knowledge of daily WBV exposure for that particular work situation. The results are usually profound and dramatic; one can immediately determine if this standard has been exceeded, if so, at what vibration frequency(s); what directional axis or axes; over what daily exposure time, etc. If the problem is to be solved said

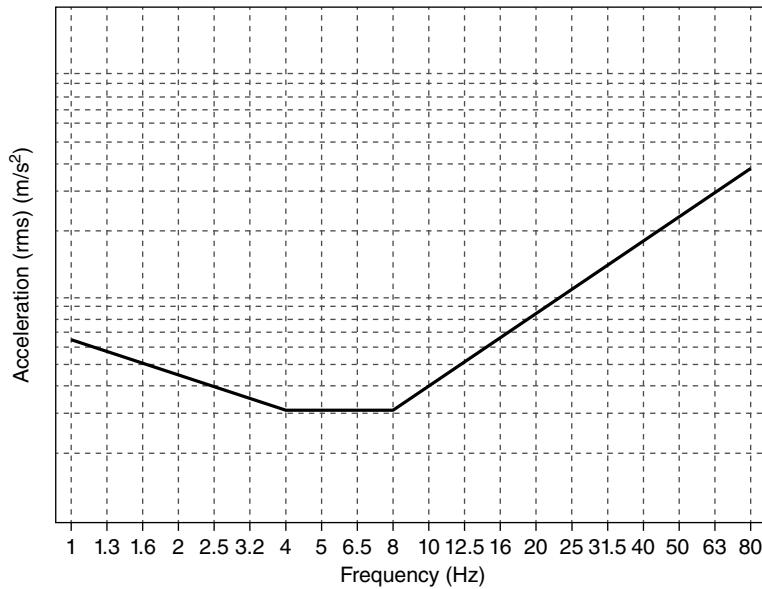

FIGURE 103.3 Early initial whole-body vibration std. weighting curve used to evaluate vertical z -axis root-mean-squared acceleration.

information can be used directly help to solve the problem. Unfortunately, highly trained personnel must do the work using expensive equipment. The standard also has another downside with regard to large peak or spiked WBV when measuring vehicles traversing off road conditions and travel over large road bumps. The term is called crest factor = the ratio of peak acceleration to rms acceleration. This standard does not determine human risk well; in fact it underestimates risk if the CF is >6 , or a modest road bump. Why? This was simply because much of the data which became the basis of this

standard were mostly based upon sinusoidal vibration and not bumps on the road impact peaks.

Thus in 1997, for other technical reasons ISO 2631 went through major revisions and the WBV weighting function graphs described above would no longer be used as given, the weighting functions per se have been retained now extending from 0.5 to 80 Hz and the WBV calculations have increased mathematically and newer [4th.power] concepts have been introduced into later versions of ISO 2631; now more robust and employing multiple sections, including much new

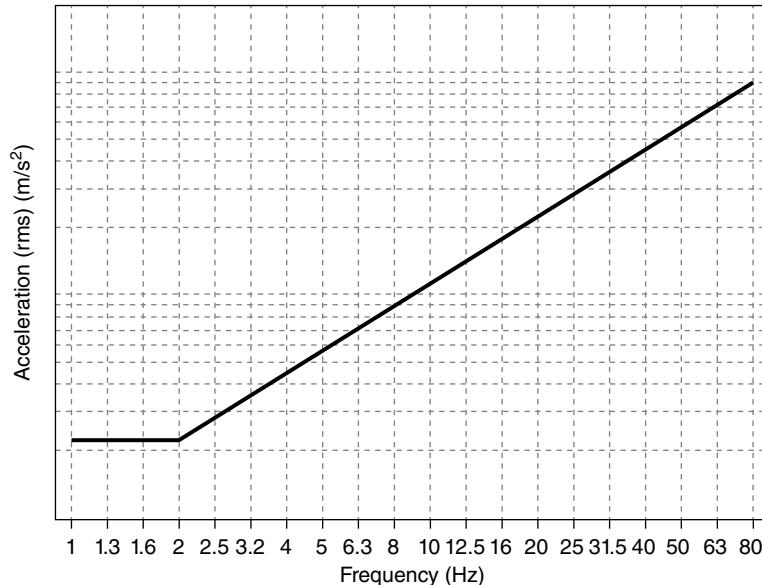

FIGURE 103.4 Early initial whole-body vibration standard weighting curve used to separately evaluate transverse x -axis and y -axis root-mean-squared acceleration.

information on sorely needed WBV impact vibration; the new focus is toward WBV and operator “posture” as an important new knowledge contribution of spinal issues resulting from WBV exposure. Thus current versions of ISO 2631 are technically much more robust, broader in scope and resulting in a more complex document.

The ACGIH [1997 to present]: WBV standard: In 1997 just as ISO chose to and replaced its original version of 2631, the ACGIH stepped in, without a WBV standard of their own, and announced they would adopt the original 2631 WBV standard, about to be replaced. ACGIH did so with full knowledge of its rich history and limitations; to this day this early version of 2631 remains the ACGIH WBV standard.

EU WBV Directive [2005]: All previous standards discussed are voluntary “consensus” standards. However, in 2005 the 28 nation European Union has taken both their WBV and HAV standards to a new level; *both* vibration standards became EU *law* [“called a Directive”] and is so enforced. The EU WBV standard uses the ISO weighting function and is briefly discussed here; the EU HAV standard also uses the ISO HAV weighting function and is discussed later with other HAV standards.

First, the EU Directive clearly states that the responsibility for the health and safety of employees exposed to either WBV or HAV rests with the employer, *not* the product manufacturer whose products are the sources of vibration. Further, the EU requires each employer to due diligence and seriously and carefully investigate [vibrating] products before purchasing said products for use by their employees, and to properly maintain these products since the employers will ultimately be held accountable! With regard to the actual WBV emanating

from a product or process and daily impinging on workers, the EU requires the said products to be triaxially acceleration tested and the EU requires the results be expressed as a “weighted triaxial acceleration vector sum”; the EU WBV standard states for an 8 h/day WBV exposures: daily exposure action value [DEAV] = 0.5 m/s/s, [weighted vector sum] and daily exposure limit value [DELV] = 1.15 m/s/s [weighted vector sum]. If for an 8 h exposure, said weighted triaxial acceleration vector sum is <0.5 m/s/s then the vibrating device can be used for a full 8 h daily shift; if this weighted value is = 0.5 m/s/s or is >0.5 m/s/s, corrective action must begin to effectively reduce WBV exposure; if the DELV weighted vector sum value = 1.15 m/s/s, this represents the upper limit value which shall *not* be exceeded.

Hand-Arm Vibration Standards Used in the United States

For HAV, all standards listed and discussed herein [ISO 5349, Parts 1 and 2, ACGIH: HAV Std., NIOSH 89-106, EU DIRECTIVE: HAV, ANSI S2.70-2006] use the same frequency-weighting function shown in Figure 103.5 when making and analyzing HAV measurements data, but there are very significant differences among these various HAV standards as to how the results are used and interpreted; especially so with the NIOSH criteria document (#89-106) which mentions this weighting function, but does not explicitly endorse it. All other HAV standards discussed here endorse the Figure 103.5 depicted weighting function. Why there are differences among these standards? Mostly because each standard is rooted and based on the medical/

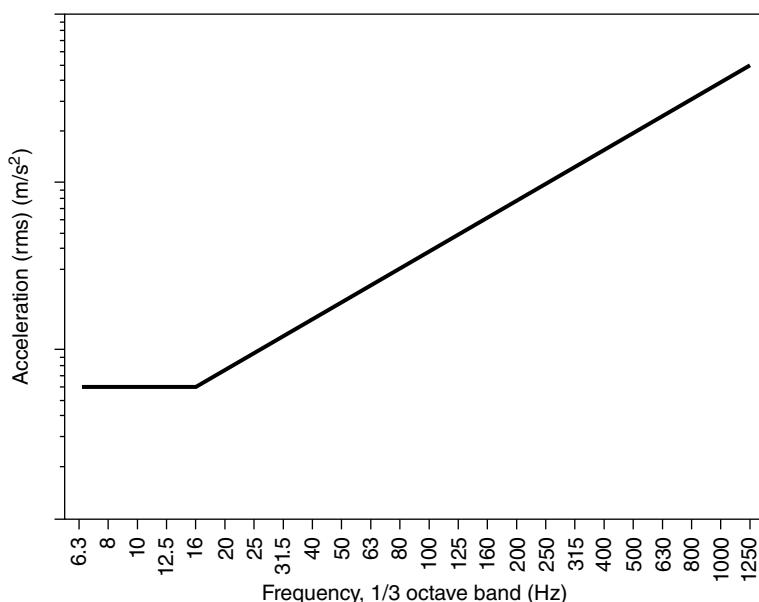

FIGURE 103.5 Per ISO 5349: Hand-arm vibration weighting curve used to evaluate *x*-, *y*-, *z*-axes root-mean-squared acceleration.

epidemiological data base available at the time of inception of each standard; over time and new studies said data bases become more robust with hopefully a better understanding of both the disease process and its etiology, but usually not without scientific probing and some controversy.

ISO 5349, Parts 1 and 2 [1984 to present]

The HAV weighting function shown in Figure 103.5, was first introduced in a very early 1980s draft version of ISO 5349; this standard was later adopted and promulgated circa 1984–1986. Here is a brief description of this weighting function: Please refer again to Figure 103.5, the graphs vertical axis depicts increasing vibration intensity in rms acceleration with the units of m/s^2 . The horizontal graph axis represents vibration frequency in one-third octave bands extending from 6.3 to 1250 Hz. Within the graph is the elbow or hockey stick-shaped HAV weighting function curve. Note that there is a flat portion of the curve extending from 6.3 to 16 Hz, then the curve angles upward beginning at 16 Hz and steadily climbs upward at the same angular slope until it reaches 1250 Hz. The shape of this HAV weighting curve implies that human response to HAV is most sensitive at the lower vibration frequencies [6.3–16 Hz], and that this sensitivity steadily diminishes as the vibration frequencies increase to a maximum frequency of 1250 Hz. In actual practice, this weighting function is separately applied to each axis, thus it is applied to vibration data from the x -axis vibration measurement; then data from the y -axis vibration measurement; then again to data from the z -axis vibration measurement. Each of these measurements thus are mathematically “weighted” for each axis. Next, depending on the HAV standard being used, said weighted axial data can either be converted into a weighted vector sum [i.e., the square root of the sum of the squares of all three weighted axes] or each weighted axis can each be individually examined and evaluated.

Figure 103.5 only defines the HAV frequency bandwidth and the weighting curve shape of the mathematical weighting function for any vibrating power tool being measured; Figure 103.5 as shown does *not* define the acceptable time-dependent *daily HAV exposure limits*; that critical job is left to each HAV standard to determine. Why this obtuse way of determining acceptable exposure limits? ISO 5349 in 1984 originally defined this weighting curve which everyone now uses as shown in Figure 103.5. However, ISO could not reach consensus on the inclusion of acceptable regular HAV *daily* exposure limits, so they simply decided to let each nation [in 1984–1986] determine for themselves what was and was not acceptable for daily exposures, but know 1984 consensus was reached to include “yearly HAV exposures” which did became part of this standard; but a standard without daily exposure limits was an unacceptable alternative for most users who needed it. So other HAV standards later arose, which contained daily exposure limits and in doing so filled the void of this otherwise comprehensive standard. Finally, know that ISO 5349, Parts 1&2, was a hallmark achievement for not only introducing the weighting function, but also for providing of a comprehensive description on how triaxial HAV measurements are made as well as excellent guidelines as to how to correctly analyze the HAV triaxial data.

ACGIH STD. for HAV [1984 to present]: After the aforementioned ISO 5349 decision not to include acceptable daily HAV exposure levels in their standard, the United States had a definite need to have a HAV document with daily exposure levels using the same ISO 5349 weighting function and other related criteria, thus a group of us approached and eventually collaborated with ACGIH to produce the very 1st U.S. HAV standard ever, which DID include acceptable daily HAV exposure values! The standard is shown in Table 103.1 and is briefly described as follows:

TABLE 103.1 ACGIH Threshold Limit Values for Exposure of the Hand to Vibration in either x, y, z directions.

Total Daily Exposure Duration*	Values of the Dominant, [†] Frequency-Weighted, rms, Component Acceleration Which Shall Not Be Exceeded	
	m/s^2	g
4 hours and <8	4	0.40
2 hours and <4	6	0.61
1 hour and <2	8	0.81
<1 hour	12	1.22

Source: From American Conference of Governmental Industrial Hygienists (ACGIH): *Threshold limit values (TLVs) for chemical substances and physical agents and Biological Exposure Indices (BEIs)*, Cincinnati, 1984-present, American Conference of Governmental Industrial Hygienists.

*The total time vibration enters the hand per day, whether continuously or intermittently.

[†]Usually one axis of vibration is dominant over the remaining two axes. If one or more vibration axes exceed the total daily exposure then the threshold limit value has been exceeded.

Note: 1 g = 9.81 m/s^2 .

rms, Root-mean-squared.

All HAV triaxial measurements are measured, weighted, and analyzed as per ISO 5349. As before the weighted values of the rms acceleration are determined separately for each of the three vibration axes; but *no* weighted vector sum is calculated, rather each of the three axes are separately compared to Table 103.1. Refer to Table 103.1, the HAV daily exposure durations and their corresponding maximum weighted acceleration values are given as:

hours and <8; [4 m/s/s]
2 h and <4; [6 m/s/s]
1 h and <2; [8 m/s/s]
<1 h [12 m/s/s]

Usually in HAV measurements one axis of vibration is dominant over the remaining two axes. Also one must know the daily exposure time for the tool being tested. The ACGIH criteria are straight forward: If one or more vibration axes exceed the daily exposure then the [standard] threshold limit value has been exceeded. Thus the axis with the largest weighted acceleration value determines if this standard has been exceeded and for how long per 8 h shift a worker can operate the tool. Why? Because using these axis by axis criteria allows one to immediately determine which axis is most troublesome and with follow up measurements and a spectrum the vibration can be attenuated. Note that 12 m/s/s is the absolute maximum permitted [for <1 h/day use]. If you want to operate a power tool for about 8 h/day, no weighted vibration axis can exceed 4 m/s/s.

What is the downside of this ACGIH standard? Simply, it has never been updated since its inception in 1984 despite prodding by many of us to do so. Although it was the 1st U.S. standard and served us very well, it is terribly out-of-date and is in serious need of revision.

NIOSH HAV CRITERIA DOCUMENT STANDARD [89-106] [1989]: This author was NIOSH's first Chief, Occupational Vibration Group and as such I can assure the reader that since 1971 to the present NIOSH was and continues to be committed to research and the elimination of all diseases related to occupational exposure to HAV and/or WBV. In the late 1970s to early 1980s NIOSH [we] conducted multiple comprehensive pneumatic power tool HAV studies in the United States which showed very high prevalences of irreversible hand-arm vibration syndrome [HAVS] [to be discussed later]. These studies not only prompted ACGIH to develop their above cited HAV standard, but also triggered internal NIOSH activity to begin developing their own sage comprehensive technical document called "criteria document for a recommended standard" in this case for HAV. After much work, in 1989 said document was approved and initially released as NIOSH # 89-106 and has never been revised. It was the premier HAV review document of its day, but it fell short as a practical matter is

unusable primarily because it did not recommend specific safe HAV exposure levels for workers. Its true value lies in fully recognizing the true causal relationship between HAV exposure and irreversible HAVS; it examined all HAV work and studies; it reviewed all existing HAV standards in use at the time and NIOSH became very concerned with the HAV "weighting function" which it acknowledged was needed but did not endorse, rather the document did endorse analyzing and comparing both unweighted and ISO weighted data to themselves and each to disease outcomes; they did endorse both administrative and engineering controls to reduce HAV workplace exposures; they did develop an excellent good work practices guide for HAV/HAVS, re. NIOSH: CIB#38, Pub.#83-110.

EU HAV Directive [2005]: All HAV standards discussed herein are voluntary "consensus" standards. However, in 2005 the 28 nation European Union has taken both their HAV and WBV standards to a new level: *both* vibration standards became EU law ["called a Directive"] and is so enforced. The EU HAV standard is briefly discussed here; the EU WBV standard has been previously discussed.

First, the EU directive clearly states that the responsibility for health and safety of employees exposed to either HAV or WBV rests with the employer, *not* the product manufacturer whose products are the sources of vibration. Further, the EU requires each employer to due diligence; seriously and carefully investigate [vibrating] products before purchasing said products for use by their employees and to properly maintain these products since the employers will ultimately be held accountable! With regard to the actual HAV emanating from all power tools and daily impinging on workers, the EU requires said power tools are to be triaxially acceleration tested and the EU requires that the results be expressed as a "weighted triaxial acceleration vector sum"; the EU HAV standard states for 8 h/day HAV exposures: DEAV = 2.5 m/s/s, [weighted vector sum] and DELV = 5.0 m/s/s [weighted vector sum]. If for example an 8 h/day exposure, said weighted triaxial acceleration vector sum is <2.5 m/s/s then the tested power tool can be used for a full 8 h daily shift; if this weighted value = 2.5 m/s/s, or is >2.5 m/s/s, corrective action must begin to effectively reduce HAV exposure; if the DELV weighted vector sum value = 5.0 m/s/s, this represents the upper limit value which shall *not* be exceeded.

ANSI: S2.70-2006 [2006]: Recall that in 1984 when ISO told member countries that it was up to each to determine acceptable daily HAV exposure criteria, while ISO 5349 chose only a yearly exposure criteria; in the United States, ACGIH responded first in 1984 with their own HAV standard which included daily HAV exposure criteria. Two years later in 1986 there followed a second equally powerful response by ANSI, HAV standard S3.34-1986. This document accepted all the measurements criteria established by ISO 5349 and then added separate sections and graphics needed to determine exposure time-dependent daily HAV

exposure limits; this standard was successfully used in the United States for two decades; it had one downside; a sophisticated and expensive Fourier spectrum analysis was required to evaluate each vibration axis, the resulting spectra were each compared to the now familiar weighting function [Figure 103.5] and the vibration axis with the highest weighted vibration value peak(s) determined the maximum daily use by operators of the tested tool.

In the year 2005, this HAV standard S3.34-1986 needed to be revised or replaced and ANSI thoughtfully made a “sea changing decision,” namely, the U.S. and EU needed *one* uniform HAV standard thus establishing “a flat playing field worldwide” for HAV. The ANSI did *not* want to continue on as before using differing national and international standards needed when the HAV field was young and our collective knowledge of the medical consequences of HAV exposure was an early work in progress! This decision was made in 2005 the same year the EU Directive became law in 28 EU member nations; the ANSI group were very technically and otherwise knowledgeable about the EU requirements; their excellent up-to-date data bases whence their technical criteria were derived; it became increasingly apparent that this new ANSI standard could be done and transitioned seamlessly for use in the United States because power tool manufacturers worldwide had already began complying with the EU law by producing new reduced vibration tools [called “Antivibration or A/V” power tools] to gain entry into the EU markets. The U.S. workers would also receive the same A/V tool benefits if both the EU Directive and the new ANSI HAV standard since *both* required the *same technical requirements and HAV limits*, which is what happened. There is single differing legal proviso and distinction between the EU and ANSI standards: The new ANSI HAV standard was unanimously approved and promulgated became and remains simply a “voluntary consensus standard” in the Unites States; and in the EU, their 2005 Directive remains as their law as originally intended. Thus in 2006 the new ANSI S2.70-2006 HAV standard emerged and was approved, promulgated, and remains to the present day; it is arguably the best overall HAV standard currently in use in the United States. As predicted, better A/V power tool products are now becoming increasingly more available to the U.S. work force because of the above actions.

Since the technical requirements of both the EU and ANSI S2.70 standards are the same [for an 8 h/day; DEAV = 2.5 m/s/s, weighted vector sum, and DELV = 5.0 m/s/s, weighted vector sum], it would be beneficial if the reader would now please reread the above EU Directive basic technical information and then return here to obtain additional information extracted from my review paper (Wasserman, 2008) of ANSI S2.70-2006 as follows:

Definitions: “Daily Exposure Action Value [DEAV] represents the health risk threshold to hand-transmitted vibration. For the purpose of this standard, health risk threshold is

defined as the dose of hand-transmitted vibration exposure sufficient to produce abnormal signs, symptoms, & laboratory findings in the vascular, bone or joint, neurological, or muscular systems of the hands & arm in some exposed individuals.”

Daily exposure limit value, “Workers who are exposed to hand-transmitted vibration at or above this level are expected to have a high health risk. For the purpose of this standard, high health risk is defined as the dose of hand-transmitted vibration exposure sufficient to produce abnormal signs, symptoms, and laboratory findings in the vascular, bone or joint, neurological, or muscular systems of the hands and arms in a high proportion of exposed individuals.”

When the DEAV is exceeded, a program to reduce worker exposure to hand-transmitted vibration needs to be initiated. Further it is recommended that workers *not* be exposed to vibration above the DELV.

A *final word* about vibration standards: The standards information provided here are simply highlights of important aspects of each standard discussed; intentionally it is informative and not comprehensive. If you plan to use these standards to collect and analyze either WBV or HAV vibration data *you must* obtain a copy of the latest version of the standard you plan to use; and thoroughly understand it before attempting to use it. Next is the needed contact information you should wish to obtain any of these occupational standard(s):

[EU VIBRATION DIRECTIVE for WBV and HAV]: European Union, Brussels, Belgium

HEALTH EFFECTS OF OCCUPATIONAL EXPOSURE TO VIBRATION

As an indication of the magnitude of the occupational vibration problem in the United States, about 8 million workers are regularly exposed daily to occupational vibration (Wasserman et al., 1974). Of these, about 6.8 million workers are exposed to WBV and the remaining 1.2 million workers are exposed to HAV. These population exposure numbers represent a diversity of industries and do reflect the very large numbers of exposed workers here in the United States and

many more workers worldwide as industries have spread far beyond the United States to other countries. These large numbers of exposed workers have justified: the large R&D research in this area; the enormous worldwide effort for exposure standards; as well as the worldwide ever increasing pipeline of markets for new AntiVibration power tools; as well development of special personal protective products called AntiVibration protective gloves; and finally for the enormous development of WBV protective seating called “air-ride seating” used worldwide and the United States in trucks, buses, heavy equipment, farm equipment, fork-lifts, hovercraft, trains and subways, and fixed plant installations. Why all of this activity? Simply because there are many heavily documented studies, over the past century, showing severe health effects some, including irreversible damage to workers resulting from regular daily occupational vibration exposures. It is important to know that the health effects of occupational exposure to WBV are very different from the health effects of HAV exposure and thus are addressed separately. The one common thing WBV and HAV do share is the physics of vibration.

Health and Safety Effects of Whole-Body Vibration Exposure

The major populations at risk from WBV are operators of moving vehicles such as trucks, buses, heavy equipment and farm vehicles, and forklift trucks and locomotive drivers. Other populations are helicopter and fixed wing aircraft pilots, hovercraft operators, and persons working near vibrating processes in plants. Early epidemiological studies of truck drivers (Gruber, 1976; Kelsey, 1975), bus drivers (Gruber and Zimmerman, 1974), and heavy equipment operators (Milby and Spear, 1974) often pointed to various musculoskeletal disorders and spinal disk disorders such as degenerative disk diseases and back pain (Hulshof and Veldhuijzen, 1987). Although musculoskeletal and spinal disorders were associated with and were linked to WBV exposure in the work situation, the results were sometimes confounded by other job duties such as lifting cargo among truck and long-distance bus drivers. These early studies led to laboratory studies that could help clarify some of the epidemiological results. For instance, Pope and Wilder in the United States and Dupuis in Germany started to look carefully at the spinal effects of WBV exposure under laboratory conditions. They discovered that, for a seated person subjected to vertical z-axis WBV exposure, the vibration significantly increased lumbar disk pressure and distortion, reduced disk moisture, and increased the risk of disk buckling and instability as well as slipped and herniated disks. Furthermore, in a seated person, the lumbar vertebrae facets tend to disengage, thus limiting vertebrae rotation and prestressing the disks and then adding vibration, exacerbating the stress on the lumbar disks (Wilder et al., 1994). In addition, most of

the vertical z-axis spinal resonance occurs in the L3 segment down to the buttocks where it touches the seat and the resonant frequency is between 4.5 and 5.5 Hz (Wilder, 1993). This means that the lumbar disk resonance is in the same frequency band as the overall human trunk resonance of 4–8 Hz, previously discussed. This is not good news to those workers exposed to WBV who happen to be lumbar spine sufferers they now have two closely allied resonances to deal with. Today the focus of much WBV research is on the spine and operator posture while working in a WBV environments. This is important because the impinging vibration must come in contact or mechanically “couple” to the person; worker posture helps determine this coupling and thus how much WBV actually reaches the spine and other parts of the body.

When the early WBV epidemiological studies were performed, few women worked on traditionally male-dominated jobs such as heavy equipment operations and truck driving. A significant number of women were driving school buses; however, it was extremely difficult to gain access to their medical records in an organized and scientific manner. Thus few epidemiological studies of women exposed to WBV have been performed. During the last few years, female truck drivers and heavy equipment operators have become more prevalent. With that influx, there are scattered reports of female drivers experiencing spontaneous abortions and other gynecological disorders (Seidel and Heide, 1986; Abrams and Wasserman, 1991) and this has prompted animal research in the United States on the effects of WBV on pregnancy.

Whole-body vibration also has a mission component that continues to be of great concern to the military worldwide (Schoenberger and Harris, 1971). Of special concern are the “performance decrements” of military personnel subjected to WBV. In particular, they are interested in ability of air crews, soldiers, and sailors to adequately perform their missions while operating, among others, high performance fighter aircraft, helicopter gunships, high performance tanks, and warships under severe storm conditions. The civilian sector is likewise concerned about the ability of a truck or bus driver to safely drive vehicles when 4–8 Hz resonant vibration appears at the driver’s steering wheel. Under these conditions, their hands can momentarily decouple from the steering wheel and there is an increased risk of a serious accident (Wasserman, 1987). Recent studies have focused on locomotive drivers and spinal issues.

In summary, WBV exposure was first considered as a generalized stressor; however, epidemiological studies have targeted the spine as being at greater risk from this exposure, but not without controversy because of confounding spinal variables. To help clarify and understand WBV’s etiological effects on the spine current WBV lab studies are focusing on worker spinal posture while working in a WBV environment. Now there is added concern about the effects of WBV on female workers and the effects on reproduction and the fetus.

Finally, what began as performance affects studies of WBV in military situations has pointed to the possibility of safety effects of WBV in the civilian sector. The extensive use of air-ride seats in trucks, buses, fork lifts, heavy equipment, and farm tractors has been shown to be effective in helping reduce regular daily WBV exposure.

Health Effects of Hand-Arm Vibration Exposure

In 1918 Dr. Alice Hamilton, the famous occupational health pioneer for whom this text is named, wrote in part the following after carefully investigating numerous medical complaints of finger blanching and related hand problems in a group of Oolitic limestone quarry cutters and carvers who used vibrating pneumatic power tools on the job in Bedford, Indiana:

"The [fingers & hands] trouble seems to be caused by three factors-long continued muscular contraction of the fingers in holding the tool, the vibrations of the tool, and cold. It is increased by too continuous use of the air hammer, by grasping the tool too tightly, by using a worn, loose air hammer, and by cold in the working place. If these features can be eliminated the trouble can probably be decidedly lessened." Alice Hamilton, MD, 1918

Dr. Hamilton's report became the first and earliest comprehensive occupational study causally linking workplace HAV exposure to disease. However, this story really begins much earlier in 1862 with a French physician named Maurice Raynaud who had a clinic in Paris. During the winter months some of his housewife patients complained of repeated cold-triggered attacks characterized by tingling or numbness in their fingers followed by finger "blanching" or whitening and the excruciating finger and hand pain they experienced until these attacks subsided (Raynaud, 1862). Although Raynaud was unable to explain the etiology of this condition, it is now called idiopathic and primary Raynaud's disease. In 1911 Loriga in Italy was the first to briefly and later reported Raynaud's disease-like symptoms in workers using vibrating pneumatic mining hand tools (Loriga, 1934). It was not until 1918 that the very famous Dr. Alice Hamilton provided a very complete, detailed, and the most extensive study to date describing the clinical effects of pneumatic hand-tool vibration and cold on the fingers and hands, stating that there was an 80% prevalence of a condition called Raynaud's phenomenon (Hamilton, 1918). Over time this condition was renamed vibration white finger and is now called HAVS. In 1978 my own NIOSH vibration group repeated the original Hamilton study, at the same location (Bedford, Indiana). We found the prevalence of HAVS to be nearly identical: 82% (Taylor et al., 1984). Sadly, nothing had changed in the 60 years between the original Hamilton study and our own follow-up study except for the new HAV-exposed workers who were afflicted with irreversible HAVS. Thus from this

simple 1918 beginning in Bedford, Indiana and for decades to the present, this one study has triggered a virtual worldwide flood of medical, epidemiological, physiological, and engineering studies all addressing various aspects of regular daily vibrating powered hand-tool use and the subsequent disease process it produces.

Classic HAVS is precipitated by exposure to HAV triggered by cold temperatures, and exacerbated by smoking (Ekenvall and Lindblad, 1989; Pelmear and Wasserman, 1998). Symptoms begin with tingling or numbness in the fingers. As the tool vibration exposure continues, a single white fingertip usually appears during a 10–15-min attack; this is the beginning onset of the so-called blanching process. The time from beginning vibrating tool use to the appearance of this first white fingertip is the blanching "latent period," which can vary from a few months to several years depending on the types of tools used on the job. As the vibration exposure continues, the number, intensity, and severity of the blanching attacks increase, now with progressive finger involvement, but usually does not include the thumbs because of their separate and copious blood supply. In rare instances, if the patient is not promptly treated and the vibration exposure removed, finger gangrene (tissue necrosis) can occur, requiring amputation of the affected digits. For the most part HAVS is considered *irreversible*, more so as the blanching process progresses. Current treatment for HAVS is palliative and *not* a cure; it includes the use of calcium-channel blocker medications, which seem to be better tolerated in older rather than in younger workers. We emphasize that other conflicting medical conditions can make the HAVS differential diagnosis more difficult. Hand-arm vibration syndrome is not carpal tunnel syndrome [CTS]; there have been cases where the afflicted worker had both HAVS and CTS. In the mid-1960s Drs. William Taylor and Peter Pelmear, working in the United Kingdom, developed an HAVS classification system, which is used in the United States and many countries of the world and bears their names (Table 103.2).

In 1986 it became necessary to modify the original Taylor-Pelmear classification system because some patients afflicted with HAVS had no blanching of the fingers; only the early neurological stages of tingling or numbness persisted. The modified classification is the Stockholm system (Tables 103.3 and 103.4) which permits separate grading of the neurological and peripheral vascular components of HAVS for each hand separately (Gemne et al., 1987).

In a comprehensive study of typical metal foundry workers using vibrating pneumatic chipping and grinding hand tools, there were two distinct findings when an incentive system was used. When payment was based on piecework, there was about a 40–50% prevalence of HAVS, with a 1- to 2.4-year latent period to blanching. In the absence of piecework, hourly paid workers in a U.S. Navy shipyard, using the same tools, do contract HAVS but

TABLE 103.2 Stages of Vibration White Fingers/HAVS (Taylor-Pelmear Original System)

Stage	Condition of Fingers	Work and Social Interference
00	No tingling, numbness, or blanching of fingers	No complaints
OT	Intermittent tingling	No interference with activities
ON	Intermittent numbness	No interference with activities
TN	Intermittent tingling and numbness	No interference with activities
1	Blanching of a fingertip with or without tingling or numbness	No interference with activities
2	Blanching of one or more fingers beyond tips, usually during winter	Possible interference with activities outside work; no interference at work
3	Extensive blanching of fingers; frequent episodes in both summer and winter	Definite interference at work, at home, and with social activities; restriction of hobbies
4	Extensive blanching of most fingers; frequent episodes in both summer and winter	Occupation usually changed because of severity of signs and symptoms

at a lower prevalence of 20% with a latent period of about 19 years (Wasserman et al., 1982). Since 1918, there are numerous other HAVS studies using a variety of different power tools, most of which show a direct causal relationship between regular daily power tool use and irreversible HAVS (Pelmear and Wasserman, 1998).

Finally, crossover situations do infrequently occur between HAV and WBV; one example is the use of a

jackhammer-type power tool. When working, if this tool is held and used with hands away from the body, it is an HAV problem; but if the tool is placed against the abdomen to damp vibration, it becomes a WBV problem, where the latter can result in an inflamed omentum (Shields and Chase, 1988; Wasserman, 1989) and the former as HAVS (Pelmear and Wasserman, 1998).

VIBRATION CONTROL

Whole-body vibration control usually includes the following: (1) using air-ride seats in vehicles when and where possible; these AR seats were developed in the early 1970s and have found wide use in vehicles such as trucks, buses, heavy construction equipment, farm vehicles, trains, hovercraft, and fixed equipment control operations. Air ride seats mechanically isolate the exposed operator by allowing this person to ride on a closed cushion of compressed air. (2) Whole-body vibration exposures can be minimized by relocating process controls away from vibrating machinery [e.g., using inexpensive closed circuit TV to remotely view and control the work process]. (3) When driving a vehicle for long periods, upon exiting the vehicle use simple motions, with minimum twisting or rotation, and then walk around for a few minutes before unloading or lifting heavy objects [Wilder et al., 1988; Wilder, 1993].

Hand-arm vibration control is multifaceted and includes the following: 1. Since 1980 various tool manufacturers have introduced newer designed power tools with reduced vibration characteristics [called “AntiVibration or A/V tools”] as alternative choices to conventional power tools. Currently not all conventional power tools have been replaced but the pipeline of new A/V tools continues to steadily grow. Try to use A/V tools when and where possible and when purchasing these tools request vibration test information showing which HAV standards they were tested and compared against.

TABLE 103.3 The Stockholm “Peripheral Vascular” Scale for HAVS (Modified Taylor-Pelmear System)

Stage	Grade	Description
0		No attacks
1	Mild	Occasional attacks affecting only the tips of one or more fingers
2	Moderate	Occasional attacks affecting the distal and middle (rarely also proximal) phalanges of one or more fingers
3	Severe	Frequent attacks affecting all phalanges of most fingers
4	Very severe	As in stage 3, with trophic skin changes in the fingertips

HAVS: Hand-Arm Vibration Syndrome

TABLE 103.4 The Stockholm “Sensorineural” Scale for HAVS (Modified Taylor-Pelmear System)

Stages	Symptoms
OSN	Exposed to vibration but no symptoms
ISN	Intermittent numbness, with or without tingling
2SN	Intermittent or persistent numbness, reduced sensory perception
3SN	Intermittent or persistent numbness, reduced tactile discrimination, or manipulative dexterity

HAVS: Hand-Arm Vibration Syndrome

2. In 1996, international standard ISO 10819, measurement and certification for reduced vibration gloves [called AntiVibration or A/V gloves] was introduced. A few years later ANSI in the United States adopted this same standard as ANSI S3.40/ISO10819. Both organizations require that tested gloves shall be only full finger protected and tested at an independent lab qualified to perform vibration transmissibility tests per the procedures outlined in said standard; those full finger gloves which meet or exceed this standard are called "certified A/V gloves" and are recommended for use together with A/V power tools, because not only do the A/V gloves provide vibration protection but they also keep the fingers and hands warm and dry to help avoid a HAVS attack triggered by cold temperatures. Only full-finger protected gloves are tested since HAVS virtually always begins at the fingertips and moves toward the palm; thus finger-exposed gloves are never recommended. Finally, using both A/V power tools and A/V gloves needs to be supplemented with the following good work practices guide to workers:

- a] Keep fingers, hands, and body warm and dry
- b] Do not smoke [vibration, cold, and nicotine all are vasoconstrictors]
- c] Let the tool do the work, grasping it as lightly as possible consistent with safe work practices
- d] Do not use the tool unnecessarily and keep it well maintained
- e] For pneumatic tools, keep the cold exhaust air away from the fingers and hands [to avoid a possible HAVS attack]
- f] If signs and symptoms of HAVS appear, seek medical help

ACKNOWLEDGEMENT

This author would like to sincerely thank Dr. Marie Bourgeois, USF for her assistance in the completion of this vibration chapter.

OCCUPATIONAL NOISE

DAVID L. DAHLSTROM

BACKGROUND

We perceive and interpret the series of vibrations being generated and conducted through the air or other media, which impacts our eardrums as “sound.” These sounds may elicit pleasure or pain, depending upon the intensity, frequency, wavelength, and duration of the vibrations. If the vibrations are offensive or unwanted, we refer to them as “noise.” When they occur at high levels as either intermittent (Impact noise) or continuous noise, they may produce harm to those exposed. Offensive noise is often associated with specific work tasks, processes, equipment, locations, and individual work practices; all can be harmful and all can be managed by administrative or engineering controls to minimize or prevent worker injury.

As we age, many people experience a gradual decrease in their hearing acuity known as *presbycusis*. Causes of presbycusis include physiological changes such as the gradual degeneration of the inner ear, changes in inner ear bone structure (otosclerosis), changes in inner ear nerve pathways to the brain, heredity, genetic factors, and more commonly these days, a history of repeated exposure to loud noise, music, or equipment (noise trauma), which damages/desensitizes the hair cells of the inner ear.

- The extent of adverse effects that result from our exposure (frequency, duration, noise type, source and level) to noisy environments in our daily lives, both occupationally and socially, are the result of our evolving modern technological advances. Short-term exposure to loud noise, such as that seen following attendance of concerts and standing too close to the speakers, can cause a temporary change in

hearing (your ears may feel stopped up) or a ringing in your ears (tinnitus). These short-term problems typically resolve within a few minutes or hours after leaving the noisy area. However, repeated exposures to loud noise can lead to permanent tinnitus and/or hearing loss.

From a health and safety standpoint, occupational noise typically refers to hazardous levels of noise generated by various industrial and construction-related processes and operations. Sustained exposure to such hazardous levels can result in a permanent hearing deficit called “noise induced hearing loss” (NIHL). Exposure to occupational noise over extended periods can promote elevations in systolic blood pressure. Occupational noise is also a recognized causal factor in industrial accidents, as elevated and chronic workplace noise tends to impede concentrate, impair communication in emergency situations, and interfere with the ability to hear warning alarms. NIHL remains one of the most common work-related health injuries, largely because noise is a pervasive occupational hazard found in a wide range of industries (ACOEM, 1989). Noise induced hearing loss can be defined as a progressive loss of hearing acuity that develops from chronic exposure to continuous and/or intermittent noise above a threshold of about 85–90 dBA (decibels measured using the A-level decibel scale) (ACOEM, 2002); (ACOEM, 2003). NIOSH recommends that all worker exposures to noise should be controlled below a level equivalent to 85 dBA for eight hours to minimize occupational noise induced hearing loss (NIOSH, 1998). NIOSH also recommends a 3 dBA exchange rate so that every increase by 3 dBA doubles the amount of the noise and halves the recommended amount of exposure time. (NIOSH, 2010).

FACTS AND STATISTICS (NIOSH, 2010)

- Four million workers go to work each day in damaging noise. Ten million people in the United States have a noise-related hearing loss. Twenty-two million workers are exposed to potentially damaging noise each year.
- In 2008, approximately 2 million U.S. workers were exposed to noise levels at work that put them at risk of hearing loss.
- In 2007, approximately 23,000 cases were reported of occupational hearing loss that was great enough to cause hearing impairment. Reported cases of hearing loss accounted for 14% of the occupational illness in 2007.
- In 2007, approximately 82% of the cases involving occupational hearing loss were reported among workers in the manufacturing sector.
- There are an estimated 16 million people working in the manufacturing sector, which accounts for approximately 13% of the U.S. workforce. According to the Bureau of Labor Statistics, occupational hearing loss is the most commonly recorded occupational illness in manufacturing sector (17,700 cases out of 59,100 cases), accounting for 1 in 9 recordable illnesses. More than 72% of these occur among workers in manufacturing.
- Most occupational hearing losses occur so gradually that workers are unaware they are losing their hearing.
- The rate of hearing loss growth is greatest during the first 10 years of exposure. This means hearing loss prevention is especially important for new workers. However, with continued exposure, the hearing loss spreads into those frequencies most needed to understand speech. This means that preventing occupational hearing loss is also important for workers in their mid and late careers.

OCCUPATIONAL HEARING LOSS

It can be difficult to distinguish between occupational and nonoccupational hearing loss. There have been statutory changes at the state level that require agencies to create programs to target early hearing loss. Hearing loss may be temporary, permanent, or a combination of the two. Temporary hearing loss, sometimes referred to as “auditory fatigue,” may become permanent with chronic exposure. The current permissible exposure limit (PEL) established by Occupational Safety and Health Administration (OSHA) is 90 dBA and the specific standard is provided in Title 29 of the Code of Federal Regulations, Part 1910.95. OSHA’s Noise Exposure Standard mandates that employers establish workplace “hearing conservation program” with audiometric testing (OSHA, 2014a, c).

Audiometric testing measures the ability of each ear to hear sound at specific frequencies. This testing is used to detect the extent of hearing loss in each ear.

Hearing loss, which is classified by the part of the auditory pathway that is damaged, may be conductive, sensorineural, central, functional, or a combination of several types. *Conductive hearing loss* results from any condition that interferes with the transfer of sound pressure waves (vibration) through the external or middle ear to the inner ear. Possible causes include ossicle injury, fluid in the middle ear, foreign body, collapsed ear canal, carcinoma, cysts, congenital abnormalities, and infection of the Eustachian tube. This condition is usually reversible through surgery and the prognosis is excellent. *Sensorineural hearing loss*, the type most commonly associated with the occupational NIHL, is the result of damage to the hair cells in the inner ear. The damage is medial to the footplate of the stapes in the oval window, the auditory nerve, or both. In most cases this condition is irreversible, occurring at high frequencies around 4 kHz (kilohertz) over months or years of exposure. Millions of industrial workers and older citizens have this form of impairment (Ward et al., 2003; Sataloff and Sataloff, 1987).

Central hearing loss (central dysacusis) is often described as perceptive deafness. The damage is situated in the central nervous system at some point between the cortex and the auditory nuclei in the medulla. The function of the auditory cortex is to interpret and integrate electrical impulses and provide the listener with meaningful information or to permit the listener to react with the actual implication of the sound. It is thought that interference with the neural pattern pathways to the cortex would manifest as the reduced ability to interpret information rather than lowering of the hearing threshold for pure tones (Ward et al., 2003; Sataloff and Sataloff, 1987).

Exposure to excessive noise is not the only cause of occupational hearing loss. There is no discernable organic damage to the auditory pathways in *functional hearing loss*; rather, an underlying psychological or emotional problem is at fault. A variety of organic solvents have also been implicated in ototoxicity and hearing loss. These include toluene, styrene, and trichloroethylene. Occupational exposure to lead, mercury, carbon monoxide, and carbon disulfide can also affect the ear (Nies, 2012). In a 20-year longitudinal study of hearing sensitivity in 319 employees from different sectors of the industry, a significant proportion of the workers in the chemical sector showed pronounced hearing loss (23%), compared to groups from nonchemical environments (5–8%) (Morata et al., 1994). Currently, there are no regulations in the United States that require occupational monitoring for the employees exposed to potentially ototoxic chemicals. Additionally, they may not receive OSHA specified hearing tests if the measured noise does not exceed the regulatory standards

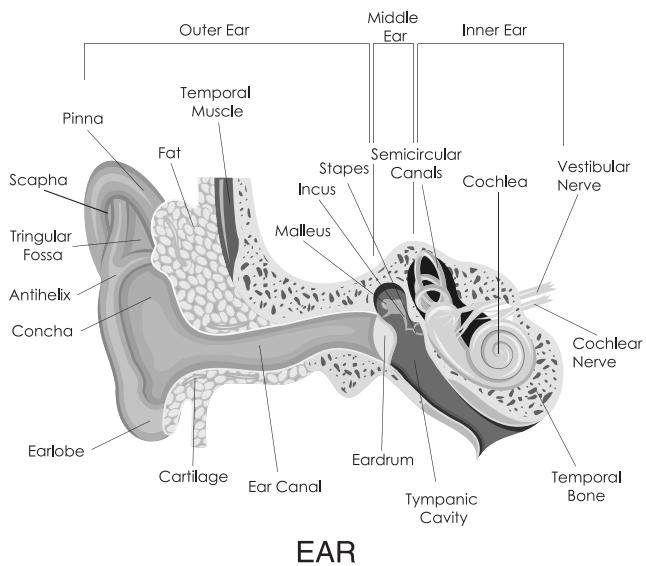

FIGURE 104.1 The Anatomy of the Human Ear.

ANATOMY OF THE EAR

Sound waves enter the pinna (external ear), pass through the auditory canal, and impinge upon the tympanic membrane (eardrum) (Figure 104.1). The eardrum is connected to the cochlea by the ossicles of the middle ear, the malleus (hammer), incus (anvil), and stapes (stirrup). As sound waves strike the eardrum, they are converted to mechanical energy (vibration) in the middle ear. This mechanical energy is transferred via the ossicles to the fenestra vestibule where it creates waves in the inner ear fluid. These waves stimulate the roughly 10,000 microscopic hair cells located on the basilar membrane along the cochlea. Different groups of hair cell sensors respond to different frequencies based on the stiffness of the hair cell. Excessive noise can damage these hair cell sensors resulting in permanent hearing loss (Silverman, 1996).

PRINCIPLES AND PHYSICS OF SOUND

Noise is a quickly modulating elastic pressure wave moving through a material medium such as a solid, liquid, or gas. When we speak of noise, we usually mean audible sound, which is a sensation detected by the ear of very small rapid changes in the air pressure above and below a static value. This static value is atmospheric pressure. When rapid variations in pressure occur between 20 and 20,000 Hz (20–20,000 times per second), sound is substantially audible even though the sound pressure variation is low. Louder sounds are caused by greater variation in pressure, provided that most of the acoustic energy is in the mid-frequencies (1000–4000 Hz) where the ear is most sensitive.

The rate at which the pressure waves are produced is the frequency measured in cycles per second in units of hertz (Hz). One cycle per second represents the number of times that an air molecule at the sound source is displaced from its equilibrium position, rebounds through the equilibrium position to its maximum displacement opposite in direction to the initial displacement and then returns to its equilibrium position (Standard, 1996). There is a period associated with the frequency of the wave, measured in seconds, which is the time required for each cycle and is merely the reciprocal of the frequency. The wavelength is measured in meters, centimeters, or feet. It is the distance measured between two equivalent points on two successive parts of the wave and is the distance the sound travels in one cycle. The amplitude of the pressure disturbance is directly related to the displacement amplitude of the sound and is expressed in units of force per unit area. Common units of pressure are newtons per meter squared (N/m^2), micropascals (μPa), dynes per centimeter squared (d/cm^2), and microbars (μbar).

The density and the compressibility of the medium through which the sound wave migrates primarily determine the speed with which sound travels. In air, the speed of sound is approximately 344 m/s at normal temperature and pressure (NTP) ($25^\circ C$ and 760 mmHg) or 331.6 m/s at standard temperature and pressure (STP) ($0^\circ C$ and 760 mmHg). The speed of sound in water is approximately 1500 m/s and in steel about 6100 m/s. Velocity of sound is the speed of sound equal to the wavelength times the frequency.

If we were to calculate the mean value of the sound pressure disturbances, we note the mean value to be zero because there are as many negative rarefactions as positive compressions. A practical approach to measuring sound pressure is the root-mean-square (rms). The rms measurement is obtained by squaring the value of the sound pressure at each instance in time, adding the squared values together, and then taking the mean over the given time. Because squaring values converts negative numbers to a positive value, the rms method produces nonzero measurements of the sound pressure magnitude.

The sound pressure range frequently encountered is remarkably wide. The weakest sound pressure that can be heard by a young, healthy, human is approximately $20 \mu Pa$ at a reference tone of 1000 Hz and is known as the threshold of hearing. The threshold of pain, which is the greatest amount of energy that can be heard without pain, is approximately 200 million μPa . A relative scale is more convenient and easily interpreted and for this purpose a logarithmic dB scale was selected (Table X). The dB is 0.1 of a Bel and is a dimensionless unit related to the logarithm of the ratio of a measured quantity to a reference quantity. The threshold of hearing of $20 \mu Pa$ becomes 0 dB, and the threshold of pain of 200,000,000 μPa becomes 140 dB. The dBA scale is used to weigh the various frequency components of the noise to

TABLE 104.1 Sound Pressure and Sound Pressure Level Values

Sound pressure in μPa	Sound pressure in dB, re: 20 μPa	Example
20	0	Threshold of hearing
63	10	
200	20	Inside bedroom
630	30	Soft whisper at 5 ft
2000	40	Quiet office
6300	50	Large office
20,000	60	Conversation at 3 ft.
63,000	70	Vacuum cleaner
200,000	80	Garbage disposal
630,000	90	Printing press plant
2,000,000	100	Electric furnace
6,300,000	110	Roll 'n' roll band
20,000,000,	120	Hydraulic press
200,000,000	140	Threshold of pain, jet aircraft, artillery fire
20,000,000,000	180	Rocket launch pad

approximate the response of the human ear. A change in sound pressure by a factor of 10 corresponds to a change in sound pressure level of 20 dB (Standard, 1996).

Usually the reference value is the smallest likely value of the quantity (Table 104.1). The dB scale approximates the human ear, which interprets loudness on a scale much closer to a logarithmic scale than a linear scale and the quantities of interest often exhibit such huge ranges of variation that a dB scale is more convenient than a linear.

Sound power describes the sound source in conditions of the amount of acoustic energy that is produced per unit time and is expressed in watts (W). The sound power level (L_w) is expressed in decibels, relative to a reference quantity of 10^{-12} W . It is the total sound power radiated by a sound source, regardless of the space into which the source is placed (Standard, 1996). The relationship is shown below:

$$L_w = 10 \log \frac{W}{W_0}$$

where W = sound power in watts, W_0 = reference sound power (10^{-12} W), and \log = logarithm to the base 10.

As sound power in free space is radiated, sound power is scattered over a sphere surface. The rate of sound power transmitted in a specified direction per unit area normal to the direction is expressed as the power intensity (W/m^2). The intensity decreases with distance from the source, but the power being the product of the intensity and area remains constant. It is not possible to measure sound power directly.

TABLE 104.2 Reference Sound Values in Air

Sound pressure	0.00002 N/m ² or 0.00002 Pa (0.0002 μbar or 0.0002 d/cm ²)
Sound intensity	$1 \times 10^{-12} \text{ W/m}^2$
Sound power	$1 \times 10^{-12} \text{ W}$

N/m², Newtons per meter squared; Pa, Pascal; μbar , microbars; d/cm², dyne per centimeter squared; W/m², Watts per meter squared; W, watts.
 $1.01 \text{ N/cm}^2 = 0.1 \text{ Pa} = 1 \mu\text{bar} = 1 \text{ d/cm}^2$.

Under most conditions, sound intensity is proportional to the square of the sound pressure (Table 104.2). Sound pressure can be more easily measured than sound intensity. A sound level meter is the principal instrument for broad noise measurement. Most sound-measuring instruments are engineered to provide a reading of rms related to a sound pressure reference quantity. For sound pressure measurements in air, the common reference quantity is 20 μPa . This reference quantity is an arbitrary pressure chosen because it approximates the normal threshold of hearing for a young, healthy human at 1000 Hz. Doubling the sound pressure represents a 6 dB increase in sound pressure level, whereas doubling the sound power results in an increase of 3 dB in the sound power level. The sound pressure level (L_p) measure from an instrument is shown below:

$$L_p = 10 \log \frac{P^2}{P_0^2}$$

where P = measured rms sound pressure, P_0 = reference rms sound pressure (20 μPa), and \log = logarithm to the base 10.

When using a sound level meter, weighting scales are used to provide varying sensitivities to sound of different frequencies. The most common weighting today is dBA and is the scale required by regulatory standards to measure sound levels. The dBA scale is thought to provide a rating of industrial broadband noise that indicates the injurious effects such noise has on the human ear. Another scale used is the C weighting scale and is used to measure total energy in an environment. In addition to frequency weighting, sound pressure can be weighted in time with fast, slow, or impulse response, which is seen in the reading response time. Regulatory standards require sound levels to be measured at slow response.

While conducting industrial noise surveys, it often becomes necessary to add levels of decibels. An industrial hygienist should be consulted to conduct the survey. One of the most basic equations for adding decibels from separate random noise sources applies the following equation:

$$L_p T = 10 \log(10^{\frac{L_p_1}{10}} + 10^{\frac{L_p_2}{10}} \dots + 10^{\frac{L_p_n}{10}})$$

where L_pT = total sound pressure level in decibels, L_{P1} , L_{P2} , L_{Pn} = individual sound pressure levels to be added, and log = logarithm to the base 10.

NOISE STANDARDS

The OSHA has set a standard of good practice for noise exposure (OSHA, 2014b, OSHA 2014c-Construction Industry Standard). The standard states that no employee may be exposed to the equivalent of a steady sound pressure level of 90 dBA for more than 8 h, or to the equivalent of a steady sound pressure level of 95 dBA for more than 4 h, and so on. It also establishes that employees are limited to a noise exposure with a 5 dB exchange rate so that 5 dB increase in sound pressure level constitutes a halving in duration of exposure time.

The OSHA requires that employers make audiometric tests available to employees when noise exposures exceed an 85 dBA criterion. When an employee's audiogram reveals a standard threshold shift (STS), the employee may not be exposed in excess of the 85 dBA criterion. In this case it is acceptable to reduce the exposure from an amount equaling the 90 dBA criterion to the permissible amount by using personal hearing protection devices. Employers are required to use feasible engineering and administrative controls to reduce employee exposures below the 90 dBA criterion. If the feasible engineering and administrative controls are not fully effective, the remainder of the required protections must be obtained by providing and requiring employees to wear personal hearing protection devices.

The American Conference of Governmental Industrial Hygienists (ACGIH, 2013) recommends the limit for employee noise exposure to a 3 dB exchange rate. This may be a better predictor of noise hazard for most practical conditions. A 3 dB increase in sound pressure level constitutes a halving in duration of exposure time. This exchange rate is based on the equal energy hypothesis, which maintains that equal amounts of sound energy will produce equal amounts of hearing impairment, regardless of how the sound energy is distributed in time. On an energy basis, the 3 dB exchange rate provides for the calculation of a mathematically valid time-weighted average (TWA) exposure to noise.

The National Institute for Occupational Safety and Health (NIOSH) (NIOSH, 1996a) is moving to an 85 dB criterion for an 8-h exposure since scientific data reflect that the excess risk of developing occupational NIHL for a 40-year lifetime exposure at the 85 dBA is 8%, which is considerably lower than the 25% excess risk at the 90 dBA PEL currently enforced by the OSHA and the Mine Safety and Health Administration (MSHA) (NIOSH, 1996a). Included in the evaluation is a recommendation for a 3 dB exchange rate, which is more firmly supported by scientific evidence and consistent with the ACGIH recommendation.

105

HEAT STRESS ILLNESS

MARIE M. BOURGEOIS AND DAVID R. JOHNSON

BACKGROUND

According to Occupational Safety and Health Administration (OSHA), operations involving elevated ambient temperatures, excessive humidity, strenuous activity, and exposure to radiant heat or direct contact with hot objects are capable of inducing heat stress illness (HSI) (OSHA, 1999). Occupational Safety and Health Administration does not have a permissible exposure limit (PEL) covering work in hot environments. The General Duty Clause requires employers to provide workers “a place of employment which is free from recognized hazards that are causing or are likely to cause death or serious physical harm to his employees.” It also requires employers to “comply with occupational safety and health standards promulgated under this Act” (OSHA, 1970).

Heat stress discussions involve a lot of acronyms so a few definitions from OSHA will help facilitate the discussion:

- Heat is a measure of energy in terms of quantity.
- Metabolic heat is a by-product of the body’s activity.
- Environmental heat is the contribution of environmental conditions to body temperature.
- Conduction is the transfer of heat between materials that contact each other.
- Convection is the transfer of heat in a moving fluid.
- Radiation is the transfer of heat energy through space.
- Evaporative cooling takes place when sweat evaporates from the skin. High humidity reduces the rate of evaporation and thus reduces the effectiveness of the body’s primary cooling mechanism.
- Thermal equilibrium is achieved when both metabolic and environmental heat production are in balance with

evaporative cooling (i.e., all heat loads are dissipated by sweating).

- Acclimatization is the physiological adaptation that occurs when a person is exposed to heat over an extended period of time. A well-designed acclimatization program exposes employees to work in a hot environment for progressively longer periods to decrease the risk of heat-related illnesses.
- Globe (G) temperature is the temperature inside a blackened, hollow, thin copper globe.
- Natural wet bulb (NWB) temperature is measured by exposing a wet sensor, such as a wet cotton wick fitted over the bulb of a thermometer, to the effects of evaporation and convection. The term natural refers to the movement of air around the sensor.
- Dry bulb (DB) temperature is measured by a thermal sensor, such as an ordinary mercury-in-glass thermometer that is shielded from direct radiant energy sources.

Source: OSHA and other sources.

There are numerous commercial and industrial occupations associated with elevated risk of heat stress illness (HSI), including foundry work, construction, asbestos removal, commercial kitchens, mining, agriculture, utilities, and fire-fighting. Additionally, any activity performed in protective clothing can increase the likelihood of heat stress illness. Heat-related illness can be defined as a range of health disorders stemming primarily from exposure to excessive heat. These conditions include but are not limited to heat stroke, heat exhaustion, heat cramps, heat syncope, and heat rashes. National Institute for Occupational Safety and Health

(NIOSH) defines heat stress exposure as the sum of metabolic heat (generated within the body) and environmental heat (heat gained from the environment) minus any heat lost to the environment through processes such as evaporation (NIOSH, 1986).

Attempts to reduce heat stress illness have led to the development of various indices. Methods are continually refined to improve preventive measures. The effective temperature scale (ET) was developed in the 1920s. It measures humidity, wind speed, and temperature, and remains useful in places with high humidity and a low solar load. Effective temperature scale was modified approximately 30 years later to incorporate the effects of radiant heat and it was called effective temperature, including the radiation component (ETR). The wet-bulb globe temperature index (WBGT) replaced the ETR, and it remains the most widely used index of heat stress (Rowlinson et al., 2014). Wet-bulb globe temperature index was developed in response to the episodic heat illness in armed forces training camps in the buildup to World War II (Budd, 2008). The basic principle is simple; the readings from a NWB thermometer, a G thermometer, and a DB thermometer when indicated are weighed and averaged to calculate a WBGT appropriate to the conditions (Budd, 2008). Natural wet bulb assesses evaporation while GT responds to the environmental heat load. Dry bulb is essentially a modifying factor that incorporates solar load.

- In sunny conditions: $WBGT = 0.7NWB + 0.2GT + 0.1DB$
- In all other conditions: $WBGT = 0.7NWB + 0.3GT$,

where:

NWB = Natural wet-bulb temperature

DB = Dry-bulb temperature

GT = Globe temperature

WBGT = Wet-bulb globe temperature index (OSHA, 1999)

Widespread adoption does not mean that the WBGT is without limitations. Metabolic rate, or work, is a key factor in worker heat stress. The International Organization for Standardization (ISO) estimation method calculates the total metabolic rate (TMR) as the sum of basal metabolism (B), posture (P), work type (W), walking (D), and climbing (C) (ISO, 2002). The WBGT has been criticized for inadequate sensitivity to humidity and air movement. In 2006, the American Conference of Governmental Industrial Hygienists (ACGIH) attempted to account for the contribution of clothing and personal protective equipment (PPE) to heat stress by replacing the unacclimatized threshold limit value (TLV) with an action limit (AL). The AL is designed to be used in conjunction with detailed simplified decision trees for screening. They also developed a formula for an effective

WBGT by adding a clothing adjustment factor (CAF) to the measured WBGT (Soule et al., 2006; ACGIH 2008).

$$WBGT_{eff} = WBGT_{measured} + CAF$$

Some have suggested predicted heat strain (PHS) to cover situations with indeterminate exposures (Bernard, 2014). The PHS was derived by the ISO and permits the calculation of individual contributors to heat exchange. In times when workers exceed the TLV or when the decision trees cannot be employed, ACGIH recommends heat strain monitoring (HST). Heat strain monitoring utilizes core body temperature and oral temperature measurements along with heart rate and perceived strain to assess worker risk (Soule et al., 2006; ACGIH, 2008). The Humidex is another method for combining the effects of humidity and elevated temperatures into a scale to assess the heat stress potential (Smoyer-Tomic and Rainham, 2001). The Humidex cannot be directly compared to the WBGT; however, it is considered a particularly useful parameter in unacclimatized worker discomfort.

SOURCES OF EXPOSURE

Occupational

Although heat-related illness morbidity and mortality is not well documented for multiple reasons, excessive heat exposure has been implicated in more than 9000 deaths since 1994 (Rogers et al., 2007; Jay and Kenny 2010; DeGroot et al., 2013). A preliminary report from the Bureau of Labor on fatal occupational injuries in 2012 noted 31 worker deaths due to exposure to the environmental heat (Bureau of Labor Statistics, 2013). Members of the military are historically considered to be at the greatest risk for heat stress illness; however, some commercial and industrial occupations are just as vulnerable (Larsen et al., 2007; Bernard and Barrow, 2013; DeGroot et al., 2013). Workers may be at greater risk for developing heat stress illness when they:

- are exposed to radiant heat sources,
- come into contact with hot objects,
- are exposed to direct sunlight for prolonged periods of times or,
- are required to use bulky or nonbreathable protective clothing and equipment (ACGIH, 2008).

The majority of early work on heat-related illnesses was done on members of the military. Although the total number of hospitalizations has dropped dramatically in the last few decades, the incidence of heatstrokes in armed forces members has increased eightfold (Carter et al., 2005). It is possible that deployment of poorly acclimatized troops to theaters in the Middle East accounts for much of the increase; however,

it may also be that prevention allowed the personnel to return to the field prematurely. The incidence of heat exhaustion and other heat-related illnesses is quite high in mining where the heat, humidity, and metabolic demands can be physically taxing (Xiang et al., 2013). Agricultural industries have one of the highest risks of heat-related morbidity and mortality. Statistics show that farm workers are up to four times likely to experience heat-related illness than workers in nonagricultural settings (Xiang et al., 2013). Firefighters may be the most obvious cohort threatened by heat-related illness. The protective clothing of firefighters lacks ventilation and they wear a self-contained breathing apparatus (SCBA) or compressed air breathing apparatus (CABA). The majority of firefighters wear a duty uniform under their gear consisting of long pants. The rationale has been that this provided an extra layer of protection. Recent trials in Toronto and New York have shown that replacing long pants and long-sleeved shirt with shorts and a t-shirt reduced the heat strain without an increase in injuries (Prezant et al., 2000; Selkirk and McLellan 2004; McLellan and Selkirk 2006). Manufacturing workers often labor in poorly ventilated facilities that can increase their risk for heat stress illnesses. This includes industries such as automobile manufacture and assembly, foundries, steelworkers, and industrial food-processing facilities.

Environmental

Occupational and environmental exposures may overlap depending on the industry (agriculture in particular). Days with high temperature and high humidity pose the greatest risk.

INDUSTRIAL HYGIENE

There is no specific OSHA standard for exposure to high temperatures because factors such as humidity, solar load, wind and air movement, metabolic load and protective clothing also contribute to the development of HSI. The United States uses WBGT-based occupational exposure limits (OELs) that is based on the ACGIH and the NIOSH recommendations. For more information, consult ACGIH *Threshold Limit Values for Chemical Substances and Physical Agents and Biological Exposure Indices* (ACGIH, 2008). Employers can utilize a combination of good work practices/training programs, worker monitoring programs, PPE, and administrative and engineering controls to keep employees healthy. Early recognition of the heat stress illness symptoms can prevent the progression to heatstroke, so employee education is a key to an effective training program. Workers in extreme conditions (excessive humidity or temperatures, semipermeable, or impermeable clothing, high metabolic load, etc.) should also be personally monitored.

MEDICAL MANAGEMENT

Heat stress illness is best managed through prevention measures. Being aware of the environmental conditions and utilizing weather forecasts and temperature instrumentation such as the WBGT device are key components for prevention. It has been estimated that 90% of the cases of heatstroke occur when the WBGT is 85 °F (30 °C) or more (Jenkins and Braen, 2000). Knowing personal risk factors for developing heat stress illness is useful in avoiding illness in susceptible individuals. The very young (<4 years old) and the elderly (>65 years old) are at increased risk, as are obese individuals, those with chronic medical problems such as diabetes, heart, lung, kidney, or dermatologic disease, and those taking certain medications such as diuretics, sedatives, tranquilizers, antiemetics, anticholinergics, stimulants, some heart and blood pressure medications, medications for psychiatric conditions, lithium, and others. Additional factors that increase the risk of developing heat stress illness include fatigue, sleep deprivation, low fitness, poor nutritional status, acute illness, strenuous exertion, alcoholism, intoxication, and a prior history of heat illness (Druryan et al., 2011).

Educating employees on how to recognize early symptoms of heat stress illness in themselves and fellow workers is of key importance. Symptoms of impending heat illness include fatigue, headache, nausea, muscle cramps, pale skin, profuse sweating, rapid heartbeat, and dizziness. Omnipresent signs of heatstroke, the most serious heat stress illness, include the absence of perspiration, hot dry red or mottled skin, throbbing headache, slow deep respirations, chills, high body temperatures ($\geq 104^{\circ}\text{F}$ or $\geq 40^{\circ}\text{C}$), behavior changes such as disorientation, mental confusion, delirium, irrational behavior, feelings of euphoria, giddiness, or impending doom, slurred speech, hallucinations, and diminished level of consciousness, or loss of consciousness.

Methods to prevent heat illness include wearing loose-fitting lightweight light-colored clothing, maintaining adequate hydration by providing cool water and liquids to workers, scheduling rest periods for workers in the shade or in cool air-conditioned environments, scheduling hot jobs for the cooler part of the day, reducing physical demands of workers in hot environments, using relief workers or assigning extra workers for physically demanding jobs, avoiding sunburn, allowing for employee acclimatization to hot environments when possible and providing employee education regarding symptoms and signs, prevention, risks, treatment, and PPE.

Once heat stress illness has occurred, treatment in general includes moving the victim to a cool environment, rapid cooling if necessary, replenishment of the fluid and electrolytes, and general supportive care.

Treatment varies depending on the type and severity of illness (CDC, NIOSH, Workplace Safety and Health Topics):

Heatstroke: Symptoms and signs of heatstroke include, mental changes, confusion, hallucinations, chills, throbbing headache, and high body temperature ($>104^{\circ}\text{F}$ or 40°C). Classically a victim of heatstroke has hot dry skin; however, there may be profuse sweating if exertional heatstroke develops rapidly in a matter of hours. Seizures and coma are the most common severe complications of heatstroke. The body's thermoregulatory mechanisms fail with resulting high temperatures and potential damage to critical organs. Laboratory testing may reveal multiple abnormalities, including acidosis, leukocytosis, markedly elevated liver enzymes, elevated creatinine kinase, hyperkalemia, hypocalcemia, hypoglycemia, and hypophosphatemia. Coagulopathy may occur and disseminated intravascular coagulopathy is seen in severe cases. Electrocardiogram (EKG) abnormalities may include tachycardia, nonspecific ST-segment and T-wave abnormalities, as well as reversible arrhythmias and heart blocks (Jenkins and Braen, 2000).

Heatstroke is a serious medical emergency; call 911, cool the worker while awaiting transport with such methods as placing ice packs in the groin or axillae, soaking their clothing in water, showering, spraying, or sponging the victim with water in conjunction with fanning the body. Emergency room treatment protocols are well established and involve rapid cooling of the victim, IV fluids, electrolytes and dextrose (carefully administered), oxygen supplementation, intubation if necessary, pharmacologic control of agitation and shivering, and intense supportive care and management of complications such as convulsions, rhabdomyolysis, and hepatic, pulmonary, and renal complications. Despite intense emergency medical care, severe cases can be fatal or leave the victim with permanent mental or physical damage. Early recognition and treatment is critical. Prompt body temperature reduction, early rehydration, and rapid transport to the hospital emergency room can result in $>95\%$ survival rate (Druyan et al., 2011). Mazerolle et al. (2011) promoted rectal thermometry and cold water immersion as the recommended methods for recognizing and treating exertional heatstroke. After reviewing 17 papers, Smith J. E. (2005) concluded that the main predictor of outcome in exertional heatstroke is the duration and degree of hyperthermia. Where possible, patients should be cooled using iced water immersion, but, if this is not possible, a combination of other techniques may be used to facilitate rapid cooling. Furthermore, he states that there is no evidence to support the use of dantrolene in these patients.

Heat Exhaustion: Symptoms and signs include heavy sweating, clammy moist skin, excessive thirst, extreme weakness or fatigue, muscle cramps, dizziness, confusion, nausea, slightly elevated body temperature ($<102^{\circ}\text{F}$ or $38\text{--}39^{\circ}\text{C}$) and fast shallow breathing. Lab testing may indicate dehydration, elevated creatinine kinase enzymes, and occasionally hypoglycemia.

Have the worker to rest in a cool, shaded or an air-conditioned place, drink plenty of water or other cool nonalcoholic beverages, and take a cool shower, bath or sponge bath. Call 911 if the worker develops more serious signs or symptoms indicating heatstroke. If treated in the emergency room the worker may receive IV fluid and electrolyte replacement. Workers may be more susceptible to heat stress illness during the following week and precautions are indicated.

Heat Syncope: Symptoms include dizziness and fainting.

Have the worker lie down flat in a cool place if symptoms of lightheadedness or dizziness begin. When feeling a little better, sit up and slowly drink water, clear juice or a sports beverage.

Heat Cramps: Symptoms of painful cramps usually occur after long periods of heavy sweating with strenuous activity and inadequate fluid replacement.

Have the worker stop activity, rest in a cool place and don't return to work for a few hours, drink clear juice or a sports beverage, and seek medical attention if cramps do not subside or if the worker has heart problems or is on a low sodium diet. Emergency room treatment may include IV fluid and electrolyte replacement.

Heat Rash (Miliaria or Prickly Heat): Symptoms include a cluster of pimples or small blisters occurring on the face, neck and upper chest, in the groin, under the scrotum, under the breasts, or in the elbow creases. The rash may be asymptomatic or cause varying intensity of itching.

The worker with heat rash should try to work in a cooler less humid environment, avoid sweat provoking activities and occlusive clothing, keep the affected area dry, take frequent cool showers, and use talc powder for comfort. Heat rash is usually mild and self-limiting. In some cases short-term use of OTC hydrocortisone cream for small areas can help with symptoms. Avoid oil-based creams. For more severe rashes with inflammation and blockage of the sweat glands, antibiotics can be prescribed.

MODE OF ACTION/HUMAN RELEVANCE FRAMEWORK

M.E. (BETTE) MEEK

The mode of action/human relevance (MOA/HR) framework is an analytical tool designed to increase transparency in the systematic consideration of the weight of evidence (WOE) of hypothesized MOA(s) for critical effects and their relevance to humans. It was developed in initiatives of the International Life Sciences Institute Risk Sciences Institute (ILSI RSI) and the International Programme on Chemical Safety (IPCS) and derives from earlier work on MOA in animals of the U.S. Environmental Protection Agency (U.S. EPA) and IPCS (Sonich-Mullin et al., 2001).

Mode of action, as previously defined, is a biologically plausible series of key events leading to an effect (Sonich-Mullin et al., 2001). Originally, MOA was considered principally in the context of late-stage key cellular, biochemical, and tissue events. A key event is an empirically observable step or its marker that is a necessary element of the MOA critical to the outcome (i.e., necessary, but not necessarily sufficient in its own right); key events are measurable and reproducible.

The MOA framework is based, then, on the premise that any human health effect caused by exposure to an exogenous substance can be described by a series of causally linked biochemical or biological key events that result in a pathological or other disease outcome. While originally and often simply conceptualized and illustrated as a linear series of key events, in reality, MOA involves interdependent networks of events with feedback loops. Disease outcomes are initiated or modified within these networks. Differences in networks between and within human and animal populations account, in part, for interspecies differences and human variability.

Early key events in hypothesized MOAs are most often related to chemical characteristics—i.e., those characteristics of structure and/or physicochemical properties that promote

interaction of the substance with biological targets. Later key events are less chemical specific and more often an expected consequence of progression of earlier key events (e.g., regenerative proliferation resulting from cytotoxicity).

An adverse outcome pathway is conceptually similar to a MOA. It was initially described by the computational eco-toxicology community (Ankley et al., 2010) and has been adopted within an international initiative to document, develop, and assess the completeness of potentially predictive tools for adverse ecological and human health effects (OECD, 2012). A focus of adverse outcome pathways is on the initial associated chemically mediated “molecular initiating event,” equivalent to an early key event in a MOA.

The terms MOA and adverse outcome pathway are conceptually interchangeable, representing essentially the subdivision of the pathway between exposure and effect in either individuals or populations into a series of hypothesized key events at different levels of biological organization (e.g., molecular, subcellular, cellular, tissue).

The development and evolution of the IPCS ILSI RSI MOA/HR framework, which has involved large numbers of scientists internationally, is described in several publications. It is supported by a series of templates, which promote systematic consideration of weight of evidence for MOA of adverse effects identified in traditional toxicity studies (Boobis et al., 2006; Boobis et al., 2008; Meek, 2008a; Meek et al., 2003; Seed et al., 2005; Meek and Klaunig, 2010). Potential application in a broader range of more predictive contexts (i.e., those where adverse effects might be predicted on the basis of MOA) has been considered more recently (Carmichael et al., 2011; Meek et al., 2014).

The framework has been illustrated by an increasing number of case studies ($n=30$, currently) (Table 106.1)

TABLE 106.1 Case Studies Illustrating Various Modes of Action

Mode of Action	Case Study	Reference
Tumors of various organs associated with mutagenic modes of action	Ethylene oxide 4-Aminobiphenyl	Meek et al. (2003) Cohen et al. (2006)
Mammary tumors associated with suppression of luteinizing hormone	Atrazine	Meek et al. (2003)
Thyroid tumors associated with increased clearance of thyroxine	Phenobarbital	Meek et al. (2003)
Bladder tumors associated with the formation of urinary tract calculi	Thiazopyr	Dellarco et al. (2006)
Liver/kidney tumors associated with sustained cytotoxicity and regenerative proliferation	Melamine Chloroform	Meek et al. (2003)
Acute renal toxicity associated with precipitation of oxalate	Ethylene glycol	Seed et al. (2005)
Androgen receptor antagonism and developmental effects	Vinclozolin	Seed et al. (2005)
Nasal tumors associated with DNA reactivity and cytotoxicity	Formaldehyde	McGregor et al. (2006)

and is widely adopted in international and national guidance and assessments (Meek et al., 2008b).

Building on this collective experience, the framework has been updated recently to more explicitly address uncertainty and to extend its utility to emerging areas in toxicity testing and non-testing methods. This update includes incorporation within a roadmap, encouraging continuous refinement of fit-for-purpose testing strategies and risk assessment, based on MOA (Meek et al., 2014).

In the framework, the WOE for hypothesized MOAs in animals is assessed based on considerations modified from those proposed originally by Bradford Hill (Hill, 1965) for assessment of causality in epidemiological studies. Human relevance or species concordance is then systematically considered, taking into account more generic information such as anatomical, physiological, and biochemical variations. If the WOE for the hypothesized MOA is sufficient and relevant to humans, implications for dose response in humans are then considered in the context of kinetic and dynamic data. Delineation of the degree of confidence in the WOE for hypothesized MOAs and their relevance to humans at each step is critical as is the delineation of critical research needs.

Establishing support for or rejection of a hypothesized MOA provides the foundation for subsequent considerations of dose response, human relevance, and estimates of risk. It involves (1) delineation of key events leading to the relevant effect in a hypothesized MOA and (2) evaluation of the available data to consider the extent of the supporting weight of evidence. Importantly, if alternative MOA(s) are supported, these are evaluated with equal rigor in separate framework analyses.

Essentially, then the framework assists in the transparent and focused incorporation of mechanistic data in risk assessment. This requires continuing interface between the risk assessment and research communities as a basis to increase common understanding and to focus additional research on relevant priorities for risk assessment.

The framework has been recently updated to more explicitly address uncertainty and take into account advances in

toxicity testing (Meek et al., 2014). It has evolved to be used not only as originally envisaged, where the outcome of chemical exposure is known, but additionally in hypothesizing potential effects resulting from exposure, based on information on putative key events in established MOAs from appropriate *in vitro* or *in silico* systems and other evidence. It draws upon the considerable experience acquired in the application of the framework in addressing documented (adverse) effects to inform the more limited knowledge base in more predictive applications. This evolution addresses the need to more efficiently assess the hazards and risks associated with the wide array of chemicals to which humans are exposed, as required by more aggressive regulatory mandates in various jurisdictions, worldwide. (See, for example, Meek and Armstrong, 2007). This necessitates the development and integration of information on key events within (hypothesized) MOAs very early in the evaluation process that will enable the effective use of data collected from lower levels of biological organization and non-test methods, such as (quantitative) structure–activity relationships ((Q)SAR) and read-across *in vitro* assays.

CARCINOGENESIS

CARLOS A. MURO-CACHO

BACKGROUND

Cancer is a group of disease that affects the genetic machinery of the cell. Since cancer can occur in any nucleated cell in the body, approximately 200 different cancer types and more than 1000 subtypes are recognized by pathologists. Despite significant scientific advances and therapeutic achievements, cancer remains responsible for one in eight deaths worldwide (WHO, 2009; Howlader et al., 2012). In the United States, cancer accounts for one in four deaths, only exceeded by heart disease. In 2012, according to the most recent data from the National Cancer Institute's Surveillance Epidemiology and End Results, 13.7 million Americans had a diagnosis of cancer and 1,638,910 Americans (848,170 men and 790,740 women) were diagnosed with cancer of all sites, resulting in 577,190 deaths (SEER, 2010; Siegel et al., 2012). The most current estimates indicate that, in 2013, 1,660,290 Americans will be diagnosed with cancer and, of these, 580,350 will die of the disease (almost 1600 people per day) (ACS, 2013).

In men, three sites (prostate, lung and bronchus, and colorectal) account for 51% of all new diagnoses, with prostate cancer accounting for 28% of the cases. In women, the three most common sites (52% of the total) are breast (29%), lung and bronchus, and colorectal (Jemal et al., 2010). Of interest is that, in the United States, from 1999 to 2008, cancer deaths have declined by more than 1% per year in men and women, except in American Indians/Alaska Natives, among whom deaths have remained stable. Death rates continue to decline for all four major cancer sites (lung, colorectal, breast, and prostate), with lung cancer accounting for almost 40% of the total decline in men; and breast cancer accounting for 34% of the total decline in women. The 5-year relative survival rate, for all cancers diagnosed between 2002

and 2008, was 68%, up from 49% in the period 1975–1977. This reduction in overall cancer deaths means that more than a million deaths have been avoided since 1990. The largest increases in death rates have been for liver cancer in men and women, esophageal cancer and melanoma in men, and lung and pancreatic cancer in women (Jemal et al., 2010; Edwards et al., 2010).

About 77% of all cancers are diagnosed in persons 55 years of age and older and, in 5% of the cancers, there is a strong hereditary component. Men have slightly less than a one in two lifetime risk of developing cancer, while for women the risk is a little more than one in three. Incidence rates in children have been increasing, especially in infants (Gapstur and Thun, 2010). Children are particularly vulnerable to environmental risk factors, including numerous toxins and detrimental exposures from air, food, water, medicines, pesticides, and ionizing radiation (NCI, 2010; Bode and Dong, 2009; Collins et al., 2008). Environmental pollution prevention acts (EPA's Resource Conservation and Recovery Act, Clean Water Act, and Clean Air Act) and controls on occupational carcinogens have prevented environmentally and occupationally related cancers (EPA, 2010; Montesano and Hall, 2001; Raaschou-Nielsen et al., 2010; Fontham et al., 2009; IOM, 2001). In addition to preventing cancer through the avoidance of risk factors, screening tests allow early detection and removal of precancerous growths (cervical and colorectal cancer) while mammary and prostatic cancer can be treated at very early stages.

Besides the obvious consequences for individuals and their families, the economic impact of cancer in society is significant. According to the National Institutes of Health (NIH), the cost of cancer, in 2008, was \$201.5 billion (\$77.4 billion for direct medical costs and \$124.0 billion

for indirect mortality costs (cost of lost productivity due to premature death) (NCI, 2010). The overall effects of cancer are, however, underestimated since non-invasive carcinomas and cutaneous basal and squamous cell carcinomas account for a significant percentage of the oncological care and are not reported to cancer registries. Since certain cancers are related to infectious agents and since, according to the World Cancer Research, one quarter to 1/3rd of new cancers are related to obesity, physical inactivity, and poor nutrition, between 30 and 40% of cancer deaths are actually preventable (WHO, 2009; Tomatis et al., 1997).

HISTORY

Cancer is not a modern disease. A possible lymphoma was observed in a hominid discovered by Louis Leakey, in 1932. Nasopharyngeal carcinomas and osteosarcomas have been reported in 3000 BC Egyptian mummies. A possible melanoma was found in mummified remains of a Peruvian Inca 2400 years ago. A cancer of the head and neck was observed in the skull of a female from the Bronze Age (1900–1600 BC). Early accounts of cancer were also recorded in the Babylonian Code of Hammurabi (1750 BC), ancient Egyptian papyri (1600 BC), the Chinese Rites of the Zhou Dynasty (1100–400 BC), and the Indian Ramayana manuscript (500 BC) (Hajdu, 2011). The Egyptian Edwin Smith Papyrus describes eight ulcerated, incurable breast tumors for which palliative cauterization was recommended. Hieroglyphic inscriptions and papyri manuscripts suggest that ancient physicians had already distinguished between benign and malignant tumors and suggested that superficial tumors could be surgically excised.

The father of medicine, Hippocrates (460–370 BC) also recognized the differences between benign and malignant tumors (Lloyd, 1984). To him, the blood vessels around a malignant tumor looked like the claws of a crab and named the disease “*karkinos*.” *Karkinos* was a giant crab that helped the nine-headed serpent *Hydra* in its battle with Herakles. The Roman physician, Celsus (28–50 BC), later translated the Greek term into *cancer*, the Latin word for crab. Galen (130–200 AD) used the word *oncos* (Greek word for swelling) to describe tumors and introduced the word “*neoplasia*” to define “a growth of a body area adverse to nature.” In 1531, Paracelsus described the term “*mala metallorum*,” among miners of silver and other metals, later recognized as radiation-induced lung cancer. In 1775, Port attributed scrotal skin cancers to prolonged exposure to soot in chimney sweeps, and in 1823 Earle reported the requirement of a “constitutional predisposition,” which would render the individual susceptible to the action of the soot. This constituted the first proposal for a “genetic–environmental” paradigm.

Over the decades, several hypotheses were proposed to explain the etiology of cancer (Diamandopoulos, 1996;

Kardinal and Yarbro, 1979). Hippocrates believed that the body had four fluids or *humors* (blood, phlegm, yellow bile, and black bile). Health was associated with a balance among these humors while too much or too little of any of them would cause the disease. Thus, an excess of black bile was thought to cause cancer. Galen embraced this theory, which remained unchallenged for over 1300 years. Among the theories that replaced the “humoral” theory was the formation of cancer by another body fluid, *lymph*. Stahl and Hoffman theorized that cancer was composed of fermenting and degenerating lymph, varying in density, acidity, and alkalinity. The “*lymph*” theory gained rapid support. John Hunter, in the 1700s, believed that tumors grow from lymph constantly thrown out by the blood. Once dyes and microscopic techniques were available, however, the structural detail of tissues and cells began to be understood and it became clear that tumors, as tissues, were composed of cells, and that mitoses, nucleomegaly, necrosis, increased the vasculature and loss of differentiation were characteristics of neoplasms.

In 1838, the German pathologist Johannes Muller showed that cancer is made up of cells and not lymph, but he believed that cancer cells did not come from normal cells but from the “*blastema*,” a sort of primordial stroma between normal tissues. His disciple, Rudolph Virchow, the father of cellular pathology, showed that all cells are derived from other cells and proposed a cellular origin of cancer, in 1863 (Virchow, 1863). He believed that chronic irritation was the cause of cancer and that cancers spread like a liquid. In the 1860s, Thiersch showed that cancers metastasize through the spread of malignant cells and not through some unidentified fluid. The role of lymphatic vessels in metastasis was established (Hajdu, 2011) and, in 1889, the “seed and soil” theory was proposed by Paget (Paget, 1889). From the late 1800s until the 1920s, “trauma” was thought to be the cause of cancer despite the failure to induce tumors in experimental animals by injury. This view was, however, partially supported by experimental studies in mouse skin where wounding induced tumors. Cohnheim postulated that tumor cells could be “embryonic” cells not eliminated during ontogenesis and Hansemann believed that they could be “dedifferentiated” normal cells that grew abnormally (anaplasia). Kelling proposed that cancer cells originated in a different organism and penetrated the body of the diseased individual. In 1901, DeVries proposed the concept of mutation and, in 1910, Johannsen proposed the term “gene” instead of “hereditary factor.” In 1914, Boveri showed that chromosomal abnormalities were often present in cancer cells (Boveri, 1914).

The role of exogenous agents as potential factors in the induction of cancer became evident, in late nineteenth and early twentieth centuries, with the development of chemical industry and the use of coal as industrial fuel and of oils as lubricants. Cancers related to industrial activity were reported in several European locations. Examples were the

“paraffin cancer,” the “mule-spinner’s cancer related to direct contact with shale-oil,” and the “aniline bladder cancer.” Before the industrial revolution, a variety of occupational causes of cancer had already been documented and the relationship of cancer to specific agents began to be established, boosting general interest in carcinogenesis. In 1915, Yamagiwa induced skin cancer in rabbits by painting their ears with benzene solutions of tar (Oliveira et al., 2007). By 1922, at least 100 radiologists had died of malignant tumors arising from their occupation, and, in 1926, Muller showed the mutagenic effects of X-rays. In 1947, Berenblum and Shubik observed successive stages of carcinogenesis using polycyclic aromatic hydrocarbons (PAH) and croton oil in the skin of mice (Berenblum and Shubik, 1947). Carcinogenesis was considered to have initiation and promotion phases. In 1954, the term “progression” was introduced by Foulds (1954).

Cancer was a contagious disease was proposed by Lusitani (1649) and Tulp (1652), based on observations of breast cancer in members of the same household. Cancer patients began to be isolated, outside of cities and towns, to prevent the spread of the disease. The importance of micro-organisms in oncogenesis was not fully realized until Pasteur and Koch established the relationship between bacterial infection and disease leading to a search for cancer “germs” in the late nineteenth century. It was believed that tumors were caused by organisms that released toxins and emaciated the host, and that metastasis were the result of the parasites attacking different organs (ACS, 2012). In 1907, Ciuffo demonstrated a viral etiology for human warts when cell-free filtrates from these lesions transmitted the disease (Ciuffo, 1907; Ronald and Janet, 2008). In 1911, Peyton Rous showed that a sarcoma, from a Plymouth Rock chicken, could be transmitted to healthy chickens using filtered cell-free tumor extracts (Rous, 1910; Levine, 1991; Keogh, 1938). In the 1950s, Burkitt described a new childhood tumor, now known as Burkitt’s lymphoma (Burkitt, 1962), and Barr visualized, by electron microscopy, herpes virus-like particles, later recognized as the Epstein–Barr virus (Epstein et al., 1965). In 1974, the link between human papilloma virus (HPV) and cervical cancer was proposed (zur Hausen et al., 1974, 1976) and, in 1975, the link between Hepatitis B virus (HBV) and hepatocellular carcinoma was established (Blumberg et al., 1975; Beasley et al., 1981). Other tumor viruses are the hepatitis C virus (HCV) (Major et al., 2001; Tan et al., 2008), Kaposi’s sarcoma virus (human herpes virus type 8) (Ganem, 2006; Chang, 1994) and the first human retrovirus, HTLV-1, recognized as the cause of adult T-cell leukemia (Butel, 2000; McLaughlin-Drubin and Munger, 2008). Sequences of polyoma virus have been identified in mesothelioma, osteosarcoma, non-Hodgkin lymphoma, brain tumors, prostate cancer and Merkel cell carcinoma, and retrovirus-like particles in seminomas, breast cancer, myeloproliferative disease, ovarian cancer,

melanoma, and prostate cancer (White and Khalili, 2004; Feng et al., 2008). Particles of human mammary tumor virus, a retrovirus similar to mouse mammary tumor virus, have been detected in human breast cancer cells. Finally, proteins from a xenotropic murine leukemia virus-related virus have been found in the stroma of human prostate cancer. However, an etiological role for these viruses remains to be proven.

Recently, a more complex view of cancer has evolved, based not on the cancer cell but on the population of malignant cells that constitute cancer. Thus, cancer can be understood as a long evolutionary process driven by sequential somatic-cell mutations, within a multicellular ecosystem, that lead to subclonal selection, in a manner that mimics a Darwinian adaptive system (Navin et al., 2011; Esteller, 2008). Traditional models of clonal evolution propose that a series of clonal expansions produce a uniform cell population that dominates the neoplasm (Cairns, 1975). It appears, however, that simultaneous competitor clones, with different genetic abnormalities, engage in clonal interference (Weinberg, 2007; Greaves and Maley, 2012) and result in tumor heterogeneity, a phenomenon than can be easily observed under the microscope (Marusyk and Polyak, 2010). These clones evolve to adapt to a particular tissue microenvironment (see below) and eventually colonize distant habitats during the metastatic process (Nowell, 1976). These metastatic clones, although genetically unique, appear to carry a signature that can be traced to the original, primary tumor (Mackay et al., 2006). For a review of the significant advances in the history of cancer and research see DeVita and Rosenberg (2012).

HALLMARKS OF CANCER

The growth of normal cells is kept under control by contact with neighboring cells and the extracellular matrix. In normal cells, growth factors interact with specific receptors, mainly with intracellular tyrosine kinase activity, and activate or deactivate interdependent signaling pathways. Cancer cells become independent of these regulatory feedbacks by producing relevant growth factors themselves, increasing the density of receptors, making these receptors constitutionally active and independent of growth factor binding, and engaging in autocrine and paracrine stimulation (Lemmon and Schlessinger, 2010; Witsch et al., 2010). The result is growth advantage and sustained proliferating ability.

Hanahan and Weinberg proposed a framework to understand neoplasia based on what they named “the six hallmarks of cancer” (Hanahan and Weinberg, 2000). The proposal was based on the concept, described above, that normal cells undergo a series of successive changes to become malignant and that tumors are complex populations where cells interact with each other and their tissue environment, which is an active participant in oncogenesis (Table 107.1).

TABLE 107.1 Hallmarks of Cancer

Enabling replicative immortality
Tumor promoting inflammation
Activating invasion and metastasis
Inducing angiogenesis
Genome instability and mutation
Resisting cell death
Deregulating cellular energetics
Sustaining proliferative signaling
Evasive growth suppressors
Avoiding immune destruction

Source: Hanahan and Weinberg, 2000, 2011.

The initial hallmarks were (1) self-sufficiency in growth signals, (2) insensitivity to antitumor signals, (3) evasion of apoptosis, (4) sustained angiogenesis, (5) tissue invasion and metastasis, and (6) unlimited replicative potential. In a recent revision (Hanahan and Weinberg, 2011), the authors suggested additional hallmarks: (7) evasion of immune surveillance, and five additional hallmarks relating to stress: (8) DNA damage and DNA replication stress, (9) oxidative stress, (10) mitotic stress, (11) proteotoxic stress, and (12) metabolic stress (Wellen and Thompson, 2010). These hallmarks do not have to be acquired in any specific order and some can overlap. At the center of the neoplastic process is, therefore, a balance between proliferation and death and interactions with normal and neoplastic cells and tissues.

Cancer Cell Proliferation Cancer cells use various mechanisms to enhance growth and circumvent death, and many tumors take advantage of the crosstalk among multiple pathways.

One example relates to “tumor suppressor genes” (TSPs) (see below). The two most important TSPs encode the RB (retinoblastoma-associated) and the TP53 proteins. The RB protein integrates signals from intra- and extracellular sources and determines if the cell should proceed through the cell cycle (Burkhardt and Sage, 2008) while TP53 receives inputs from intracellular sensors to assess the degree of cellular stress and DNA damage (Sykes et al., 2006). If abnormalities are detected, the cell cycle is arrested so that the damage can be repaired or, alternatively, apoptotic programs are triggered. Another example is the avoidance of “cell-to-cell contact inhibition.” The growth of normal cells is restricted by interaction with neighboring cells to maintain tissue architecture and homeostasis. Cancer cells bypass this inhibitory control by mechanisms still to be understood. Candidates, however, are the cytoplasmic product of the NF2 gene, which couples cell-surface adhesion molecules to transmembrane receptor tyrosine kinases (Curto, 2007), and the tumor suppressor gene LKB1 epithelial polarity protein, which can overrule the mitogenic effects of the oncogene Myc (Partanen et al., 2009).

Other mechanisms to enhance proliferation are mutations that compromise Ras GTPase activity, responsible for a negative-feedback that normally limits signal transmission, loss-of-function of PTEN phosphatase, which degrades the product of PI3-kinase, phosphatidylinositol (Jiang et al., 2009) trisphosphate (PIP3) amplifying PI3K signaling and promoting oncogenesis, and activation of the mTOR kinase, which can inhibit PI3K signaling and proliferation (Sudarsanam and Johnson, 2010). Yet another mechanism is the corruption of the TGF- β pathway. TGF- β is best known for its antiproliferative effects, which are avoided by cancer cells in ways far more elaborate than the simple shutdown of its signaling circuitry (Ikushima and Miyazono, 2010; Massagué, 2008; Bierie and Moses, 2006). Cancer cells can down-regulate TGF- β receptors (Muñoz-Antonia et al., 2009; Báez et al., 2005; West et al., 2000; Muro-Cacho et al., 1999, 2001; Anderson et al., 1999) or activate what is called the “epithelial-to-mesenchymal transition” (EMT) (see below) that confers on cancer cells traits associated with high grade malignancy. In cancer cells, however, there seems to be an optimal range of pathway activation beyond which sustained proliferation is incompatible with other essential cellular functions, leading to cell senescence or death (Collado and Serrano, 2010).

Cell Death When cells suffer an exogenous attack, they typically undergo “necrosis.” In necrosis, the cytoplasmic membrane of the dying cell ruptures and intracytoplasmic, pro-inflammatory products are released to the environment. This results in the recruitment of histiocytes and inflammatory cells that, in effort to rid the tissues of the cellular debris, can damage adjacent normal tissues in a process that we recognize as inflammation. Given the extraordinary high number of cells in the body and the immense daily turnover, organisms have developed sophisticated mechanisms for the silent disposal of cellular material. An efficient mechanism is “apoptosis” or “programmed cell death,” a form of cell suicide triggered by internal sensors. In contrast to necrosis, in apoptosis the DNA becomes fragmented in a controlled manner and the cytoplasmic membrane condenses, preventing the release of inflammatory products to the extracellular milieu. The cells break in what are called “apoptotic bodies” whose surface is recognized by histiocytes, which engulf them without damage to adjacent tissues. Apoptosis is therefore a natural counterpart to mitosis and cell growth (Adams and Cory, 2007) and is mediated by two major circuits, the “extrinsic” Fas ligand/Fas receptor, which receives and processes extracellular death-inducing signals, and the “intrinsic,” which senses and integrates intracellular signals. Key roles are played by members of the BCL-2 family (Bcl-xL, Bcl-w, Mcl-1) and the pro-apoptotic proteins Bax and Bak. If apoptosis is to proceed, Bax and Bak will disrupt the integrity of the outer mitochondrial membrane, causing the release of pro-apoptotic signaling proteins such

as cytochrome C, which activates an otherwise latent proteolytic cascade (caspase 8 in the extrinsic pathway and caspase 9 on the intrinsic) leading to DNA fragmentation. Bax and Bak share BH3 motifs with the anti-apoptotic Bcl-2-like proteins and other proteins, such as Bim, which also contribute to the regulation of apoptosis (Willis and Adams, 2005). Cancer cells circumvent apoptosis via several mechanisms. One is the loss of TP53 function that eliminates the critical damage sensor from the apoptosis-inducing circuitry.

Another mechanism is the modulation of the length of the telomeres that protect the ends of chromosomes (Park et al., 2009; Kang et al., 2004; Masutomi et al., 2005). Telomeres are composed of multiple tandem hexanucleotide repeats that are progressively shortened in cultured, non-immortalized, cells. In these cells, the ends of chromosomal DNAs form end-to-end fusions that generate unstable dicentric chromosomes incompatible with cell survival. Telomerase, the specialized DNA polymerase that adds telomere repeat segments to the ends of telomeric DNA, is almost absent in non-immortalized cells but expressed at significant levels in spontaneously immortalized cells and cancer cells. By extending telomeric DNA, telomerase eliminates the progressive telomere erosion that would otherwise occur in its absence. This correlates with a resistance to senescence and apoptosis (Blasco, 2005).

Angiogenesis Cancer cells, as normal cells, require nutrients and oxygen for proliferation. During tumor progression, angiogenesis is activated by an “angiogenic switch” that generates new vessels to sustain neoplastic growth (Hanahan and Folkman, 1996). Well-known angiogenesis inducers and inhibitors are vascular endothelial growth factor-A (VEGF-A) and thrombospondin-1 (TSP-1), respectively. Vascular endothelial growth factor signaling can be activated, via three receptor tyrosine kinases (VEGFR-1–3), by hypoxia and oncogene activation (Ferrara, 2008, 2010). Other pro-angiogenic proteins are members of the fibroblast growth factor (FGF) family (Folkman, 2006; Baeriswyl and Christofori, 2009; Ribatti, 2009).

Invasion The invasion–metastasis cascade (Fidler, 2003) is a succession of changes in cells and tissues that allows cancer cells to invade locally gaining access to adjacent blood and lymphatic vessels invading the lymphatic system and peripheral blood. Cancer cells then leave the lumina of these vessels (extravasation) to “colonize” the distant tissues where they form micrometastases that grow into macroscopic tumors. Epithelial cells take advantage of a program called EMT that allows them to acquire the abilities to invade, resist apoptosis, and metastasize (Klymkowsky and Savagner, 2009; Polyak and Weinberg, 2009; Yilmaz et al., 2007; Barrallo-Gimeno and Nieto, 2005). The expression of pleiotropically acting transcriptional factors (Snail, Slug, Twist, and Zeb1/2), known to regulate migratory processes during

embryogenesis (Micalizzi et al., 2010; Schmalhofer et al., 2009), contribute to significant changes such as loss of adherens junction, conversion from a polygonal/epithelial to a spindly/fibroblastic morphology, expression of matrix-degrading enzymes, increased motility, and resistance to apoptosis.

Kinases and growth factors such as epidermal growth factor receptor (EGFR), fibroblast growth factor receptor (FGFR), insulin-like growth factor receptor (IGFR), and MET are likely responsible for reduced intercellular adhesion, in part via loss of E-cadherin (Perl et al., 1998; Thiery, 2002). Loss of E-cadherin function is necessary but not sufficient for EMT. The extracellular matrix provides a scaffold where cells interact with integrins, fibronectin, collagen, and laminin. Also, calcium-dependent guanosine triphosphatases (GTPases), extracellular-matrix signals induce cytoskeletal changes that facilitate cell migration via cytoplasmic extensions called filopodia that coalesce into larger lamellipodia. Various members of the matrix metalloproteinase (MMP) family (MMP1, MMP-2, and MMP-9) are also implicated in invasion (Egeblad and Werb, 2002; Lopez-Otin and Matrisian, 2007; Martin and Matrisian, 2007). Interestingly, tumor-associated macrophages activate myofibroblasts and recruit endothelial progenitor cells via the release of SDF-1 (Orimo et al., 2005). Cancer cells may also regulate the expression of other molecules [ezrin, serine-threonine kinase 11, EREG (EGFR ligand), COX-2] to target colonization in other organs (Khanna et al., 2004; Ji et al., 2007; Minn et al., 2005).

Metastasis Metastases are responsible for 90% of deaths in cancer patients (Fidler, 2003). Metastases often appear in critical anatomical locations where they compromise vital structures. More often, however, metastases are numerous and in multiple organs leading to organ and system failures (Cairns, 1975). It is known, however, that only a small fraction of the cells in the primary tumor have the capacity to metastasize and that, in general, excision of tumors that measure 2 cm or less prevents metastatic disease (Chambers et al., 2002; Koscielny et al., 1984; Kinouchi et al., 1999). Cancer cells appear in the bone marrow in small numbers very early in the disease and can be found in peripheral blood using sensitive techniques (Luzzi et al., 1998). Several hypotheses for the generation of metastases have been proposed. A “linear” model of tumor progression (Nguyen et al., 2009; Fidler, 2003), proposes that cells in the primary tumor undergo successive rounds of mutation and selection giving rise to a biologically heterogeneous cellular population in which a subset of malignant clones have accumulated the necessary genetic alterations for metastasis (Gupta and Massague, 2006; Vogelstein et al., 1988; Foulds, 1954). In contrast, a “parallel” model argues that cancer cells disseminate very early, colonize multiple distant sites, and accumulate genetic changes independently from those incurred by the primary tumor (Hynes, 2003; Klein, 2009). The

metastatic competence of these cells is under investigation. Gene expression studies (Sahai, 2007; Perou et al., 2000; Sorlie et al., 2001; van Veer et al., 2002; van de Vijver et al., 2002) seem to favor the linear model. Genomic studies have revealed “metastasis signatures” in the primary tumor that allow the prediction of a poor prognosis, suggesting that metastatic capacity is an inherent property of the primary tumor and that, within the primary tumor, are clones of cells with various metastatic proclivities and expression profiles (Ding et al., 2010). Furthermore, metastasis genes are found in gene-expression signatures of primary tumors (Weilbaecher et al., 2011; Kang et al., 2003; Bos et al., 2009). Thus, breast cancers carrying a lung-metastatic signature tend to metastasize to the lung (Minn et al., 2005).

Tumor Stroma Cancer cells grow in a mixture of cells and extracellular matrices known as “stroma.” Many resident and circulating cells are observed under the microscope in intimate association with the cancer cells. The roles played by these cells in oncogenesis are now better understood. Normal fibroblasts are mesenchymal cells that provide structural support in normal tissues. The term “cancer-associated fibroblast” is used to describe cells with similarities to these fibroblasts and also the “myofibroblast,” whose biological roles and properties differ markedly from those of tissue-derived fibroblasts and are identified by the expression of smooth muscle actin (SMA). Myofibroblasts increase in wounds and at sites of chronic inflammation. Although beneficial to tissue repair, myofibroblasts contribute to the pathological fibrosis observed in tissues such as lung, kidney, and liver. Recruited myofibroblasts and reprogrammed variants of normal tissue-derived fibroblastic cells have been shown to enhance cancer cell proliferation, angiogenesis, invasion, and metastasis (Pietras and Ostman, 2010; Kalluri and Zeisberg, 2006; Bhowmick et al., 2004). Because they secrete a variety of extracellular matrix components, cancer-associated fibroblasts are implicated in the formation of the desmoplastic stroma that characterizes many invasive carcinomas. This desmoplasia is one of the factors that allow pathologists to diagnose invasion even at a very early stage. The old concept of desmoplasia being a mechanical attempt of the host to protect against the local expansion of the tumor is obviously simplistic.

Also prominent, among the stromal constituents, are “endothelial” cells that form a tumor-associated vasculature. Several interconnected signaling pathways have been implicated in endothelial cell recruitment and development (Notch, Neuropilin, Robo, Eph-A/B, VEGF, angiopoietin, and FGF) (Ahmed, 2009; Dejana et al., 2009; Carmeliet and Jain, 2000). Closely related to endothelial cells are the cells lining lymphatic vessels (Tammela and Alitalo, 2010) that actively grow at the periphery of tumors in a lymphangiogenic process that provides new channels for metastatic seeding. Another important cell is the “pericyte,” a

specialized mesenchymal cell type (related to smooth muscle cells) with finger-like projections that wrap around the endothelial tubing of blood vessels. In normal tissues, pericytes are known to provide paracrine support signals to the normally quiescent endothelium (Gaengel et al., 2009) but they can also collaborate with endothelial cells to synthesize the basement membrane in support of tumor endothelium (Bergers and Song, 2005).

Tumor Microenvironment Cancers are not uniform masses of identical cells. Tumor heterogeneity can be recognized microscopically. Differences in cellular morphology that allows pathologists not only to provide a diagnosis of cancer but also to estimate the potential clinical behavior of the tumor by recognizing features that can be grouped in histological grades. Sequencing the genomes of cancer cells, microdissected from different sectors of a tumor, has revealed prominent intratumoral genetic heterogeneity. At the cellular and molecular levels, therefore, oncogenic events cannot be fully understood by studying cancer cells in isolation. The habitat where they exist, the “tumor microenvironment,” is rich in cellular products, extracellular matrix signals, and complex interactions among cancer cells and non-neoplastic cell types that, together, make tumor growth possible. Incipient neoplasias may begin by recruiting and activating stromal cells that assemble into an initial pre-neoplastic stroma. Cancer cells interact with this stroma reprogramming normal stromal cells to serve the needs of the neoplasm. Ultimately, signals originating in the tumor stroma enable cancer cells to invade normal adjacent tissues and metastasize.

A complete, graphic depiction of the network of microenvironmental signaling interactions is still far beyond our reach, as the great majority of signaling molecules and pathways remain to be identified. Certain transcription factors (SNAIL, TWIST), however, are activated and initiate a stem cell transcriptional program. This results in reduced expression of epithelial genes such as E-cadherin, and increased expression of mesenchymal (vimentin, metalloproteases, N-cadherin) and “stemness” genes (Oct-4, Nanog) (Kessenbrock et al., 2010). The cancer cell microenvironment may also induce abnormal signaling pathway activation. Tumor-invading macrophages and other immune cells as well as activated fibroblasts produce cytokines and growth factor ligands that can activate EMT-inducing signaling pathways (Hynes, 2003). Circulating cancer cells, released from the primary tumor, leave this microenvironment and, upon homing to a distant organ, encounter another naive, normal, tissue microenvironment. The succession of reciprocal cancer cell to stromal cell interactions must now be repeated in this tissue. Some tissue microenvironments, however, appear to be natural “niches” that are already supportive of seeded cancer cells (Coghlin and Murray, 2010). Implicit in this term is the notion that cancer

cells seeded in such sites may not need to begin by inducing a supportive stroma because it already preexists, at least in part. Such permissive state may be intrinsic to the tissue site (Talmadge and Fidler, 2010) or pre-induced by circulating factors released by the primary tumor. The best documented components of induced pre-metastatic niches are tumor-promoting inflammatory cells, although other cell types and the extracellular matrix may well prove to play important roles in different metastatic contexts.

Cancer Stem Cells Some authors have proposed that the tumor microenvironment also serves to maintain a pool of “cancer stem cells” (CSC) in a relatively quiescent but active state (Reya et al., 2001; Gilbertson and Rich, 2007) that may self-renew as well as spawn more differentiated derivatives (Singh and Settleman, 2010). An increasing number of human tumors are reported to contain subpopulations with the properties of CSCs that appear to be more resistant to chemotherapy. Also, certain tumors may transform their own cancer cells into stromal cell types rather than relying on recruited host cells to provide this function. An important stromal cell type is the “cancer-associated fibroblast” that can enhance tumor proliferation, angiogenesis, and invasion and metastasis (Kalluri and Zeisberg, 2006; Bhowmick et al., 2004). Because they secrete a variety of extracellular matrix components, cancer-associated fibroblasts are implicated in the formation of the desmoplastic stroma that characterizes many invasive carcinomas (van de Stolpe, 2013).

Cancer stem cells can be identified in the blood in small numbers. This “circulating tumor cells” (CTCs) can originate in both primary tumors and metastases (van de Stolpe, 2013). Furthermore, contrary to previous beliefs, differentiated cells could revert to a pluripotent state from which, in theory, they could generate other cell types (Takahashi et al., 2007). Also, in epithelial tumors, cancer stem cells could generate non-epithelial cells, depending on the type of signals present in the microenvironment or niche. It is generally accepted that during tumor progression accumulation of genetic defects in cancer cells results in multiple genetically different clones. In fact, pathologists often observe metastases with different morphology than their primary tumors and, occasionally, they come across tumors that defy any attempt of phenotypic classification even with the most sophisticated techniques. This morphological diversity, in many of these cases, could be the result of stem cells undergoing differentiation across different phenotypes. In fact, Ewing sarcoma is now considered a tumor derived from cancer stem cells (Suvà et al., 2009; Meltzer, 2007).

Cancer and the Immune System Tumors are often surrounded and infiltrated by various densities of immune system cells. Pathologists have suspected that these inflammatory infiltrates sometimes offer protection against the tumor but other times can be facilitators of tumor growth.

It is now clear that infiltrating immune cells can be both tumor antagonizing and tumor promoting (Dvorak, 1986; Grivennikov et al., 2010). Tumor-promoting inflammatory cells are macrophages, mast cells, neutrophils, and T- and B-lymphocytes. A variety of signaling molecules have been implicated in tumor promotion: EGF, VEGF, FGF2, inflammatory chemokines and cytokines, proangiogenic and/or proinvasive matrix-degrading enzymes, including MMP-9 and other matrix metalloproteinases, cysteine cathepsin proteases, and heparanase (Qian and Pollard, 2010). Tumor-infiltrating inflammatory cells have been shown to induce and help sustain tumor angiogenesis, to stimulate cancer cell proliferation, to facilitate, via their presence at the margins of tumors, tissue invasion, and to support the metastatic dissemination and seeding of cancer cells (Coffelt et al., 2010; Egeblad et al., 2010; Qian and Pollard, 2010; Joyce and Pollard, 2009). Similarly, subclasses of B- and T-lymphocytes may facilitate the recruitment, activation, and persistence of such wound-healing and tumor-promoting macrophages and neutrophils (Biswas and Mantovani, 2010) while other subclasses of B- and T-lymphocytes and innate immune cell types can mount demonstrable tumor-killing responses.

HEREDITY AND SUSCEPTIBILITY

Rare families accumulate cases of early onset cancer affecting several generations strongly indicating that inherited factors are important causes of cancer. In hereditary cancer syndromes, one abnormal copy of the gene is inherited in the germ line from either parent, whereas the other copy is inactivated in a somatic cell, typically because of random processes whereby genes, chromosomes, or both are rearranged, deleted, or replaced. As a result, “loss of heterozygosity” is frequent at the position of the TSP gene and in a cancer cell there is biallelic inactivation of the gene (Foulkes, 2008). Inherited biallelic mutations in TSP genes are very rare and often result in a phenotype that differs from the phenotype of a monoallelic mutation. In some genes, such as *BRCA1* and *APC*, biallelic truncating mutations are incompatible with intrauterine development and are therefore lethal. Recently, large-scale consortia examining thousands of cases and controls have identified 30 or more susceptibility loci for lung, prostate, breast, and colorectal cancer.

GENES AND CANCER

The unravelling of the DNA structure, by Watson and Crick, in 1953, changed the way we understood the neoplastic process shifting the emphasis from the cellular (disease of cells) to the molecular level (disease of genes). Cancer growth was then understood as initiated by a mutation and maintained by proliferation factors that generated similar

cells or “clones” (Nowell, 2002). In the late 1960s, it was discovered that carcinogens have the ability to bind and damage DNA by forming adducts or causing DNA strand breaks (Poirier, 2004). In the 1970s and 1980s, studies of the role of RNA and DNA viruses in tumor induction led to the discovery of oncogenes and the birth of contemporary cancer biology (zur Hausen, 2001). To date, more than 70 cellular proto-oncogenes have been identified through studies of oncogenic retroviruses and almost all of these genes code for key cell signaling proteins involved in the control of cellular proliferation and apoptosis. In 1971, studies in inherited and sporadic forms of retinoblastoma, showed that infants with the inherited disease had a 30,000-fold higher chance of developing Rb than did children with the sporadic disease, providing the first evidence for the existence of cellular genes, now known as TSP, which in contrast to proto-oncogenes function to prevent rather than to promote cancer. In 1976, Bishop and Varmus proved that oncogenes have a cellular origin and that carcinogenic events activate cellular genes to promote cancer (Stehelin et al., 1976). The *src* oncogene and the process of reverse transcription were discovered and *src* was proven to be a cellular gene acquired by RSV from the chicken genome. In 1979, Lane and Levine showed that products of DNA tumor viruses function through physical interactions with cellular proteins, specifically p53. In 1982 and 1983, it was shown that the *ras* proto-oncogene was present in normal cells, and that *ras* oncogenes, in human bladder carcinoma cell lines, mouse sarcoma viruses, and rat mammary carcinomas, contained a mutation that was crucial for inducing cellular transformation. In 1989, Vogelstein reported a common loss-of-heterozygosity at the p53 locus in human colorectal cancers

(Vogelstein and Kinzler, 2004), suggesting that p53 was actually a TSP gene rather than an oncogene.

Oncogenes Oncogenes encode proteins that control cell proliferation and apoptosis (Table 107.2). These proteins can be transcription factors, chromatin remodelers, growth factors, growth factor receptors, signal transducers, or apoptosis regulators (Santarosa and Ashworth, 2004). They can be activated by mutation or gene fusion, juxtaposition to enhancer elements, or amplification. Translocations and mutations are typically initiating events, in the early stages of neoplasia, whereas amplification usually occurs during tumor progression (Croce, 2008). Examples of translocations are Burkitt’s lymphoma, where the *MYC* oncogene (chromosome 8q24) becomes activated as a result of its juxtaposition to one of the loci for immunoglobulin genes (chromosomes 14q, 22q, and 2p), and chronic myelogenous leukemia (CML), where a reciprocal t(9;22) chromosomal translocation that fuses the *ABL* proto-oncogene to the *BCR* gene creating a chimeric protein with enhanced tyrosine kinase activity (Dalla Favera et al., 1982; Groffen et al., 1984; Shtivelman et al., 1985). Since every malignant cell carries these translocations, deregulation of these genes are likely early events in the formation of the tumor. When CML converts to acute leukemia, it acquires an additional t(9;22) translocation, an isochromosome 17, or a trisomy of chromosome 8, and when follicular lymphoma progresses to a more aggressive clinical type, it often carries a t(8;14) translocation in addition to the original t(14;18) translocation (Croce, 2008; Konopka et al., 1985). In general, mesenchymal neoplasms (hematopoietic tumors and soft-tissue sarcomas) are initiated by the activation of an oncogene, followed

TABLE 107.2 List of Common and Important Genes Involved in Oncogenesis

Gene Function	Gene
Oncogene	BAX, BCL2L1, CASP8, CDK4, ELK1, ETS1, HGF, JAK2, JUNB, JUND, KIT, KITLG, MCL1, MET, MOS, MYB, NFKBIA, NRAS, PIK3CA, PML, PRKCA, RAF1, RARA, REL, ROS1, RUNX1, SRC, STAT3, ZHX2
Tumor suppressor gene (TSP)	ATM, BRCA1, BRCA2, CDH1, CDKN2B, CDKN3, E2F1, FHIT, FOXD3, HIC1, IGF2R, MEN1, MGMT, MLH1, NF1, NF2, RASSF1, RUNX3, S100A4, SERPINB5, SMAD4, STK11, TP73, TSC1, VHL, WT1, WWOX, XRCC1
Oncogene and TSP	BCR, EGF, ERBB2, ESR1, FOS, HRAS, JUN, KRAS, MDM2, MYC, MYCN, NFKB1, PIK3C2A, RB1, RET, SH3PXD2A, TGFB1, TNF, TP53
Transcription factor	ABL1, BRCA1, BRCA2, CDKN2A, CTNNB1, E2F1, ELK1, ESR1, ETS1, FOS, FOXD3, HIC1, JUN, JUNB, JUND, MDM2, MEN1, MYB, MYC, MYCN, NF1, NFKB1, PML, RARA, RB1, REL, RUNX1, RUNX3, SMAD4, STAT3, TGFB1, TNF, TP53, TP73, TSC1, VHL, WT1, ZHX2
Cell cycle	ATM, BRCA1, BRCA2, CCND1, CDK4, CDKN1A, CDKN2A, CDKN2B, CDKN3, E2F1, HGF, MEN1, STK11, TP53
Angiogenesis	AKT1, CTNNB1, EGF, ERBB2, NF1, PML, RUNX1, TGFB1
Apoptosis	BAX, BCL2, BCL2L1, BRCA1, CASP8, E2F1, MCL1, MGMT, TNF, VHL
Cell adhesion	APC, CDH1, CDKN2A, CTNNB1, KITLG, NF1, NF2, TGFB1
Epithelial–mesenchymal transition	BRCA2, CDKN2B, CTNNB1, ERBB2, HGF, JAK2, KIT, MCL1, NF1, RUNX3, S100A4, SMAD4, TGFB1, VHL

by alterations in tumor-suppressor genes and other oncogenes. In contrast, most carcinomas are initiated by the loss of function of a tumor-suppressor gene, followed by alterations in oncogenes and additional tumor-suppressor genes (Huebner and Croce, 2001; Croce, 2008, 8). Mutations in oncogenes (chromosomal translocations, gene amplifications, or intragenic mutations) result in their activation and the mutation needs to occur in only one allele. One example of activating mutation is *BRAF*, where valine changes to glutamate at codon 599, a residue within the activation loop of the kinase domain (Croce, 2008), normally regulated by phosphorylation at adjacent residues (Thr598 and Ser601). The change to glutamate constitutively activates BRAF kinase that phosphorylates downstream targets such as extracellular signal-regulated kinase (ERK), leading to aberrant growth (Davies et al., 2002; Wan, 2004).

Tumor Suppressor Genes (TSPs) Tumor suppressor genes can be divided into classes based on the primary function of the proteins they encode. Anti-oncogenes, such as cyclin-dependent kinase inhibitor 2A (*CDKN2A*) and retinoblastoma 1 (*RB1*), which encode p16INK4A and RB1, respectively, antagonize the growth-promoting activities of oncogenes, such as *CDK4* and *CCND1*, which encode CDK4 and cyclin D1, respectively. DNA damage checkpoint genes, such as ataxia telangiectasia mutated (*ATM*) and *TP53*, which encode ATM and p53, respectively, induce cell death or senescence in response to DNA damage or DNA replication stress. Caretaker genes (DNA repair genes and mitotic checkpoint genes, such as *MLH1*, breast cancer susceptibility 1 (*BRCA1*), *MYH* (*MUTYH*), and xeroderma pigmentosum group A (*XPA*)) encode proteins that help to maintain genomic stability. Mutations in these genes impair DNA repair, mitotic recombination, or chromosomal segregation.

MicroRNA GENES MicroRNA genes regulate gene expression but do not encode proteins. They are single RNA strands of 21–23 nucleotides that can bind a complementary sequence on a messenger RNA (mRNA) causing its degradation or blocking the translation of a protein (Croce, 2008). They are often located in chromosomal regions that undergo rearrangements, deletions, and amplifications. MicroRNA genes can be up-regulated or down-regulated in cancer cells (Calin et al., 2005; Yanaihara et al., 2006), and their function is tissue specific. The up-regulated genes function as oncogenes by down-regulating TSP genes, whereas the down-regulated genes function as TSP genes by down-regulating oncogenes (Croce, 2008). Up-regulation of microRNA genes can be due to amplification, deregulation of a transcription factor, or demethylation of CpG islands in the promoter regions of the gene. Down regulation can be accomplished by deletions, epigenetic silencing, or loss of the expression of one or more transcription factors.

GENETIC ABNORMALITIES

Like all cells in the human body, a cancer cell is a direct descendant, through a lineage of mitotic cell divisions, of the fertilized egg from which the patient developed and, therefore, carries a copy of its diploid genome. To undergo malignant transformation, a normal cell has to endure heritable changes involving multiple, independent genes, a concept that explains the long latency period for cancer development (Barrett and Wiseman, 1987). The cancer cell genome, therefore, acquires a set of somatic mutations (substitutions of one base by another, insertions or deletions of small or large segments of DNA), rearrangements, gene amplification with increases in copy number beyond the two gene copies in the normal diploid genome, or decreases in copy number that may result in complete absence of a DNA sequence. The cancer cell may have also acquired, from exogenous sources, completely new DNA sequences, notably those of viruses such as HPV, Epstein–Barr virus, hepatitis B virus, human T lymphotropic virus 1, and human herpes virus 8, each of which is known to contribute to the genesis of one or more type of cancer. In addition, the cancer genome acquires epigenetic changes that alter chromatin structure and gene expression (see Epigenetics below).

Mutations

The size of the full repertoire of human cancer genes is a matter of speculation. Some cancer genomes carry 100,000 point mutations whereas others have fewer than 1000. Studies in mice, however, suggest that more than 2000 genes, when mutated, may have the potential to contribute to carcinogenesis (Futreal et al., 2004). Since cancer is the result of multiple mutations or genetic abnormalities, mutated genes contribute, rather than cause, cancer. Mutations can occur in the germ line (hereditary predisposition to cancer) or in somatic cells (sporadic tumors) (Knudson, 2002). So far, 291 cancer genes have been reported, more than 1% of the 22,000 protein-coding genes in the human genome. Ninety percent of cancer genes show somatic mutations in cancer, 20% show germline mutations, and 10% show both (Futreal et al., 2004). Approximately 90% of the known somatically mutated cancer genes are “dominant,” that is, a mutation of just one allele is sufficient to contribute to cancer development, typically by activation of the encoded protein. The remaining 10% act in a “recessive” manner, requiring mutations in both alleles that, typically, result in abrogation of protein function. Recessive cancer genes are characterized by diverse mutation types, ranging from single-base substitutions to whole gene deletions. In each dominantly acting cancer gene, however, the repertoire of cancer-causing somatic mutations is usually more constrained, both with respect to the type of mutation and its location in the gene. The most common mutation class among the known cancer

genes is a chromosomal translocation that creates a chimeric gene or apposes a gene to the regulatory elements. Several genes with small insertions and deletions of coding microsatellites/mononucleotide repeats that lead to protein truncation in MMR-deficient tumors have been proposed as cancer genes (Duval and Hamelin, 2002). More than 70% of cancer genes with somatic mutations in the census are associated with leukemias, lymphomas, and sarcomas, even though these cancers account for <10% of human cancer cases. Tyrosine kinases are more common than serine/threonine kinases (27 cancer genes encode protein-kinase domains, compared with the 6.3 expected in a random selection of the human genome), accounting for approximately one quarter of all known protein kinases and 2/3rd of the protein kinases encoded by cancer genes. Interestingly, phosphatases are not prominent in the cancer gene. A substantial proportion of germ line-mutated genes that cause cancer predisposition are involved in DNA maintenance and repair.

Some mutations are causally implicated in oncogenesis and have been named “driver mutations.” Driver mutations confer growth advantage to the cancer cell and, although, may not be required for maintenance of the cancer phenotype, they have been positively selected. Some studies indicate that there may be as many as 20 driver mutations in individual cancers, considerably more than the five to seven previously predicted. “Passenger mutations,” on the other hand, have not been selected, do not confer clonal growth advantage, and have not contributed to the development of the cancer. Passenger mutations are found within cancer genomes because somatic mutations without functional consequences often occur during cell division. Thus, when a cell acquires a driver mutation it already has biologically inert somatic mutations within its genome that will be perpetuated via clonal expansion. Driver mutations cluster in cancer genes, whereas passenger mutations are more or less randomly distributed. Building on the success of previous multinational, collaborative initiatives such as the Human Genome Project and the HapMap consortium, the International Cancer Genome Consortium (ICGC) (<http://www.icgc.org/home>) will attempt to characterize somatically acquired genetic events in at least 50 classes of cancer, including those with the highest global incidence and mortality.

Loeb proposed the existence of a “mutator phenotype” to explain the fact that the mutation rate in nonmalignant cells is not sufficient to generate the large numbers of mutations observed in cancer (Loeb et al., 1974; Loeb and Loeb, 2000; Loeb and Monnat, 2008; Beckman and Loeb, 2006). It has been estimated that a cell undergoes >20,000 DNA damaging events and >10,000 replication errors per cell per day (Preston, 2005). When a solid tumor is clinically detected, it has 10^8 – 10^9 cells and a volume of 1 cm^3 , and it has accumulated tens of thousands of mutations (Greenman et al., 2007; Fox et al., 2009). More than 1000 different genes have been

reported to be mutated in human tumors, although no set of mutated genes is diagnostic of a specific tumor. Many genes contain multiple mutations and many tumors contain as many as 100 mutations. Some genes, such as *TP53* and *KRAS*, are frequently mutated in diverse types of cancer whereas others are rare and/or restricted to one cancer type. Recent studies have shown that four genes are altered in more than 20% of the tumors analyzed. The *TP53* tumor-suppressor and DNA damage checkpoint gene was among the most frequently mutated genes. The remaining genes encode either classical oncoproteins, such as the EGFR and the small GTPase RAS, or TSP proteins, such as the cyclin-dependent kinase 4 inhibitor p16INK4A (encoded by cyclin-dependent kinase inhibitor 2A (*CDKN2A*)), the phosphatase and tensin homologue deleted on chromosome 10 (PTEN) and neurofibromatosis type 1 (NF1). Certain gene families such as protein kinases are frequent cancer genes. Furthermore, cancer genes cluster on certain signaling pathways. For example, in the classical MAPK/ERK pathway upstream mutations are found in cell membrane-bound receptor tyrosine kinases such as EGFR, ERBB2, FGFR1, FGFR2, FGFR3, PDGFR α , and PDGFR β and also in the downstream cytoplasmic components NF1, PTPN11, HRAS, KRAS, NRAS, and BRAF. Furthermore, the length of “microsatellites,” repetitive nucleotide sequences that are hot spots for mutagenesis, have been found highly mutated in some tumors and have been used to establish cellular heterogeneity and as prognostic indicators of progression from a premalignant condition (Thibodeau et al., 1993; Boland et al., 1998; Risinger et al., 1993).

Chromosomal Abnormalities

Clonal chromosome aberrations (chromosomal rearrangements, chromosomal imbalances, and genomic losses) have been found in all major tumor types (<http://cgap.nci.nih.gov/>) and can be caused by environmental and occupational exposures and also by cytotoxic therapy (Fröhling and Döhner 2008).

Chromosomal Rearrangements Recurrent chromosomal rearrangements can form a “chimeric fusion gene” by fusion of parts of two genes (typically genes that encode tyrosine kinases or transcription factors), or alter the expression of a normal gene. The best example of a tyrosine kinase gene is the Philadelphia chromosome (Nowell and Hungerford, 1960), present in virtually all patients with CML, in 20% of patients with acute lymphoblastic leukemia (ALL), and in rare cases of acute myeloid leukemia (AML). The Philadelphia chromosome is the result of the reciprocal translocation t(9;22)(q34.1;q11.23) (Rowley, 1973) in which sequences of the *BCR* gene (22q11.23) are fused to fragments of the gene that encodes the ABL1 tyrosine kinase (9q34.1). The fusion results in the production of the chimeric protein,

BCR–ABL1, that has the catalytic domain of ABL1 fused to a BCR domain that promotes aberrant tyrosine kinase activity independent of normal regulatory controls (Fröhling and Döhner, 2008). Another example is the inversion [inv(2) (p22-p21p23)], present in 7% of Japanese patients with non-small cell carcinoma, which results in a fusion gene with fragments of *EML4* and the gene encoding the ALK receptor tyrosine kinase. One important example of a transcription factor is Ewing sarcoma (EWS), where translocations t(11;22)(q24.1-q24.3;q12.2) and t(21;22)(q22.3;q12.2) fuse the *EWSR1* gene (22q12.2) to a gene that encodes a member of the ETS family of transcription factors. In 85% of the cases, the partner is *FLI1* (11q24.1-q24.3) and in 10% of the cases *ERG* (21q22.3) (Delattre et al., 1992; Sorensen et al., 1994). In the *EWSR1* portion of the fusion protein resides a potent transactivation domain that induces the transcription of various genes (Owen and Lessnick, 2006; Riggi and Stamenkovic, 2007). An example of deregulation of a normal gene is Burkitt lymphoma. When regulatory sequences, such as promoters or enhancers, are joined to the coding region of a proto-oncogene, its expression is altered. In Burkitt lymphoma, the enhancer of an immunoglobulin gene [*IGHG1* (14q32.33), *IGKC* (2p12), *IGLC1* (22q11.2)] drives the constitutive expression of the gene encoding the MYC transcription factor (8q24.21) (Küppers, 2005).

Chromosomal Imbalances Gains or losses of genetic material can involve large chromosomal segments or small intragenic duplications or deletions. *Large-scale genomic gains* typically result from non-disjunctions, unbalanced translocations, or amplifications. Analysis of the RNAs corresponding to these regions has uncovered new breast cancer genes and potential new oncogenes in melanoma [*MITF* (3p14.2-p14.1) and *NEDD9* (6p25-p24)] (Garraway et al., 2005; Kim et al., 2006) and hepatocellular carcinoma [*YAP1* (11q13) and *BIRC2* (11q22)] (60-62). Identification of *focal genomic gains* involving small regions or single genes often requires sensitive techniques (Dutt and Beroukhim, 2007). In breast cancer, array-based CGH and SNP genotyping have revealed the amplification of a small segment of 6q25.1, the location of the gene that encodes estrogen receptor 1 (*ESR1*) (Holst et al., 2007; Albertson, 2008). Overexpression of this gene correlates with increased sensitivity to tamoxifen. Also, in a subgroup of patients with non-small-cell lung carcinoma, a 480-kb segment on 14q13 contains the *NKX2-1* oncogene coding for a transcription factor (Weir, 2007), and point mutations have been reported in the catalytic domain of the EGFR receptor tyrosine kinase, implicated the response to the kinase inhibitors (Sharma et al., 2007). Genomic losses range from complete or partial chromosomal monosomies, to single gene or intragenic deletions detectable only by high resolution techniques. *Large-scale genomic losses* involving several genes are frequent in cancer (Knudson, 2001). Examples are *RBI*

(13q14.2), *TP53* (17p13.1), *APC* (5q21-q22), *NFI* (17q11.2), *PTEN* (10q23.3), and *ATM* (11q22-q23). For many recurrent genomic losses, such as 1p deletions in neuroblastoma (Okawa et al., 2008), 3p deletions in lung cancer (Zabarovsky et al., 2002), and 7q deletions in myeloid cancers (Curtiss et al., 2005; Döhner et al., 1998), the critical genes are unknown. RNA interference screening in combination with high resolution DNA copy-number analysis identified the frequent deletion in colon cancer of the *REST* gene (4q12a) (Westbrook et al., 2005). *Genomic losses that result in allelic insufficiency* are more difficult to study (Fodde and Smits, 2002) but RNA interference has identified *RPS14* as a causal gene of the 5q minus syndrome (Boultonwood et al., 2002), a myelodysplastic syndrome with a deletion in 5q (List et al., 2006). *Genomic losses that affect non-coding genes*, such as microRNA genes (90, 91), have also been identified. The loss of specific microRNAs with tumor-suppressive activity may contribute to oncogenesis. This is the case of the deletion, in 50% of patients with CML, of *MIRN15A* and *MIRN16-1* (13q14.3) that negatively regulate *BCL2* expression (Cimmino et al., 2005).

Genomic Instability

Genomic instability can occur in a variety of forms. “chromosomal instability” (CIN) is the rate at which changes in chromosome number and structure occur over time when compared to normal cells. In “microsatellite instability” (MSI or MIN), there are changes in the number of the oligonucleotide repeats in microsatellite sequences. Base pair mutations are increased in several hereditary, cancer-prone, syndromes such as hereditary non-polyposis colon cancer (HNPCC or Lynch syndrome) where mutations in DNA mismatch repair genes lead to microsatellite instability (MSI) (Lynch, 2012), or hereditary MYH-associated polyposis. Germline mutations in *MYH* (*MUTYH*), a DNA base excision repair (BER) gene, leads to increased GC to TA transversion frequencies. Mutations in genes that repair DNA double-strand breaks or DNA inter-strand cross links, such as breast cancer susceptibility 1 (*BRCA1*) (Wood et al., 2007), Werner syndrome helicase (*WRN*), Bloom syndrome helicase (*BLM*), and the Fanconi anaemia genes, have also been linked to breast cancer, leukemias, and lymphomas. Finally, germline mutations in nucleotide excision DNA repair genes predispose to skin cancer.

Interdependency of Signaling Pathways

Many signaling pathways are known to play a role in oncogenesis. Many of these pathways interact with each other carrying signals from different growth factors and often becoming constitutively activated and independent of normal regulatory feedbacks. In some cases, and due to the central role played at critical crossroads in the cellular machinery,

some proteins are excellent targets for therapy. One example is the “signal transducer and activator of transcription” (STAT) proteins (Darnell, 1997; Yu et al., 2009). Signal transducer and activator of transcription are latent cytoplasmic transcription factors but their constitutive activation, notably Stat3 and Stat5, is often detected in various types of tumor cells and cells transformed by oncoproteins that activate tyrosine kinase signaling pathways (Yu et al., 2009). Signal transducer and activator of transcriptions are activated by tyrosine phosphorylation following the binding of cytokines or growth factors to cognate receptors on the cell surface. Tyrosine kinases that mediate STAT activation include growth factor receptors and cytoplasmic tyrosine kinases, particularly Janus kinase (JAK) and Src kinase families (Garcia et al., 2001). Once tyrosine is phosphorylated, two STAT monomers form dimers through reciprocal phosphotyrosine–SH2 interactions, translocate to the nucleus, and bind to STAT-specific DNA-response elements of target genes to induce gene transcription. To date, there are seven STAT family members identified in mammals (Stat1, Stat2, Stat3, Stat4, Stat5a, Stat5b, and Stat6). Signal transducer and activator of transcriptions with diverse biological functions include differentiation, proliferation, development, apoptosis, and inflammation. Aberrant Stat3, for instance, promotes uncontrolled growth and survival through dysregulation of gene expression, including cyclin D1, c-Myc, Bcl-xL, Mcl-1, and survivin genes, and thereby contributes to oncogenesis (Shor et al., 2007; Diaz et al., 2006; Gritsko, 2006). Moreover, recent studies reveal that persistently active Stat3 induces tumor angiogenesis by upregulation of vascular endothelial growth factor induction and immune evasion (Mora et al., 2002).

Epigenetics

Classic genetics alone cannot explain the diversity of phenotypes within a population nor the different susceptibilities to a disease in identical twins. In 1939, Waddington introduced the field of epigenetics describing “the causal interactions between genes and their products, which bring the phenotype into being” (Waddington, 1942). Epigenetics will later be defined as “heritable changes in gene expression that are not due to any alteration in the DNA sequence” (Jones and Baylin, 2007). Epigenetic modifications regulate chromatin accessibility and compactness and determine what genetic information is made available to the cellular machinery (Sharma et al., 2010) and allow the cancer cell to adapt to changes in its microenvironment. The combinatorial patterns of these modifications are collectively called “epigenome.” The cancer epigenome contains global changes in DNA methylation and histone modification patterns as well as altered expression profiles of chromatin-modifying enzymes that are heritable and can promote oncogenesis (Bernstein et al., 2007; Suzuki et al., 2008; Kouzarides, 2007; Jiang and

Lui, 2009; Bird, 2002). The most important epigenetic mechanisms are DNA methylation, covalent histone modification, incorporation of histone variants and nucleosome remodeling, and non-coding RNAs, including microRNAs (miRNAs),

1. *DNA Methylation.* The low level of DNA methylation in tumors compared with normal tissue counterparts was one of the first epigenetic alterations to be found in human cancer. The loss of methylation is mainly due to hypomethylation of repetitive DNA sequences and demethylation of coding regions and introns, the regions that allow alternative versions of messenger RNA (mRNA) (Deng et al., 2008). During the development of a neoplasm, the degree of hypomethylation of genomic DNA increases as the lesion progresses from a benign proliferation of cells to an invasive cancer. The initial finding of global hypomethylation of DNA was soon followed by the identification of hypermethylated TSP genes (Suzuki et al., 2008) and the more recent discovery of the inactivation of microRNA (miRNA) genes by DNA methylation (Bird, 2002; Prendergast et al., 1991). In normal cells, DNA methylation plays a critical role in the control of gene activity and the architecture of the nucleus. In humans, DNA methylation occurs by covalent modification of cytosine residues that precede guanines within the CpG dinucleotides, which are concentrated in “CpG islands” short CpG-rich DNA stretches at the 5' end of genes, and large repetitive sequences (centromeric repeats, retro-transposon elements, rDNA etc.) (Takai et al., 2002; Wang, 2004). Recent studies show that 100–400 hypermethylated CpG islands occur in the promoter regions of a given tumor. These islands are usually not methylated in normal cells, although methylation of certain subgroups of promoter CpG islands can be detected in normal tissues. Methylation occurs via the cooperative activity of the de novo methyltransferases DNMT3A and DNMT3B and the maintenance DNA methyltransferase DNMT1 (Okano et al., 1999). CpG islands are found in about 60% of human gene promoters but DNA methylation is also important in the regulation of non-CpG island promoters.

Genomic imprinting also requires DNA hypermethylation at one of the two parental alleles of a gene to ensure monoallelic and a similar gene-dosage reduction is involved during X-chromosome inactivation in females. Cells that lack the stabilizing effect of DNA methylation because they have spontaneous defects in DNA methyl transferases (DNMTs) or experimentally disrupted DNMTs have prominent nuclear abnormalities. DNA methylation is the basis for epigenetic phenomena such as imprinting, X-chromosome

inactivation or formation of heterochromatin (Barski et al., 2007; Wang et al., 2008). In 70–80% of CpG dinucleotides, in mammalian cells, there is a modification at the C5 position of the cytosine base (5mC) (Feinberg et al., 1983; Riggs et al., 1983). In 60% of gene promoters CpG islands are free of methylation regardless of their active state. In cancer cells, however, promoter CpG islands tend to become hypermethylated leading to silencing of the corresponding gene (Takai et al., 2002; Wang, 2004). Recent reports have identified genomic regions, with distinct DNA methylation patterns that regulate gene expression profiles and chromatin compartmentalization. Although DNA methylation is a very stable phenomenon, reprogramming of DNA methylation can occur via oxidation by the TET family of proteins to 5-hydroxymethylcytosine (5hmC) or via deamination to thymine by AID/APOBEC1 followed by base excision repair (BER) (Riggs et al., 1983).

2. *Histone Modifications.* The coiling of DNA around nucleosome particles is the basis for the organization of eukaryotic genomes. A multitude of different post-translational modifications of the core histone proteins (H2A, H2B, H3, and H4) allows for demarcation of specific chromatin regions and states (Jenuwein, 2006). Histone modifications can be dynamically added or removed and associated with both active and repressed regions of chromatin. More than a dozen reported histone modifications can modify more than 150 conserved residues within histone proteins (Jones and Baylin, 2007). This number of different modifications has a high combinatorial potential, which would yield a hugely complex histone code and it is under debate, whether such a code exists or whether histone modifications are a consequence and mere reflection of dynamic processes altering DNA accessibility such as transcription factor or RNA polymerase II (RNAPII) binding or chromatin remodeling (Wang et al., 2008; Schones et al., 2008). Certain histone modifications such as acetylation or phosphorylation are thought to change chromatin structure by altering the net positive charge of the histone proteins, thereby rendering the underlying DNA sequence information more accessible. Alternatively, histone modifications can be recognized by specific protein domains that in turn might enforce or stabilize the chromatin signature and provide a platform for the recruitment of additional factors. Chromatin regulators, histone modifiers, and histone modification binding proteins, are present at distinct genomic loci and frequently bring together regulators associated with opposing activities. Aside from gene regulatory functions, which occur in a relatively local and confined chromatin region, histone modifications can also span large regions, as

exemplified by X-chromosome inactivation in female mammal. Large chromatin blocks associated with gene silencing have been identified on mammalian autosomes (Hassler and Egger, 2012). Further, exchange of canonical histones by variants is connected to transcriptional activity as well as chromatin structure. DNA accessibility can be affected by the structure of nucleosomes and their interaction with DNA by exchanging canonical histones with histone variants or by histone modifications, respectively.

Additionally, the position and the density of nucleosomes on the DNA string can determine the level of accessibility. Active genes have characteristic nucleosome depleted regions (NDRs) flanked by positioned nucleosomes upstream of their transcription start sites, which contain binding sequences for transcription factors. Repressed genes usually lack an NDR, but DNA sequence, binding of transcription factors and the action of chromatin remodeling complexes have been suggested to act in a multistep process to determine local nucleosome composition and density (Baylin and Ohm, 2006). DNA methylation occurs in the context of chemical modifications of histone proteins (Sharma et al., 2010). Histones are not merely DNA-packaging proteins, but molecular structures that participate in the regulation of gene expression. They store epigenetic information through post-translational modifications such as lysine acetylation, arginine and lysine methylation, and serine phosphorylation. These modifications affect gene transcription and DNA repair. It has been proposed that distinct histone modifications form a “histone code” (Jenuwein, 2006). The N-terminal tail of histones can undergo post-translational covalent modifications to help regulate transcription, replication, and repair. It has been proposed that these modifications are stored in a “histone code,” a form of cellular epigenetic memory that contributes to the structure and activity of different chromatin regions. Non-histone proteins would gain access to the chromatin and would decode this message. Numerous histone modifications have been identified. They are regulated by histone acetyltransferases (HATs) and histone methyltransferases (HMTs), which add acetyl and methyl groups, respectively, and histone deacetylases (HDACs) and histone demethylases (HDMs), which remove acetyl and methyl groups, respectively (Okano et al., 1999; Feinberg et al., 2006). Furthermore, histone modifications and DNA methylation interact with each other to determine the gene expression status, chromatin organization, and cellular identity. Acetylation of histone lysines, for example, is generally associated with transcriptional activation. The functional consequences of the methylation of histones depend on the type of residue (lysine or arginine) and the specific site of

methylation. Methylation of H3 at K4 is closely linked to transcriptional activation (Riggs et al., 1983; Eden et al., 2003; Wilson et al., 2007) whereas methylation of H3 at K9 or K27 and of H4 at K20 is associated with transcriptional repression (Cedar and Bergman, 2009). Hypermethylation can silence genes such as Rb, p16, and BRCA. In cancer, there is also loss of histone acetylation, which is mediated by HDACs and results in gene repression. Histone deacetylases are often found to be overexpressed in various types of cancer. Hypermethylation of the CpG-island promoter can affect genes involved in the cell cycle, DNA repair, the metabolism of carcinogens, cell-to-cell interaction, apoptosis, and angiogenesis, all of which are involved in the development of cancer. Hypermethylation occurs at different stages in the development of cancer and in different cellular networks, and it interacts with genetic lesions. Such interactions can be seen when hypermethylation inactivates the CpG island of the promoter of the DNA-repair genes *hMLH1*, *BRCA1*, *MGMT* (O6-methylguanine–DNA methyltransferase), and the gene associated with Werner's syndrome (*WRN*) (26,51-53.). Each tumor type can be assigned a specific, defining DNA "hypermethylome." Such patterns of epigenetic inactivation occur not only in sporadic tumors but also in inherited cancer syndromes in which hypermethylation can be the second lesion in Knudson's two-hit model of how cancer develops (Hassler and Egger, 2012).

3. *Deregulation of non-coding RNAs.* In recent years, it has become clear that non-coding RNAs are important modulators of chromatin regulation and gene expression. Whole genome and transcriptome sequencing has revealed that at least 90% of the genome is actively transcribed, although <2% represent protein-coding genes. Thus, the non-coding part of the transcriptome has become a new focus in the study of gene expression and regulation (Baylin and Ohm, 2006). Currently, two major groups of non-coding RNAs are recognized: small ncRNAs and long ncRNAs (lncRNAs) (Lu et al., 2005; Chan et al., 2005; Deng et al., 2008).

Small ncRNAs Small nc RNAs are processed from longer precursors and comprise, in addition to transfer RNAs (tRNAs) and ribosomal RNAs (rRNAs), the microRNAs (miRNAs), piwi interacting RNAs (piRNAs), small nuclear RNAs (snoRNAs), and other less well-characterized RNAs (He et al., 2004; Saito et al., 2006; Fabbri et al., 2007; Friedman et al., 2009). MicroRNAs consist of a single RNA strand of 21–23 nucleotides that can bind a complementary sequence on a messenger RNA (mRNA) causing its degradation or blocking the translation of a protein. They are expressed in a tissue-specific manner and participate in the

control of cell proliferation, apoptosis, and differentiation. They are often located in chromosomal regions that undergo rearrangements, deletions, and amplifications. As is the case for normal genes, expression of miRNAs can be regulated by epigenetic mechanisms (Jones and Baylin, 2007) but miRNAs can also modulate epigenetic regulatory mechanisms by targeting enzymes responsible for DNA methylation and histone modification (Jones and Baylin, 2002), and they can function as either TSP genes or oncogenes depending on the target genes. Thus, oncogenic miRNAs, target growth inhibitory pathways and are often upregulated in cancer. An example is miR-21, which targets PTEN in glioblastoma. DNA hypermethylation in the miRNA 5' regulatory region can lead to down-regulation of miRNA (Barski et al., 2007). This reveals a tumor-suppressor function for miRNAs as in the examples of downregulated *let-7* and *miR-15/miR-16*, which target the *RAS* and *BCL2* oncogenes, respectively. Methylation silencing of *miR-124a* causes activation of the cyclin D–kinase 6 oncogene (*CDK6*), a common epigenetic abnormality in cancer.

Long ncRNAs (lncRNAs) Long ncRNAs are a heterogeneous class of mRNA-like transcripts from 200 nt up to 100 kb, which do not code for proteins that, excluding ribosomal and mitochondrial RNA, appear to make up the bulk of the human transcriptome. They can be transcribed from sense or antisense strand, in a bidirectional way and fulfill important regulatory roles in gene expression and regulation by assembling protein complexes and localizing them to their genomic target DNA sequence. Another class of non-coding RNAs is the transcribed ultraconserved regions (T-UCRs) that are aberrant in several cancers, including adult chronic lymphocytic leukemia, colorectal and hepatocellular carcinomas, and neuroblastomas. Although distinct T-UCR expression signatures are associated with specific cancer types and their high sequence conservation across species argues for functional properties, their precise mode of action in the cell is still unknown.

The epigenetic code is not permanently stable. In addition to spontaneous reactions, affecting chromatin and DNA methylation, genome maintenance itself involves extensive alterations in the components of chromatin. For instance, repair of double-strand breaks involves extensive phosphorylation of histone H2AX followed by modification of histones by ubiquitination and sumoylation (Jenuwein et al., 2001; Wang et al., 2008; Haberland et al., 2009; Shi, 2007) all of which are required for efficient double-strand break repair. Also, repair of single-strand breaks involves the formation of large chains of poly(adenosine diphosphate [ADP]-ribose) on target proteins by the enzyme poly(ADP-ribose) polymerase (PARP). The chains of poly (ADP-ribose) probably serve as a platform to recruit the appropriate mechanism of repair. It is likely that the degeneration of the epigenetic code that facilitates oncogenesis

originates in part from both damage and the subsequent genome maintenance. Little is known about the maintenance machinery of the epigenome and its contribution to cancer (Bernstein et al., 2007). In addition to initiating carcinogenesis, genome instability also drives the progression from benign to malignant tumors by permitting additional genetic and epigenetic changes that facilitate evolution to a more aggressive state.

Cell Cycle

The cell cycle has four sequential phases. During the S phase, DNA replication occurs, and in the M phase the cell divides into two daughter cells. Separating S and M phase are two gap phases named G1 and G2 (Williams, 2012). During G1, following mitosis, the cell is sensitive to positive and negative network signals. G2 is the gap after S phase when the cell prepares for entry into mitosis (Murray, 1992). G0 is a state when cells have reversibly withdrawn from cell division (Zetterberg and Larsson, 1985). Most cells reside in these “out-of-cycle” states while some cells are actively proliferating, mainly in the stem-transit amplifying compartments of self-renewing tissues, such as epithelia and bone marrow (Potten and Loeffler, 1990). Progression through the cell cycle is driven by the cyclin-dependent kinase (CDK) family of serine/threonine kinases and their regulatory partners the cyclins (Malumbres and Barbacid, 2006). Cyclin D-CDK4, cyclin D-CDK6, and cyclin E-CDK2 drives G1 progression through the restriction point, which commits the cell to complete the cycle (Planas-Silva and Weinberg, 1997). S phase is initiated by cyclin A-CDK2, and cyclin B-CDK1 regulates progression through G2 and entry into mitosis (Nigg, 2001). Progression through each cell cycle phase and transition from one phase to the next are monitored by sensor mechanisms, called checkpoints, which maintain the correct order of events (Hartwell and Weinert, 1989). If the sensor mechanisms detect aberrant or incomplete cell cycle events (DNA damage), checkpoint pathways carry the signal to effectors that can trigger cell cycle arrest (Bartek et al., 2004; Musacchio and Salmon, 2007). Effector proteins include CDK inhibitors (CDKIs). For example, G1 arrest can be induced by the Ink4 family [INK4A (p16), INK4B (p15), INK4C (p18), and INK4D (p19)] of CDKIs, which inhibit CDK4 and CDK6, or, alternatively, via the Cip/Kip family of inhibitors (p21, p27, p57), which suppress CDK2 activity (Malumbres and Barbacid, 2009; Hanahan and Weinberg, 2000).

Deregulation of the cell cycle engine is at the center of the uncontrolled cell proliferation that characterizes the malignant phenotype. Mitogens release the brakes of cell cycle progression by stimulating G1–S CDK activities, which trigger the phosphorylation of pRb proteins, leading to the disruption of their interaction with the E2F family of transcription factors. In cancer cells, the pRb brakes are often

defective, resulting in E2F-dependent G1–S gene expression even in the absence of mitogens (Harbour and Dean, 2000). Several cancer genes directly control transitions from the resting stage (G0 or G1) to the replicating phase (S) of the cell cycle. The products of these genes include cdk4 (a kinase), cyclin D1 (activates cdk4), Rb (transcription factor), and p16 (inhibits cdk4) (Bartek et al., 2004; Musacchio and Salmon, 2007; Malumbres and Barbacid, 2009). The genes encoding Rb and p16 are TSPs, inactivated by mutation, whereas those encoding cdk4 and cyclin D1 are oncogenes, activated by mutation (Barbacid et al., 2005). Many mutations are mutually exclusive allowing the cell to acquire a growth advantage when only one mutation is present. Importantly, since there are less signaling pathways than genes, there is a plethora of interconnections that lead to the same result. One example is the TP53 pathway. The p53 protein is a transcription factor that, normally, inhibits cell growth and stimulates cell death in response to cellular stress. Typically, a point mutation prevents p53 from binding its cognate recognition sequence but the p53 pathway can also be altered by *MDM2* gene and products of DNA tumor viruses (i.e., E6 protein of HPV). Adding to this complexity is the fact that the same mutation may have different effects depending on the cell type. For instance, *KRAS2* gene mutations in normal pancreatic duct cells appear to initiate the neoplastic process while the same mutation in colonic or ovarian epithelial cells produces self-limiting, hyperplastic or borderline lesions that do not progress to carcinoma. Also, in some tumors, *RAS* genes function as oncogenes while, in others, *RAS* genes can function as TSP.

CHEMICAL CARCINOGENESIS

The important role played by chemical products in carcinogenesis is reflected in the fact that up to 8% of all human cancers are of occupational origin (Fröhling and Döhner, 2008). Thus, the risk of lung cancer for men exposed to specific carcinogens in the workplace is 9.2% while for bladder cancer, the population risk is one in five men and 1 in 10 women (Fonger, 1996). So far, approximately six million chemicals have been identified and registered with the chemical abstracts service. Of those, more than 50,000 are regularly used in commerce and industry, although <1000 have been properly scrutinized as to their carcinogenic potential (Elespuru, 1996). Today, the list of known or potential carcinogens, published in the 12th Edition of Reports Carcinogens by the National Toxicology Program, Public Health Service, U.S. Department of Health and Human Services, includes more than 200 substances. In some cases, cancer may develop only after prolonged exposure (i.e., tobacco) while in others, cancer may develop even after a brief exposure (i.e., asbestos). Section 301(b)(4) of the Public Health Service Act provides that the Secretary of the

TABLE 107.3 Classification of Carcinogens (IARC Monographs on the evaluation of Carcinogenic Risk in Humans. International Agency for Research on Cancer – <http://monographs.iarc.fr/ENG/Classification/>)

Carcinogen Group	Description	Number of Carcinogens
Group 1	Carcinogenic to humans	109
Group 2A	Probably carcinogenic to humans	65
Group 2B	Possibly carcinogenic to humans	275
Group 3	Not classifiable	505
Group 4	Probably not carcinogenic to humans	1

Department of Health and Human Services shall publish a biennial report with the list of substances known to be either “carcinogens” (sufficient evidence of carcinogenicity from human studies indicating causal relationship between exposure and cancer) or “reasonably anticipated to be carcinogens” (limited evidence of causality in human studies, sufficient evidence of carcinogenicity from animal studies with increased incidence of malignant and/or malignant and benign tumors, less than sufficient evidence of carcinogenicity in humans or animals, but the substance belongs to a structurally related class of substances known to be carcinogenic, anticipated to be a carcinogen, or convincing information that the agent acts through mechanisms known to cause cancer in humans). Also, the IARC classifies the evidence for carcinogenicity of specific exposures into four categories (Table 107.3).

Pott first recognized, in 1775, the relationship between exposure to environmental substances and neoplasia. Pott described cancerous changes in the scrotal skin of London chimney sweeps as a result of repeated contamination with soot. Daily baths were recommended in 1890, a high incidence of bladder cancer in chemical and rubber industry workers was observed across Europe. By the end of the nineteenth century it had become evident that occupational exposure to certain chemicals or mixtures of chemicals had carcinogenic effects. The first experiment on chemical carcinogenesis was carried out, in 1915, by the pathologist Yamagawa. He rubbed rabbit ears with coal tar and observed the development of papillomas and carcinomas. In the 1930s, high molecular weight polycyclic aromatic hydrocarbons (PAHs) were proven to induce skin cancer in mice and, in fact, the active component in coal tar pitch turned out to be a PAH. Berenblum and Shubik using PAHs and croton oil showed that cutaneous cancer, in mice, developed in several stages (Berenblum and Shubik, 1947) (see below).

Prior to Watson and Crick, chemical carcinogens were believed to produce cancer by interaction with proteins. By the end of the 1960s, however, a correlation between the DNA binding capacity of a particular carcinogen and its

biological potency was established. Electrophilic substances, with affinity for negative charges, could bind proteins and DNA and induce cancer directly while inert, neutralophilic chemicals, on the other hand, acted as pro-carcinogens since they required enzymatic conversion. Although this metabolic conversion was known since the 1940s, it was not until the 1960s that the cytochrome P450 was discovered (Luch, 2005). Cytochrome-P450-dependent monooxygenases (CYPs) were shown to be associated with an NADPH-dependent reductase (Luch, 2005) and, today, 57 genes encoding these enzymes, are recognized. These enzymes appear to be somewhat tissue specific and operate with high stereo-selectivity forming metabolites that differ in their biological activity. Further metabolism occurs on target cells where carcinogens or their metabolic products either directly, by genotoxic mechanisms (formation of DNA adducts, chromosome breakage, fusion, deletion, mis-segregation, and non-disjunction), or indirectly, by non-genotoxic mechanisms (induction of inflammation, immunosuppression, formation of reactive oxygen species, receptor activation, and epigenetic silencing). These changes affect gene expression, cell-cycle control, DNA repair, cell differentiation, and apoptosis, resulting in hypermutability, genomic instability, loss of proliferation control, and resistance to apoptosis, all recognized features of cancer cells.

Tests that measure DNA affinity have been developed to characterize the degree of genotoxicity of carcinogens and to identify their DNA-reactive metabolites. These studies have confirmed the relationship between DNA-binding activity and both mutagenicity and carcinogenicity, also establishing that the formation of DNA adducts is a relevant bio-indicator of cancer risk. Baseline levels of carcinogen DNA adducts in normal human tissues are estimated to be in the range of 1/107–0.2/108 nucleotides. Certain mutations are common both in human cancers and in animal models of chemical carcinogenesis. An example is the codon 12 of KRAS that is frequently mutated in human cancers, including lung adenocarcinoma, and is also a preferential binding site for DNA-damaging metabolites of a variety of carcinogens.

Phases of Carcinogenesis

In humans, there is a 20–50-year lag from exposure to a carcinogen to the clinical detection of a tumor. Analysis of cancers at different stages suggests a sequential order of mutations and genome rearrangements, although some cancers have only a limited of relevant genetic changes. The initial targets of carcinogenesis research were “PAHs”. Chrysene was identified as a carcinogenic compound in tar, and benzopyrene was later shown to be tar’s most potent carcinogenic agent. Benzopyrene then became the most intensely studied chemical carcinogen because it was believed that its chemical structure was related to that of steroid hormones, and steroid hormones were, at the time, the only endogenous compounds reported to induce tumors in mice and humans (Carrell et al., 1997).

This structure-function concept was supported by the synthesis of 3-methylcholanthrene, a potent carcinogen that could possibly be produced *in vivo* from cholesterol-derived bile acids. Later it was shown that compounds with different chemical structures could induce tumors, and analogies began to be seen between chemical carcinogens and radiation. This raised the possibility that carcinogens acted as radiomimetic compounds by reversible binding to purines and DNA bases or through reactive metabolites, stimulating an intense research effort intended to clarify the mechanistic aspects of cancer induction. It also became clear that age and individual differences were at the center of the susceptibility to cancer, and these differences, presumably of a genetic origin, could therefore be inherited (Melnick, 1996). Furthermore, it was observed that a long latent period could lapse from exposure to carcinogens to the development of cancer. In 1941 Rous and Kidd began to paint the skin of rabbits with tar and found that if this painting was interrupted, tumors would disappear only to reappear if the application of tar was reestablished. Therefore it seemed that a reversible process was taking place in those cells that did not attain the complete neoplastic state. These cells had undergone what Friedewald and Rous called “initiation.” Since then, the process of chemical carcinogenesis has been understood as the result of three distinct successive stages: initiation, promotion, and progression.

Initiation Initiation is the induction of an irreversibly altered cell through a mutational event that may differ for different tissues or for different initiators in the same tissue (Barbacid, 1986). It is induced by the genetic changes that predispose susceptible normal cells to malignant change and immortality. Cellular division remains symmetrical by creating two initiated cells protected from apoptosis. Initiation can begin with errors in replication or with spontaneous mutations, supported by normal occurrences such as DNA depurination and deamination. Spontaneous initiation, less common than induced initiation, has been confirmed in

laboratory animals (Pitot and Dragan, 1991). Initiated cells can remain latent for months or years, or can grow in an autonomous and clonal fashion. DNA damage is at the center of this process. Proliferating cells have less time to repair the damaged DNA and remove DNA adducts. DNA damage in stem cells is particularly relevant because of their long lifespan and wide tissue distribution.

Promotion Promotion is the process by which the initiated cell clonally expands into a detectable cell mass that is either benign or preneoplastic. At this stage, different chemicals may have different carcinogenic consequences, depending on the effect of cell proliferation in the initiated cell. The concept of promotion was introduced when it was discovered that chemical substances with low carcinogenic activity induced cancer under experimental conditions (Berenblum and Shubik, 1947). Promoter compounds do not interact directly with DNA and can have biological effects without being metabolically activated (Yuspa et al., 1983). They may also indirectly damage the DNA by oxidation. At first, it was believed that promoters acted via epigenetic mechanisms but, today, we know that promotion also involves genetic changes (Hanahan and Weinberg, 2000). The results are increased cellular proliferation, alterations in genetic expression, and changes in the control of cellular growth (Barrett and Anderson, 1993). In order to be effective, promoters must be present for weeks, months, or years. Promotion is reversible and can be modulated by physiological factors (Yuspa et al., 1983). Prolonged exposure or high doses, however, will induce neoplasia without initiation (Pitot and Dragan, 1991).

Progression Cells must undergo additional changes in their progression to a malignant neoplasm (Barrett and Wiseman, 1987). Progression phase, characterized by rapid, irreversible growth, genetic instability and cellular changes in metabolism and morphology, is the acquisition of the neoplastic phenotype by genetic and epigenetic processes with cell proliferation occurring without exogenous stimuli. (Oliveira et al., 2007). Some tumor promoters, however, although effective in producing multiple pre-neoplastic foci, are not particularly effective in influencing the progression of these lesions to malignant neoplasms. This suggests that promotion and progression were independent phenomena. Angiogenesis, essential in the neoplastic process, precedes the development of characteristics of malignancy, and its inhibition has been shown to delay the neoplastic process. (Oliveira, 2007).

DNA Damage

Contrary to initial assumptions that DNA, given its role in genetic information transfer, is extraordinarily stable, it has been shown that DNA is a dynamic macromolecule that is subjected to continuous changes and reacts easily with a variety of chemical and physical compounds present in the

environment. DNA is made up of an array of nucleophilic centers with which DNA damaging agents, typically electrophilic, form adducts through one or more covalent bonds to the base sugar of phosphate. Ultraviolet radiation, for instance, causes 2+2 cyclo-addition reactions at the 5,6 double bonds of the adjacent pyrimidines. Ionizing radiation, on the other hand, may subtract hydrogen atoms, generating free radical species, or cause an excision of an O–H bond of water to form the highly reactive hydroxyl radical •OH. DNA is also the target of reactive oxygen species, produced intracellularly, as products of mitochondrial respiration. Tumor promoters, such as 12-O-tetradecanoylphorbol-13-acetate, are known to increase the amount of intracellular oxidative damage. Furthermore, enzymatic oxidation of exogenous and endogenous toxins by the mixed function oxygenase systems, cytochrome P-450, and flavin monooxygenase, can activate xenobiotics such as polycyclic hydrocarbons, mycotoxins, and alkylating agents (Rissle, 1997). These compounds, in turn, produce electrophiles with capabilities for DNA damage (Szeliga, 1997).

DNA damage stimulates replication-dependent phenomena such as sister chromatid exchanges, chromosomal aberrations, and gene amplification. Replication of these DNA lesions is an essential factor in the generation of genetic defects and proliferating cells are more susceptible to neoplastic transformation than non-proliferating cells, following genotoxic treatment. Mutation rates increase during the S-phase of cells pre-exposed to DNA-damaging agents (Wang et al., 1993). The cumulative damage to the DNA is significant. In a single day, each normal cell can undergo more than 10,000 DNA damaging events, 10^4 single-strand breaks and spontaneous base losses, and 10^5 UV photo-products in each sun-exposed keratinocyte (De Bont and van Larebeke, 2004). The consequences are more than 900 phosphorylation events involving more than 700 proteins. The importance of DNA damage in the development of cancer is highlighted by the observation that an elevated incidence of cancer is detected in situations where DNA repair mechanisms are deficient. Several cancer-prone syndromes seem to be related to an inherent inability to recover after DNA damage. It has also been shown that when DNA repair fails, mutations accumulate.

DNA Damage Recognition and Repair

Chemical carcinogens can attack and change the structure of DNA by alkylation, oxidation, dimerization, deamination, and the formation of aromatic adducts. The carcinogen–DNA adducts that are formed have varying mutagenic abilities. Human cells use various DNA repair mechanisms to counteract the DNA damage caused both by endogenous and environmental chemicals: (1) “BER” removes products of alkylation and oxidation, (2 “nucleotide excision repair” (NER) excises oligonucleotide segments containing larger adducts, (3) “mismatch repair” scans the DNA for

misincorporation by DNA polymerases, (4) “oxidative demethylation,” (5) transcription-coupled repair (TCR), repairs lesions that block transcription, (6) “double-strand break repair and recombination” avoids errors by copying the opposite DNA strand, and (7) not yet characterized mechanisms that repair cross-links between strands. These mechanisms affect signal-transduction and effector systems connected with replication, transcription, recombination, chromatin remodeling, and differentiation, and ultimately determine survival, senescence, or death. Most DNA lesions are repaired by more than one mechanism and, as a result, only few DNA lesions escape repair. Those that do, at the time of DNA replication, can direct the incorporation of non-complementary nucleotides resulting in mutation.

Repair pathways often focus on a specific category of DNA lesion (Friedberg, 2003; Friedberg et al., 2006). Thus, BER mechanisms remove a damaged base that is refilled by DNA synthesis (Slupphaug et al., 2003; Caldecott, 2008; Barnes and Lindahl, 2004). Nucleotide-excission repair eliminates helix-distorting DNA lesions. Transcription-coupled repair, strongly linked with NER and possibly with BER, targets lesions that impair transcription. Non-homologous end joining and homologous recombination repair various types of double-strand breaks. In addition, some repair proteins are used only once. For instance, O-6-methylguanine-DNA methyltransferase repairs a single O-6-methylguanine lesion by transferring the methyl from a guanine in DNA to a cysteine in the enzyme, thereby inactivating itself (Verbeek et al., 2008).

Base Excision Repair The first step in the excision repair process is the recognition of an abnormality. This recognition process must be able to detect the relatively small amount of damaged DNA that is found within the remaining normal genome. In addition, it should not interfere with DNA replication, recombination, or transcription. Following recognition, the damaged portion of the DNA is removed by the action of a glycosylase. DNA glycosylases are monomeric enzymes that catalyze the hydrolysis of the N-glycosyl bond of damaged, modified, or mismatched bases in the DNA, resulting in their detachment from the sugar-phosphate backbone (Barnes et al., 1993). The resultant abasic sugar, now without an attached purine or pyrimidine, is subjected to endonucleolytic cleavage and excision from the DNA. A DNA polymerase then synthesizes a repair patch containing the appropriate nucleotide sequence. The patch is manufactured in the 5' to 3' direction using the complementary, undamaged strand as a template. DNA ligase then connects the 3' terminus of the patch to the parental strand. This type of repair, resulting in the removal of only one or a few nucleotides, is termed *BER* (Barnes, Lindahl, Sedgwick, 1993). Base excision repair is used for the repair of small alkyl or aromatic adducts. However, larger adducts require

the removal of more than just one or a few bases in the vicinity of adduct. For these adducts, NER is used (Hoeijmakers, 1993).

Nucleotide Excision Repair As many as 200 bases, including the adduct, can be removed by the NER, a process similar to BER except that the multiprotein complex that directs the endonucleolytic attack on the damaged DNA excises an entire oligonucleotide containing the lesion in question (Gillet and Scharer, 2006). The process involves lesion recognition, incision of the damaged strand on both sides of the lesion at some distance, removal of the damage-containing oligomer, and gap-filling DNA synthesis. A specialized nucleotide excision pathway exists to take care of the preferential elimination of all types of injury in the transcribed strand of active genes. This process, called *transcription coupled repair*, corrects damage in structural genes transcribed by RNA polymerase II. It prevents the blockage of transcription and replication by injuries to the template. A second type of NER, designated *global genome repair*, removes lesions in the remainder of the genome preventing the long-term effects of DNA injury (Hanawalt, 2002; Hanawalt and Mellon, 1993). The NER process is mediated in *Escherichia coli* by the products of the urvA, B, and C genes. This process is presently the only system in which the precise mode of action is entirely known. In humans, the genes whose products affect this repair are mutated in the various complementation groups of the hereditary disease, xeroderma pigmentosum (Hoeijmakers, 2001, 2009). Patients with xeroderma pigmentosum have acute photosensitivity, a 2000-fold increase in the incidence of skin cancers in sun-exposed skin and, in some cases, accelerated neurodegeneration. Patients with this disorder display an inherited inability to repair DNA damage induced by ultraviolet light. The ultraviolet light causes the formation of pyrimidine dimers, which these patients are unable to excise. Xeroderma pigmentosum is genetically heterogeneous. Cell hybridization studies have led to the identification of seven excision-deficient complementation groups, designated XP-A to XP-G. Mutated genes in these groups code for the proteins that are responsible for the NER process in humans.

Mismatch Repair DNA mismatches occur when conventional, but noncomplementary, Watson–Crick bases lie opposite each other in the DNA helix. Mismatch repair systems exist to remove replication errors and reduce the mutation rate. To correct these replication errors, the repair system must be able to distinguish between parental and newly synthesized strands. In *E. coli* this process is accomplished by adenine methylation at GATC sequences (Shrivastav et al., 2008). Although methylation of these GATC sequences is complete in nonreplicating DNA, during replication methylation lags behind the replication machinery.

Thus newly synthesized strands are transiently under-methylated. The *E. coli* mismatch repair system recognizes only unmethylated DNA strands. Consequently this methyl-directed mismatch repair system operates only on newly synthesized strands in the region immediately behind the replication fork. Mismatch repair in *E. coli* is a multistep process that involves several proteins. First the MutS protein recognizes and binds to the mismatched DNA. This MutS binding is independent of methylation. Next the MutL protein recognizes and binds to the MutS–DNA complex. The MutS–DNA–MutL complex then activates the MutH protein. MutH is an unmethylated GATC-specific endonuclease, which nicks an unmethylated GATC sequence adjacent to the mismatch (Barnes and Lindahl, 2004). Helicase then unwinds the DNA, and a specific exonuclease digests the mismatch. The gap created is then filled by DNA polymerase using the opposite strand as a template. DNA ligase then seals the repaired strand.

This repair process can recognize and repair single base pair mismatches as well as small additions or deletions. However, not all mismatches are repaired equally. Transition mispairs, guanine to thymidine (G-T) or adenine to cytosine (A-C), involve purine to pyrimidine binding. Transversion mispairs (AA, G-G, G-A, T-T, C-C, and C-T) involve purine to purine or pyrimidine to pyrimidine binding. A successful repair leads to normal stacking and intrahelical configuration. Thus transition mispairs are repaired more efficiently by the mismatch process than are transversion mispairs. Furthermore, these types of mismatches are most likely to be missed by the proofreading action of DNA polymerase. Consequently, the mismatch repair process is able to repair most efficiently those errors that are most commonly made by DNA polymerase (Huen and Chen, 2008). Components of the *E. coli* mismatch repair system appear to have been conserved throughout evolution. Multiple proteins have been found in humans that are homologous to the *E. coli* MutS and MutL proteins (Kanaar et al., 2008). Indeed, with the exception of strand discrimination, the mechanism of eukaryotic mismatch repair parallels that of *E. coli*. The only exception appears to be that no MutH homologs have been found in humans. Instead of recognizing adenine methylation of GATC sequences, strand discrimination in humans occurs as a result of discontinuities in newly synthesized strands. Furthermore, in the *E. coli* repair process, GATC sequences and MutH function are not needed if the DNA strands are nicked. Thus the mismatch repair process is virtually identical in both *E. coli* and humans because, even in *E. coli*, mismatch repair can be directed by strand discontinuities. In addition to its role in repairing damaged DNA, the mismatch repair process serves to prevent chromosomal recombination between nonidentical sequences during meiosis. Indeed inhibition of mismatch repair has been shown to allow

recombination not only between nonidentical sequences but also in interspecies recombination. Consequently mismatch repair controls both the fidelity of DNA replication, as well as the maintenance of a genetic barrier between species. Because MutS and MutL homologs have been shown to be involved in the prevention of replication errors and chromosomal rearrangements in humans, mutations in the genes that code for these proteins can be expected to lead to disease states in humans. In fact, mutations in these MutL and MutS genes have been shown to be associated with a high incidence of colon cancer in a condition known as "hereditary nonpolyposis colon cancer." Chemical carcinogens that damage these mismatch repair genes, therefore, may lead to a predisposition to cancer.

As stated previously, DNA repair enzymes can modify carcinogenic damage by the removal of DNA adducts. DNA repair rates can be determined by measuring unscheduled DNA synthesis and the removal of DNA adducts using a single-cell autoradiographic technique. DNA damage in some domains of the genome is processed much more efficiently than in others. As previously discussed, patients with xeroderma pigmentosum have markedly decreased excision repair rates and have increased rates of skin cancer after exposure to ultraviolet light. A reduced capacity of mononuclear cells to repair the aromatic amine adducts have also been found in individuals who have first-degree relatives with cancer. Finally a decrease in DNA repair rates has also been seen in fibroblasts of lung cancer patients compared with normal controls. Furthermore, differences in the repair response to damage may also account for some of the significant differences in carcinogenic response seen when different organisms, such as humans and rodents, are compared.

Cell Cycle Arrest

Abrogation of cell checkpoints, with agents such as methylxanthine analogs or pentoxifylline, increases the cytotoxicity of DNA-damaging agents. Replication of a damaged template would certainly result in irreversible chromosomal aberrations and a high mutation rate. Two particular checkpoints are thought to be particularly important following DNA damage: the G1 checkpoint located between the G1 and S phases (preceding DNA replication), and the G2 checkpoint, located between the G2 and M phases (preceding chromosome segregation). A complex involved in the G2 checkpoint is CyclinB–p34(Cdk2). CyclinB levels begin to accumulate in late S-phase. At the G2–M transition, Cdk25C dephosphorylates p34(Cdk2), leading to the activation of CyclinB–p34(Cdk2) kinase activity and entry in mitosis. CyclinB is then degraded near the end of mitosis. Treatment of cells with a variety of DNA-damaging agents prevents dephosphorylation of p34(Cdk2) and, therefore, leads to the activation of CyclinB–p34(Cdk2) kinase activity

(Lock, 1992; O'Connor et al., 1992; Tsao et al., 1992). Nitrogen mustard, on the other hand, prevents activation by phosphorylation of Cdk25C, which is required for the dephosphorylation and activation of p34(Cdk2) (O'Connor et al., 1992; Kohn et al., 1994). Mutations that cause loss of the G2 checkpoint increase the cytotoxicity of DNA-damaging agents. DNA damage following such mutations generally leads to cell death instead of carcinogenesis. Loss of the G1 checkpoint, on the other hand, triggers genomic instability at the time of interaction of unrepaired DNA with the DNA replication machinery, leading to deletion-type mutations and aberrant gene amplification (Slischenmeyer et al., 1993). The inactivation of the G1 checkpoint serves as an initiation step, which makes the cell susceptible to unregulated growth (initiation), one of the hallmarks of cancer, increasing the probability of subsequent genetic alterations and establishing the fully developed neoplastic phenotype. Control at the G1 checkpoint is dependent on CyclinD1 (degraded at the G1/S transition) and CyclinE (degraded in mid-S phase). Overexpression of either CyclinD1 or CyclinE and activation of the CyclinD1–Cdk and CyclinE–Cdk complexes results in entry into the S-phase and decreased G1 time (Resnitzky et al., 1994). These complexes act to phosphorylate pRb, the product of the retinoblastoma gene, a tumor-suppressor gene (Cance et al., 1990). Unphosphorylated pRb maintains cells in G1, whereas phosphorylation inactivates pRb and allows exit from G1. Another tumor-suppressor gene, p53, is necessary for G1 phase arrest after DNA damage (Kuerbitz et al., 1992). Lack of p53 permits damage-resistant DNA synthesis and increases the incidence of selected types of mutations (Smith et al., 1996). This has been shown after a variety of DNA-damage mechanisms such as ionizing radiation (strand breaks), alkylation by methylmethane sulfonate (MMS), UV radiation (photodimers), and a variety of environmental carcinogens (Hollstein et al., 1991). After DNA damage, p53 binds a consensus binding site (Kern et al., 1991; El-Deiry et al., 1992) and activates the transcription of several "downstream" genes (Perry and Levine, 1993). One of these genes codes for the p21 protein that binds and inactivates cyclin/Cdk complexes and prevents the progression of the cell cycle beyond G1. Another gene is the "cyclin-inhibiting protein" gene CIP1 (WAF1 or SDI1). The p53 protein also activates the BAX gene, involved in the regulation of apoptosis (Hollander et al., 1993; Zhan et al., 1993). Apoptosis is a cell suicide mechanism that leads to "programmed cell death." Apoptotic cells undergo cell shrinkage and chromosomal condensation in response to DNA damage (Goldsworthy, 1996). These changes prevent the replication of cells that have sustained a degree of genetic damage beyond repair. P53 also activates the "growth arrest and DNA damage inducible gene" GADD45 (Hollander et al., 1993; Zhan et al., 1993). The GADD family of genes is composed of five members whose transcripts are increased following

various types of DNA damage (Fornace, 1992), leading to transient growth arrest often in G1 phase. Alkylating agents such as MMS, some chemotherapeutic drugs, oxidizing agents, and UV radiation induce three of the members: GADD34, GADD45, GADD153 (Fornace, 1992). GADD33 and GADD7 transcripts are expressed in a more limited range of cell types. Transcript levels of the GADD45 gene are present in very low amounts in most untreated cells. Thus in human liver, GADD45 composes <0.01% of the total cellular mRNA (Hollander et al., 1993). Following DNA damage, however, GADD45 transcript levels begin to increase only 1 h after exposure, reaching maximal production after several hours post-treatment (Fornace, 1992).

Mutations in the p53 tumor-suppressor gene occur at high frequency in a variety of human tumors (Livingstone et al., 1992). These include deletions of the entire gene with complete loss of p53 expression and missense point mutations, giving rise to mutant p53 proteins lacking wild-type p53 activity (Hollstein et al., 1991). The central portion of the p53 protein binds DNA in a sequence-specific manner, inhibiting cell proliferation at the G1 transition. The majority of mutations are located in this essential region, and tumor-derived mutant forms of p53 have reduced specific DNA-binding activity. Furthermore, the wild-type p53 protein forms stable homo-oligomers and seems to bind DNA as a tetramer. Mutant p53 interferes with the function of wild-type p53 by forming heterodimers and forcing the latter into an abnormal conformation that is unable to bind DNA. The p53 protein can also repress the transcription of a variety of promoters, including *c-fos*, *c-jun*, *c-myc*, IL-6, and Rb. The p53 protein regulates its own function through the activation of the MDM2 gene. The MDM2 gene codes for a protein that binds and inhibits p53 (Oliner et al., 1993). This inhibition by MDM2 acts to limit the duration of p53-mediated G1 arrest and allows the cell to progress through the remainder of the cell cycle. Many human tumor types are caused by mutation or deletion of p53 and loss of this G1 checkpoint (Livingstone et al., 1992). It has been proposed that the wild-type p53 protein functions as a sensor of DNA strand breaks and that after binding to ssDNA, it may undergo a conformational change that increases its stability and favors its accumulation, probably through poorly understood phosphorylation mechanisms, resulting in G1 arrest or apoptosis. The G2 checkpoint, on the other hand, seems to function with independence of the presence of p53. Mammalian genes and gene products known to be activated at the transcriptional or post-transcriptional level in response to DNA-damaging agents include not only those related specifically to DNA-repair processes but also transcription factors, growth factors, growth factor receptors, protective enzymes, and proteins associated with inflammation and tissue injury and repair (Fornace, 1992; Herrlich and Rahmsdorf, 1994). These findings are consistent with the current understanding of the molecular basis of carcinogenesis as a multistep

process, including genetic and epigenetic phenomena. Therefore it is essential to further advance our understanding of the intricate molecular mechanisms that govern chemical carcinogenesis. This will allow us to improve strategies for assessing human cancer risk.

CHEMICAL AGENTS THAT DAMAGE DNA

Chemical damage to DNA contributory to carcinogenesis can occur through both endogenous and exogenous processes. Exogenous processes arise from nutritional habits, socio-economic strata, and lifestyle that include exposures to physical agents (e.g., ionizing radiation), chemical agents, and biological agents (e.g., *Helicobacter pylori*, Epstein-Barr virus, human papilloma virus, *Schistosoma haemotobium*), while endogenous factors include genetic makeup, age, immune system abnormalities, endocrine imbalances, and chronic inflammatory process such as ulcerative colitis or pancreatitis. (Oliveira, 2007). Endogenous modifications in the DNA include methylation by S-adenosylmethionine, modification by lipid peroxidation products, chlorination, glycosylation, oxidation, and nitrosylation (Grosse et al., 2009). Reactive oxygen and nitrogen species are particularly relevant because the activated species are generated by host cells and more than 50,000 nucleotides/cell are replaced every day.

In order to form covalent adducts with DNA and with other cellular macromolecules, many carcinogens require activation by hepatic P-450 aryl hydroxylases into reactive electrophiles, which can be mutagens and carcinogens. For instance, on DNA replication, 7,8-dihydro-8-oxoguanine can pair equally well with its normal partner or with adenine, leading to a GC→TA transversion. Other lesions, such as ionizing radiation, which induces double-strand breaks, are mainly cytotoxic or cytostatic. Finally, others can have both effects. DNA damage can also interfere with normal transcription or induce replication arrest, triggering cell death or cellular senescence.

Most human carcinogens have been found to be active in genetic toxicology tests (Bartsch and Malaveille, 1990) while others can induce chromosomal changes without gene mutations or directly damaging the DNA (Barrett and Wiseman, 1987). Other compounds may act through epigenetic mechanisms, and some may act through a combination of different mechanisms (MacLeod, 1996). Because many chemicals act by a combination of direct and indirect mechanisms, and those mechanisms may differ in different cell types, classifications according to mechanism of action cannot be comprehensive or definitive. Nevertheless, chemical carcinogens have been classified in two main groups: “genotoxic” (DNA reactive) for compounds that undergo chemical reaction with DNA and “non-genotoxic” (epigenetic).

Genotoxic Carcinogens

Nucleic acids are chemically unstable complex molecules that can be altered by numerous environmental agents and by intracellular metabolism. The consequences for the living organism of this genotoxicity include short-term genetic instability, programmed cell death or apoptosis, inheritance of mutations, and cancer. Eukaryotic chromosomes in mammalian cells are organized in multiple adjacent replicons (estimated 20,000 in the human genome) with an average size of 150 kb (Kornberg and Baker, 1992). Each replicon contains a replication origin that replicates sequentially in a timely order in S-phase and completes replication within 10 h. At any given time, approximately 2000 replicons must be replicated at an average rate of 2.5 kb/min. DNA damage can affect replicon initiation by inhibiting the number of replicons being initiated or by increasing the frequency of initiation through de novo activation of normally silent replication origins. Alternatively, DNA damage may cause a block in replicon elongation. All creatures, from viruses to humans, have developed mechanisms to either repair or tolerate DNA lesions. Several hours after treatment with genotoxic agents, mammalian cells start to recover from damage-induced inhibition of DNA replication, resuming synthesis of normal size DNA at a normal rate. Furthermore, replication of mammalian genomes seems to occur in the presence of permanent lesions such as chemical adducts. Thus, psoralen mono-adducts, induced in the gene of dihydrofolate reductase by 4' OHmethyl-4,5',8-trimethylpsoralen, persist at high efficiency, a phenomenon that has also been observed in other models (Wauthier et al., 1990; Vos and Hanawalt, 1999).

Replication of damaged chromosomes is accomplished through a variety of redundant mechanisms. In general, DNA lesions on the leading strand block the synthesis of both strands. DNA damage on the lagging strand, however, interrupts synthesis of the damaged fragment, although fragments downstream from the lesion can still be synthesized. The mechanisms proposed for replication past-DNA lesions are direct translesion synthesis or bypass replication (expected to be error prone), post-replication repair (expected to be error free), and homologous strand exchange between sister DNA molecules. Direct translesional synthesis requires that the DNA replication complex directly copy the damaged template by incorporating a nucleotide opposite to the lesion, perhaps by a specific DNA polymerase. This nucleotide may not necessarily be the complementary base to the altered nucleotide and, as a result, mutations may occur. Post-replication repair involves the filling of 1–2 kb gaps by homologous recombination using complete undamaged daughter DNA molecules. This avoids the direct copying of the lesion. Mammalian cells exposed to DNA-damaging agents undergo a temporary inhibition of replicon initiation, perhaps because of the preferential loss of small newly

synthesized DNA molecules through DNA strand breaks, either induced directly by the DNA-damaging agent or indirectly by excision repair-dependent strand incision. This delay in replicon initiation allows time for excision repair, decreasing the chances of genetic instability and mutagenic fixation. Specific regulatory mechanisms, such as post-translational inactivation of cofactors, operate to undo the temporary shut-down of replicon initiation (Waga et al., 1994). Paradoxically, DNA damage can also stimulate initiation of DNA replication, leading to the selective amplification of critical genes (Jussila, 1996).

Complete carcinogens can qualitatively and quantitatively change the cell's genetic information. They exhibit a direct analogy between their structure and activity, are mutagenic in *in vitro* assays, are active in high doses, and may affect several animal species, and damage different organs. In high doses, they cause toxicity and cell proliferation, increasing DNA replication, and influencing its carcinogenic activity (Cohen, 1998). Following transmembranar diffusion they are metabolized in electrophilic compounds that enter the nucleus and interact with nucleophilic sites (DNA, RNA, and proteins) changing their structural integrity and establishing covalent bonds known as adducts (Straub and Burlingame, 1981). Adduct formation is the first critical step in the process of carcinogenesis. Adduct formation may differ in number and in area of DNA damage. Lack of adduct repair before DNA replication may allow for mutations in the proto-oncogenes and tumor-suppressor genes, essential elements of the initiation stage. (Oliveira, 2007).

The formation of adducts may cause mutations through deletions, frameshift, or nucleotide transposition, or the adducts may cause DNA chain breakage by their sheer numbers. A positive association has been discerned in animal models between the quantity of adducts formed and the number of neoplasms developed. (Oliveira, 2007).

Chemicals that Cross-Link DNA

Alkylating Agents Alkylating agents are electrophilic compounds that have an affinity for nucleophilic centers in organic macromolecules (Table 107.4). Alkylating agent–DNA adducts are believed to cause the mutations that ultimately induce a significant fraction of human tumors (many chemicals that belong to this group are proven or suspected carcinogens) and are important mediators of the cytotoxic effects of anti-cancer drugs. In general, bifunctional alkylating agents are potent cytotoxic agents, whereas monofunctional alkylating agents exhibit lower cytotoxicity and are more efficient mutagens. Bifunctional alkylating agents can react with two different nucleophilic centers in DNA. If the two sites are on opposite polynucleotide strands, interstrand DNA crosslinks result. If the sites are on the same chain, intrastrand crosslinks result. Interstrand DNA crosslinks prevent DNA strand

TABLE 107.4 Alkylating Agents Classified as Carcinogens by the U.S. Department of Health and Human Services.**Known to be Human Carcinogens**

Aflatoxins, alcoholic beverages, 4-aminobiphenyl, phenacetin, aristolochic acids, arsenic, asbestos, azathioprine, benzene, benzidine. Beryllium, bis(chloromethyl) ether, technical-grade chloromethyl methyl ether, 1,3-butadiene, cadmium, chlorambucil, 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea, chromium hexavalent compounds, coal tars, coal-tar pitches, coke-oven emissions, cyclophosphamide, cyclosporin A, diethylstilbestrol, dyes metabolized to benzidine, erionite, estrogens, ethylene oxide, formaldehyde, hepatitis B virus, hepatitis C virus, human papillomavirus, melphalan, methoxsalen with ultraviolet A therapy, mineral oils, mustard gas, 2-naphthylamine, neutrons, nickel compounds, radon, silica crystalline (respirable size), solar radiation, soots, strong inorganic acid mists containing sulfuric acid, tamoxifen, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, thiotepa, thorium dioxide, tobacco, ultraviolet radiation, vinyl chloride, wood dust, X-radiation and γ -radiation

1. Reasonably Anticipated to be Human Carcinogens

Acetaldehyde, 2-acetylaminofluorene, acrylamide, acrylonitrile, adriamycin, 2-aminoanthraquinone, *o*-aminoazotoluene, 1-amino-2,4-dibromoanthraquinone, 2-amino-3,4 dimethylimidazo [4,5-*f*]quinoline 2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline, 1-amino-2 methylanthraquinone, 2-amino-3 methylimidazo [4,5-*f*]quinoline, 2-amino-1-methyl-6 phenylimidazo[4,5-*b*]pyridine, amitrole, *o*-anisidine and its hydrochloride azacitidine, basic red 9, monohydrochloride, benz[a]anthracene, benzo[b]fluoranthene, benzo[j]fluoranthene, benzo[k]fluoranthene, benzo[a]pyrene benzotrichloride, 2,2 bis(bromomethyl)-1,3-propanediol, bis(chloroethyl) nitrosourea, bromodichloromethane, 1,4-butanediol dimethanesulfonate, butylated hydroxyanisole, captafol, carbon tetrachloride, ceramic fibers, chloramphenicol, chloreindic acid, chlorinated paraffins, chloroform, 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea, 3-chloro-2-methylpropene, 4-chloro-*o*-phenylenediamine, chloroprene, *p*-chloro-*o*-toluidine and its hydrochloride, chlorozotocin, cisplatin, cobalt sulfate, cobalt–tungsten carbide: powders and hard metals, *p*-cresidine, cupferron, dacarbazine, danthron, 2,4-diaminoanisole sulfate, 2,4-diaminotoluene, diazoaminobenzene, dibenz[a,h]acridine, dibenz[a,j]acridine, dibenz[a,h]anthracene, 7H-dibenzo[c,g]carbazole, dibenzo[a,e]pyrene, dibenzo[a,h]pyrene, dibenzo[a,i]pyrene, dibenzo[a,l]pyrene, 1,2-dibromo-3-chloropropane, 1,2-dibromoethane, 2,3-dibromo-1-propanol, 1,4-dichlorobenzene, 3,3'-dichlorobenzidine and its dihydrochloride dichlorodiphenyltrichloroethane, 1,2-dichloroethane, dichloromethane, 1,3-dichloropropene, diepoxybutane, diesel exhaust particulates, di(2-ethylhexyl) phthalate, diethyl sulfate, diglycidyl resorcinol ether, 3,3'-dimethoxybenzidine (see 3,3'-dimethoxybenzidine and dyes metabolized to 3,3'-dimethoxybenzidine), 4-dimethylaminoazobenzene, 3,3'-dimethylbenzidine (see 3,3'-dimethylbenzidine and dyes metabolized to 3,3'-dimethylbenzidine), dimethylcarbamoyl chloride, 1,1-dimethylhydrazine, dimethyl sulfate, dimethylvinyl chloride, 1,6-dinitropyrene 1,8-dinitropyrene, 1,4-dioxane, disperse blue 1, dyes metabolized to 3,3'-dimethoxybenzidine, dyes metabolized to 3,3'-dimethylbenzidine, epichlorohydrin, ethylene thiourea, ethyl methanesulfonate furan, glass wool fibers (inhalatable), glycidol, hexachlorobenzene, hexachloroethane, hexamethylphosphoramide, hydrazine and hydrazine sulfate, hydrazobenzene, indeno[1,2,3-*cd*]pyrene, iron dextran complex, isoprene, kepone, lead, lindane, hexachlorocyclohexane 2-methylaziridine, 5-methylchrysene, 4,4'-methylenebis (2-chloroaniline), 4,4'-methylenebis(*N,N*-dimethyl)benzenamine, 4,4'-methyleneedianiline and its dihydrochloride, methyleugenol, methyl methanesulfonate, *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, metronidazole, michler's ketone, mirex, naphthalene, nickel metallic, nitrilotriacetic acid, *o*-nitroanisole, nitrobenzene, 6-nitrochrysene, nitrofen, nitrogen mustard, hydrochloride, nitromethane2-nitropropane, 1-nitropyrene, 4-nitropyrene, *N*-nitrosodi-*n*-butylamine, *N*-nitrosodiethanolamine, *N*-nitrosodiethylamine, *N*-nitrosodimethylamine, *N*-nitrosodi-*n*-propylamine, *N*-nitroso-*N*-ethylurea, 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone, *N*-nitroso-*N*-methylurea, *N*-nitrosomethylvinylamine, *N*-nitrosomorpholine, *N*-nitrosonornicotine, *N*-nitrosopiperidine, *N*-nitrosopyrrolidine, *N*-nitrososarcosine, *o*-nitrotoluene, norethisterone, ochratoxin A, 4,4'-oxydianiline, oxymetholone, phenacetin, phenazopyridine hydrochloride, phenolphthalein, phenoxybenzamine hydrochloride, phentytoin and phentytoin sodium, polybrominated biphenyls, polychlorinated biphenyls, procarbazine and its hydrochloride, progesterone, 1,3-propane sultone, β -propiolactone, propylene oxide, propylthiouracil, reserpine, riddelliine, safrole, selenium sulfide, streptozotocin, styrene, styrene-7,8-oxide, sulfallate, tetrachloroethylene, tetrafluoroethylene, tetranitromethane, thioacetamide, 4,4'-thiodianiline, thiourea, toluene diisocyanates, *o*-toluidine and its hydrochloride, toxaphene, trichloroethylene, 2,4,6-trichlorophenol, 1,2,3trichloropropane, tris(2,3-dibromopropyl) phosphate, ultraviolet radiation, urethane, vinyl bromide, 4-vinyl-1-cyclohexene diepoxide, vinyl fluoride

separation and block replication and transcription (Borowy-Borowski et al., 1990a, 1990b). Alkylating agents can be classified as species that react with nucleophiles by either SN1 or SN2 mechanism. SN2 agents (low oxyphilic), such as dialkyl sulfates and methyl methane sulfonate, transfer the alkyl group upon nucleophilic attack by DNA. SN1 agents (high oxyphilic) such as *N*-nitroso compounds (alkyl nitrosoureas, dialkyl nitrosamines, and *N*-alkyl-*N'* nitro-*N*-nitrosoguanidine) degrade to alkylidiazohydroxides that

secondarily react with DNA. Alkylating agents may have one or two reactive groups and are able to alkylate all four bases, although with different reactivity. In general, the ring nitrogens of the bases are more nucleophilic than the oxygens. The alkylation of base residues in DNA appears to be non-random, and the relative distribution of alkylation damage may play a role in the generation of mutational hot spots. Thus the adduct O6alk-gua has been shown to be the principal biological lesion inducing a G to A transition mutation. Alternatively,

steric effects may also play a role in the exposure of specific sites to the alkylating action (Kornberg, 1991). Because SN1 agents modify the exocyclic base oxygens more frequently than SN2 compounds, they are more mutagenic and carcinogenic. Furthermore, ethylating agents are more potent mutagens than methylating agents. One of the first alkylating agents studied, mustard gas (sulfur mustard) used as a chemical warfare agent, damaged external tissues and was also shown to inhibit cell division. Studies in *Drosophila* demonstrated the mutagenic activity of the mustards, even before DNA was discovered to be responsible for transmission of genetic information. Nitrogen mustards were shown to react as aziridinium cation intermediates with the N7 atom of guanine, forming crosslinks that join the two antiparallel strands of DNA as 1,3 interstrand adducts in 5'-GNC-3' sequences. Haloethyl nitrosoureas have also been used as anticancer drugs because they form dC-CH₂-CH₂-dG interstrand crosslinks between N1 of guanine and N3 of cytosine. Recent studies indicate that a group of chemicals termed *tobacco-specific nitrosamines*, present in tobacco and in other environmental samples, may be converted by metabolic activation to carcinogenic species such as methyldiazohydroxide. The carcinogenic mechanism may be caused by O6alk-gua formation, which has been shown to activate K-ras in the mouse lung.

Psoralens Furocoumarins with planar tricyclic configurations (psoralens) can intercalate into DNA and form covalent adducts to pyrimidines upon subsequent photoactivation by long-wavelength UV radiation. This produces significant helix distortion, kinking, and unwinding of DNA leading to the arrest of DNA replication in dividing cells.

Chemicals that are Metabolized to Electrophilic Reactants A variety of relatively nonpolar, chemically unreactive compounds undergo metabolic activation to more reactive forms that interact with nucleophilic centers in DNA. This mechanism of action is dependent on specific metabolism that protects cells from cytotoxic effects, converting toxic nonpolar chemicals to water-soluble extractable forms. Some products of these reactions are particularly reactive with DNA. Examples of these type of enzymatic systems are the cytochrome P-450 system, glutathione-S-transferases, sulfotransferases, acetyltransferases, UDP-glucuronosyltransferases, and adenosylating and methylating enzymes (Hollenberg, 1992).

Aromatic Amines and Nitrosamines Aromatic amines were implicated in urinary cancers in workers of the dye industry as early as 1895. Experimental studies in dogs confirmed a causative role in 1937. Epidemiological studies implicated 2-naphthylamine as a potent carcinogen in 1954. Because these compounds acted systemically, it was suspected that some form of metabolic activation was involved in their carcinogenic action. In rats, *N*-2-acetyl-2-aminofluorene (AAF),

used as an insecticide, results in malignant tumors (liver and bladder) with latent periods of more than 100 days. N-oxidation, by the cytochrome P-450, converted this biochemically inert aromatic amide into an *in vivo*-reactive proximate carcinogen, a mechanism found to be true for carcinogenic aromatic amides and amines in general. Thus a proximate carcinogen can become a highly reactive alkylating agent, an ultimate carcinogen following formation of electrophilic metabolites by cytosolic enzymes. Dimethylnitrosamine, implicated in the development of liver cirrhosis in two workers, has been shown to induce hepatocellular carcinoma in rats. Nitropyrenes and dinitropyrenes have been found in diesel exhaust, urban air, coal fly ash, and certain broiled foods. High temperature cooking can convert tryptophan and glutamic acids to mutagenic heterocyclic aromatic amines. Many of these compounds have been shown to be carcinogenic in experimental animals and have been implicated in human cancer. Arylamines and nitroaromatic compounds form DNA adducts at C8, N2, and O6 of Gua, C8, and N6 of Ade. Aminofluorene induces mutations by base-pair substitutions, predominantly GC-to-TA transversions. Its N-acetyl cognate, AAF, induces mutations by frame shifts in GC base pairs.

Polycyclic Aromatic Hydrocarbons (PAHs) Polycyclic aromatic hydrocarbons are metabolized by liver monooxygenases. It is believed that PAHs are initially converted to a reactive epoxide intermediate that subsequently reacts with a nucleophile or is hydrolyzed by epoxide hydrolase. The most extensively studied is benzo[α]pyrene (BP). Isolated from crude coal tar (Brookes, 1990), this potent carcinogenic PAH is present in the environment as a result of cigarette smoke and automobile exhaust fumes. Unmodified BP is an unreactive non-polar compound with a planar configuration that intercalates between the hydrogen-bonded base pairs in duplex DNA. It is known, however, that components of the P-450 system known as *aryl-hydrocarbon hydroxylases* metabolize BP and other PAHs to phenols and epoxides (Brookes, 1990). Phenols are oxidized to quinones. Epoxides (4,5-epoxide, 7,8-epoxide, 9,10-epoxide) are converted to excretable dihydrodiols. The ultimate carcinogenic form is an anti-diol-epoxide that binds predominantly to the exocyclic 2-amino position of guanine (Brookes, 1990). Reactions also occur at Ade-N6 and Cyt-N4, although GC4o-TA mutations seem to be the most frequent in a variety of models.

Natural Products

Aflatoxins Among the most potent liver carcinogens known, aflatoxins (difuranocoumarins) are mycotoxins produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus* that infest peanuts, corn, and other agricultural products. The most potent is aflatoxin B₁ (AFB₁), which is oxidized by the mixed function oxygenases of the P-450

system in the microsomal fraction of liver extracts, giving rise to aflatoxin B₁-8,9-epoxide (Kensler et al., 2011), which forms a major adduct at the N7 position of deoxyguanosine (Simonich et al., 2007). These adducts can then undergo ring opening to generate two pyrimidine adducts. These DNA modifications may then cause malignancy by the activation of proto-oncogenes or the abolishment of tumor-suppressor genes. Aflatoxin B₁ adducts are strong blocks to DNA replication and highly mutagenic, predominantly GC-to-TA transversion and frameshift mutations.

Mitomycin C Mitomycins are a group of antibiotics generated by *Streptomyces caespitosus*. The major adduct is the guanine-N2-linked mono-adduct precursor to other adducts. Interstrand crosslinks are formed at 5'-GG sequences and intrastrand crosslinks at 5'-TG sequences.

N-Methyl-N'-Nitro-N-Nitrosoguanidine Interaction of N-methyl-N'-nitro-N-nitrosoguanidine with cysteine residues such as those found in glutathione gives origin to highly electrophilic methylating intermediates (O'Brien et al., 1996).

4-Nitroquinoline 1-oxide 4-Nitroquinoline 1-oxide can give rise to 8-hydroxyguanine, leading to strand breakage, and can be converted to the proximate carcinogen 4-OH-aminoquinoline 1-oxide that is acylated by a seryl-AMP enzyme complex that introduces quinoline groups into DNA.

Base Analogs Analogs of the four naturally occurring bases in DNA can be incorporated during DNA replication. Thymidine analogs include 5-bromouracil, 5-fluorouracil, and 5-iodouracil. The most important adenine analog is 2-aminopurine.

Non-Genotoxic Carcinogens

Non-genotoxic carcinogens do not require metabolic activation. Those that have their activity mediated by a receptor are considered "cytotoxic", while those that are not are considered "mitogenic" (Cohen, 1991). As they act solely as promoters, they do not react directly with DNA and generate neither adducts nor positive responses on mutagenicity tests. (Butterworth et al., 1992) The non-genotoxic carcinogens modulate cell growth and death and may potentiate the effects of genotoxic compounds; however, they do not show a direct correlation between their structure and their activity, although their concentration does limit their behavior. (Oliveira, 2007.) Two classes of chemicals that are generally inactive in assays for mutagenicity are the mineral fibers and the hormones.

Hormones Estrogens are major factors in the risk for different cancers in women (Preston-Martin et al., 1990). Thus, the

natural estrogen 17-beta-estradiol increases the incidence of a variety of tumors in experimental animals, and diethylstilbestrol (DES) administration to pregnant women is directly related to the development of clear-cell adenocarcinoma. Diethylstilbestrol binds to microtubules disrupting tubulin assembly and may induce aneuploidy suggesting a carcinogenic mechanism independent of estrogen receptors. It has been proposed that estrogens induce cancer primarily by stimulating cell proliferation but there is evidence that estrogens can also induce heritable alterations, even after single-dose or short-term exposures (Newbold et al., 1990).

Asbestos The name "asbestos" refers to a group of naturally occurring mineral fibers, including amphiboles (crocidolite, amosite, tremolite, anthophyllite, and actinolite) and serpentine fibers (chrysotile) (Huan et al., 2011). Exposure to asbestos, used in industry and households for decades, induces asbestosis, pleural plaques, lung cancer, mesothelioma, and other non-respiratory diseases (Currie et al., 2009; Straif et al., 2009). Asbestos has been classified as a Group I human carcinogen by the International Agency for Research on Cancer. As a result, the U.S. Environmental Protection Agency has restricted the industrial use of asbestos since the early 1970s. Asbestos is, however, widely used in many developing countries (Virta, 2003) and continues to be an important health problem due to the long latency period of asbestos-induced diseases (Huang et al., 2011). In addition, there is evidence suggesting a synergistic effect of tobacco smoke and asbestos exposure on mutagenicity and lung cancer risks (Kamp et al., 1992; Nymark et al., 2006, 2008; Selikoff et al., 1968). The mechanisms by which asbestos fibers produce malignancy and fibrosis are not entirely clear but fiber dimensions, surface and crystal properties, shape, chemical composition, physical durability, and exposure route, duration and dose are important factors (Sanchez et al., 2009). All types of asbestos are carcinogenic (Straif et al., 2009).

Oncogenesis appears to be induced via both mutagenic and non-mutagenic mechanisms (Barrett, 1992; Kane, 1996; Nymark et al., 2008). Unlike chemical mutagens that generate genetic alterations by covalent binding to/modifying the DNA structures, asbestos-induced mutagenicity can be mediated, directly, through physical interaction with the mitotic machinery of dividing cells or, indirectly, as a result of damaging of DNA and chromosome by asbestos-induced reactive oxygen (ROS) and nitrogen species (RNS) (Gulumian, 2005; Hardy and Aust, 1995; Jaurand, 1997; Kamp and Weitzman, 1999; Shukla et al., 2003a, 2003b). Persistence of asbestos fibers in the lungs triggers prolonged radical production and chronic inflammation at the sites of fiber deposition. Most cell types, except lymphocytes, are able to phagocytize fibers and physical interaction of asbestos fibers with mitotic machineries leads to mis-segregation of chromosomes during mitosis and aneuploidy (Hesterberg

and Barrett, 1985; Palekar et al., 1987; Pelin et al., 1992; Yegles et al., 1993, 1995). Furthermore, asbestos-generated ROS and RNS produce dose-dependent DNA and chromosomal abnormalities, such as 8-hydroxydeoxyguanosine, DNA single-strand breaks and chromosome fragments (Jaurand et al., 1987; Kamp et al., 1995). This occurs in all relevant lung and pleural target cells, although, compared to alveolar epithelial and mesothelial cells, bronchial epithelial cells show less DNA damage, possibly due to their greater antioxidant capacity (Nygren et al., 2004; Puhakka et al., 2002).

In mesothelial cells (Unfried et al., 2002) the frequency of G→T transversions is higher than the frequency of expected spontaneous mutations. In addition, target cells and cells in the microenvironment release inflammatory mediators and growth factors that activate multiple signaling cascades responsible for fibrosis and malignancy (Kamp et al., 1998; Kane, 1992, 2006; Manning et al., 2002; Mossman and Churg, 1998; Shukla et al., 2003a; Mossman, 1990, 1993). Gene expression microarray studies (Hevel et al., 2008; Nymark et al., 2007) have shown that, in mesothelial and epithelial cells, asbestos fibers alter the p53 signaling pathway, possibly explaining the resistance to apoptosis in mesothelioma cells (Fennell and Rudd, 2004; Burmeister et al., 2004; Johnson and Jaramillo, 1997; Kopnin et al., 2004; Levresse et al., 2000; Matsuoka et al., 2003; Paakkko et al., 1998; Panduri et al., 2003; Topinka et al., 2004). Also of interest is that TNF- α , which prevents cell death via a nuclear factor (NF)- κ B-dependent mechanism (Yang et al., 2006), is induced by asbestos. Furthermore, the AKT/mammalian target of rapamycin (mTOR) signaling pathway, which promotes the growth of apoptosis-resistant cells (Chiang and Abraham, 2007; Guertin and Sabatini, 2007), has been implicated in the increased survival of mesothelioma cells (Wilson et al., 2008). Inhibiting mTOR with rapamycin or silencing p-S6K, a major downstream target of mTOR, leads to cell death in these apoptosis-resistant cells.

TOBACCO

According to the WHO, 5.5 trillion cigarettes were consumed in 2000, and 1 billion men and 250 million women are daily smokers (Mackay and Eriksen, 2002; WHO, 2002; WHO, 2003). Between 1965 and 2004, adult cigarette smoking declined from 42 to 21% and, between 2005 and 2011, there was a modest decline from 21 to 19% accounting for 2 million people. On the other hand, the number of smokers reporting light or intermittent smoking (<10 cigarettes/day) increased from 16% in 2005 to 22% in 2011 (22%). Tobacco causes 1.2 million deaths annually and of today's world population, 500 million will die of tobacco use, with cancer one of the main causes of death (IARC, 1985, 1986). The American Cancer Society (ACS) estimates that, in 2013, about 174,100 Americans will die of tobacco-related diseases. Cigarette

smoking causes 90% of lung cancer and is associated with cancers of the oral cavity, larynx, oropharynx, hypopharynx, sinonasal cavity, esophagus, stomach, liver, pancreas, bladder, cervix, colorectal, ureter and kidney, as well as myeloid leukemia. Furthermore, smokeless tobacco is known to cause oral cavity cancer and possibly pancreatic cancer (Hoffmann et al., 2001; Vainio and Weiderpass, 2003; Hecht, 1999). Tobacco contains nicotine, responsible for the addiction, and more than 60 carcinogens, most of them formed after combustion. The total amount of carcinogens in cigarette smoke is 1–3 mg per cigarette. Strong carcinogens, such as nitrosamines [4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) and *N*⁺-nitrosonornicotine (NNN)], PAHs (benzo [*a*]pyrene) and aromatic amines (4-aminobiphenyl) play important roles in carcinogenesis despite occurring in smaller amounts (1–200 ng per cigarette) than weak carcinogens such as acetaldehyde (1 mg per cigarette) (Swauger et al., 2002; Phillips, 1983; Hoffmann et al., 1987, 1995; Cooper et al., 1954; Hecht and Hoffmann, 1988). Carcinogens are metabolically activated by cytochrome P450 enzymes (P450s) (Guengerich, 2001). Most metabolites are detoxified and excreted but some are electrophilic and react with DNA forming covalently bound DNA adducts (Wiencke, 2002; Phillips, 2002; Boysen and Hecht, 2003), typically leading to G-T and G-A mutations (Loechler et al., 1984; Singer and Essigmann, 1991; Seo et al., 2000) that, if occurring in crucial regions of oncogenes such as *RAS* and *MYC* or in tumor-suppressor genes such as *TP53* and *CDKN2A* (which encodes p16), will result in loss of normal cellular growth-control mechanisms (Osada and Takahashi, 2002).

Nicotine and carcinogens can also bind to the cellular receptors directly, activating enzymes such as serine threonine kinase AKT (protein kinase B) and protein kinase A (PKA). This, in turn, can result in decreased apoptosis, increased angiogenesis, and cell transformation. Tobacco products also contain tumor promoters and co-carcinogens, which can activate protein kinase C (PKC), activator protein 1 (AP1), and other cellular factors (Hoffmann Wynder, 1971; Denissenko et al., 1996; Hoffmann et al., 1994; Spiegelhalder and Bartsch, 1996; Hoffmann et al., 1994; IARC, 1985). Six important carcinogens that can form DNA adducts are: (1) benzo[*a*]pyrene (BaP), which is metabolized to epoxides, which are then converted to diol epoxides by epoxide hydrolases (EHs) and P450s, (2) 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), which is metabolized to α -hydroxy NNKs, which then spontaneously decompose to aldehydes and undergo reduction to 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL), which is converted to NNAL-glucuronides and α -hydroxylated to diazonium ions, (3) *N*-nitrosodimethylamine (NDMA), which undergoes α -hydroxylation to formaldehyde and α -hydroxy NDMA, which spontaneously decomposes to methyldiazonium ions that produce methyl adducts and can be detoxified to nitrite and methylamine, (4)

N'-nitrosonornicotine (NNN), which is metabolized to the unstable α -hydroxyNNNs, which produces diazonium ions and is detoxified to norcotinine, β -hydroxyNNNs and NNN-*N*-oxide, (5) ethylene oxide, which reacts directly with DNA and can undergo detoxification by GST catalysis to mercapturic acids, hydration to ethylene glycol, and oxidation to CO₂, and (6) 4-aminobiphenyl (4-ABP), which undergoes *N*-oxidation to a hydroxylamine.

THE FUTURE OF ONCOLOGY

The Human Genome Project has opened the genomics field for biology. Building on this success, the National Cancer Institute has launched the Cancer Genome Atlas Project, with the intent of sequencing the genomes of thousands of human tumors and compared them to the genomes of normal tissues. Diagnosis and treatment of cancer is, thus, moving to a "Personalized Medicine" approach based on these genomics data. Drugs will likely be developed and used to target a specific patient's tumor. Tumor heterogeneity, the result of active proliferation of different tumoral clones, will likely require the use of multiple drugs in a successive coordinated fashion but this targeted therapy is expected to be less toxic and more successful in killing tumor cells. The road to achieve this goal is not exempt of difficulties but we are entering an exciting era in cancer research and treatment and many fields are converging to either cure most cancers or convert them in low morbidity, survivable chronic diseases.

GENOTOXICITY TESTING STRATEGIES, GUIDELINES, AND METHODS

CHING-HUNG HSU AND QINGLI WANG

Genotoxicity testing is widely used to detect the ability of substances or chemicals to induce genetic damage (mutations or chromosome aberrations (CAs) or other DNA damage). Numerous genotoxic assays have been developed, and several of them are commonly used in regulatory toxicology by regulatory authorities. This chapter describes and summarizes some *in vitro* and *in vivo* genotoxicity assays that are primarily recommended by regulatory agencies and/or organizations (e.g., International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH), Organization for Economic Co-operation and Development (OECD), Food and Drug Administration (FDA), Environmental Protection Agency (EPA)) for use in regulatory registration of chemicals, drugs, biological products, and food ingredients. An abbreviated strategy is presented, highlighting the current standard test battery of genotoxicity assays and the updated guidelines for testing genetic damage developed by various regulatory authorities. In addition, nonanimal alternative methods for prediction of genotoxicity and several new genotoxicity techniques and/or methods in the field of genotoxicology are also presented in this chapter.

INTRODUCTION

Genotoxic testing has been increasingly applied to detect the ability of substances or chemicals to produce mutations or CAs or other DNA damage. Mutations are heritable alterations in the structural DNA content in somatic cells or germ cells that can cause harmful effects, such as cancer, birth defects, and inherited diseases. DNA damage is also involved

in genetic toxicity, which may result in mutations and the nonheritable changes associated with mutagenesis. In early years, genetic damage mainly focused on the heritable gene and chromosomal germ cell mutations in individuals. However, with the increasing development of cancer research, accumulating evidence has demonstrated that most of the carcinogenic chemicals are mutagenic. Therefore, the genotoxicity testing shifted from heritable mutations to carcinogenesis. Numerous known human carcinogens have shown to be as non-mutagenic in human germ cells, but some germ cell mutagens are shown to be both mutagenic and carcinogenic to somatic cells *in vivo*; therefore, germ cell mutagenicity is also being considered as a factor of genetic damage by the regulatory authorities. In the 1970s, the genetic toxicity test compilations were firstly published. Given the high predictive value of cancer using the *in vitro* genetic toxicity testing, the United States and other regulatory authorities began to require pre-market genotoxicity testing for chemicals and drugs. The formal guidelines on how to conduct the tests were developed and recommended by the United States and other international organizations [such as the ICH and the International OECD]. In particular, the OECD test guidelines (TGs) are considered to be a gold standard for regulatory toxicity testing, which have been worldwide accepted. The OECD TGs undergo periodic revision to reflect scientific advances and include recently adopted OECD principles. Most existing TGs on genotoxicity were last revised in the mid-1990s. Similar to OECD TGs, the Expert Working Group (Safety) of the ICH has developed a comprehensive set of safety guidelines to reveal potential risks of carcinogenicity, genotoxicity, and reproductive toxicity in accordance with the ICH Process. The

veterinary equivalent to the ICH is the International Co-operation of Harmonisation of Technical Requirements for Registration of Veterinary Medicinal Products and Veterinary Pharmaceuticals (VICH). The OECD and ICH/VICH guidelines comprise two sets of internationally harmonized genotoxicity guidelines in regulatory purpose. The United States, as one of tripartite regulatory bodies, also follows the ICH guidelines as technical requirements for the registration of drugs and biological products. The pharmaceutical industry in the three regions has agreed to a harmonized approach through the acceptance and implementation of the ICH. In this chapter, these genotoxicity assays for testing chemicals, drugs, and biological products or food additives for humans will be emphasized. The current generalized strategy for genotoxicity testing primarily covers three areas, namely, gene mutation, CA or breakage (clastogenicity), and chromosome loss or gain (aneuploidy). To detect all of these end points, many different assays are employed *in vitro* and *in vivo*. *In vitro* genotoxic assays include the bacterial mutagenesis assay for detecting gene mutations and mammalian cell mutagenicity assays for detection of clastogenicity. On the other hand, *in vivo* genotoxicity assays include mammalian bone marrow cell micronucleus (MN) assay or CA for testing the clastogenicity and/or aneuploidy (Kirkland et al., 2005; Kirkland et al., 2006; Kirkland and Speit, 2008). To date, the genetic toxicity test battery consists of a bacterial (Ames) assay, an *in vitro* cytogenetic assay, and *in vivo* rodent genotoxicity (Claxton et al., 2010; Mahadevan et al., 2011), that has been widely adopted for regulatory purpose. Substances or chemicals that are positive in these assays (*in vitro* or *in vivo*) are considered to be of the greatest concern that have a potential to increase cancer risk to some extent. In recent years, an *in vitro* mammalian cell MN assay was adopted by the OECD. Meanwhile, the OECD is working on three TGs (*in vitro* CA, *in vivo* MN, and CA). A recent breakthrough is that the rodent single cell gel electrophoresis (SCGE) (comet assay) has been added into the ICH guidance (ICH, 2011) because of its numerous advantages, especially *in vivo* (Burlinson, 2012).

In this chapter, the authors aim to present a brief overview of the development of genotoxicity tests for regulatory purposes and support rationales for the types of tests regulated by the United States, OECD, or other regulatory authorities and the scientific and practical issues that will need to be resolved in the future. More detailed descriptions of testing strategies, test methods, and decision processes are also addressed in this chapter.

GENOTOXICITY

Overview

Genetic toxicity testing was first developed in the early 1950s (Demerec, 1951; Demerec and Hanson, 1951) to identify

potential carcinogens. Genotoxic potential can be manifested in various ways; however, the most common end points studied include gene mutations, structural/numerical CAs, DNA damage or strand breakages, and DNA repair. These end points are investigated in both *in vitro* and *in vivo* assays, but any single testing has its limitation that cannot detect all these changes. Among these genotoxicity tests, the bacterial mutagenicity assay is the most widely used because it is simple, saves time, inexpensive, and least likely to falsely detect a noncarcinogen as a carcinogen. The bacterial reverse mutation assay, usually was called the Ames test, is commonly employed as an initial screen for genotoxicity and, in particular, for point mutation. The Ames test is also required in regulatory toxicology for approval and marketing of a chemical, drug, or food additive, which has the ability to predict the mutagenicity and carcinogenicity because of its reliability, robustness, and reproducibility.

The mammalian cell cytogenetic assays are primarily used to detect a chromosome damage, and they include CA, MN, and mouse lymphoma assay (MLA) (Mahadevan et al., 2011). Generally, the chromosomal mutations have two major categories associated with changes both in chromosome structure (namely, CAs) and the number of chromosomes (also called numerical aberrations). Chromosomal mutations and related events cause many human genetic diseases. There is accumulating evidence that chromosome mutations and related events are involved in cancer occurrence in humans and experimental animals. The chromosomal mutations in somatic cells play a critical role in processes leading to cancer. If mutations occur in proto-oncogenes, tumor suppressor genes, and/or DNA damage response genes, they can result in various genetic diseases. In the CA, the most common structural CAs are observed at metaphase. In the MN, the analysis of CAs at interphase is performed via scoring the forming MN, which represent a proportion of fragments or whole chromosome lagging in anaphase and are not included in the main nucleus. The MLA detects forward mutations at the thymidine kinase (*Tk*) locus of the L5178Y (*Tk*^{+/−}-3.7.2C) cell line derived from a mouse thymic lymphoma. The MLA has the capability to measure a wide range of genetic events, including point mutations, deletions (intragenic) and multilocus, chromosomal rearrangements, mitotic recombination, and nondisjunction (Moore et al., 1985a, 1985b; Applegate et al., 1990; Wang et al., 2009). In these assays, mammalian cells are used, such as Chinese hamster ovary (CHO) cells, L5179Y/*Tk*^{+/−}-3.7.2C mouse lymphoma cells, Chinese hamster lung (CHL and V79) cells, or human peripheral lymphocytes.

In vivo genotoxicity assays, as *in vitro* counterpart, primarily include *in vivo* MN and CA for detecting chromosome damage effects in mammalian cells. The OECD guideline 474 for mammalian erythrocyte MN test (OECD, 1997a) and TG 475 for mammalian bone marrow CA test (OECD, 1997b) were adopted in July 1997. In these assays,

TABLE 108.1 Some Common Assays Used for Testing Genetic Toxicity

Assay name	Endpoint	<i>In Vitro/In Vivo</i>
Bacterial reverse mutation assay (Ames test)	Gene mutation	<i>In vitro</i>
Mouse lymphoma (L5178Y/ <i>Tk</i> ^{+/−} -3.7.2C) forward mutation assay	Gene mutation and chromosome mutation	<i>In vitro</i>
Mammalian cell <i>Hprt</i> mutation	Gene mutation	<i>In vitro</i>
Rodent lymphocyte <i>Hprt</i> mutation assay	Gene mutation	<i>In vivo</i>
Rodent erythrocyte and lymphocyte <i>Pig-a</i> genes mutation assay	Gene mutation	<i>In vivo</i>
Mouse spot test	Gene mutation	<i>In vivo</i>
Mouse specific locus test	Gene mutation	<i>In vivo</i>
<i>Tk</i> gene mutation assay	Gene mutation and chromosome mutation	<i>In vivo</i>
Transgenic rodent gene mutation assay (somatic and germ cells)	Gene mutation	<i>In vivo</i>
Mammalian chromosomal aberration assay	Clastogenicity	<i>In vitro</i>
Mammalian micronucleus assay	Clastogenicity, aneugenicity	<i>In vitro</i>
Rodent chromosomal aberration assay (somatic and germ cells)	Clastogenicity	<i>In vivo</i>
Rodent micronucleus assay (bone marrow and peripheral blood)	Clastogenicity, aneugenicity	<i>In vivo</i>
Micronucleus assay (human lymphocytes)	Clastogenicity, aneugenicity	<i>In vivo</i>
Rodent dominant lethal test	Clastogenicity (germ cell)	<i>In vivo</i>
Mouse heritable translocation assay	Clastogenicity (germ cell)	<i>In vivo</i>
Mammalian spermatogonial chromosome aberration test	Chromosome aberration(germ cell)	<i>In vivo</i>
Comet assay	DNA strand break	<i>In vitro/In vivo</i>
Alkaline elution assay	DNA strand break	<i>In vitro/In vivo</i>
Unscheduled DNA synthesis (UDS) assay	DNA repair	<i>In vitro/In vivo</i>
Sister chromatid exchange in mammalian cells	DNA damage	<i>In vitro/In vivo</i>
DNA adduct analysis	DNA adducts	<i>In vitro</i>

mice and rats are usually used. Theoretically, other appropriate mammalian species may be used. Both red blood cells from peripheral lymphocytes cultured and bone marrow from treated rodents were used to analyze CAs. The *in vivo* assays, especially related to assessing a mutagenic hazard, also allow consideration of *in vivo* metabolism, pharmacokinetics, and DNA repair processes, although they may vary among species and tissues. An *in vivo* test is also useful for further investigation of a mutagenic effect detected by these *in vitro* assays (OECD TG 473 (OECD, 1997c) and TG 487 (OECD, 2010)). Generally, when these assays alone are inadequate to evaluate the genetic toxicity, more *in vivo* assays are often required to evaluate a DNA damage end point as a surrogate. These *in vivo* assays, which have the most published protocols, include the DNA strand break assays such as the comet assay and alkaline elution assay, *in vivo* transgenic rodent (TGR) mutation assay, DNA covalent binding assay, and liver unscheduled DNA synthesis (UDS) assay (ICH, 2011). Aside from chromosomal damage, assessment of gene mutation is also an important part of genotoxicity testing employed in nonclinical safety evaluation. Recently, the rodent *Pig-a* gene mutation assay is increasingly used. If there is a loss of function of the *Pig-a* gene in red blood cells, it will result in a lack of cell surface expression of specific proteins that are targeted to the surface by glycosylphosphatidylinositol (GPI) anchors. This cell surface phenotype is readily assessed by flow cytometric analysis.

Classification (or Types of Genetic Toxicity Testing)

Genetic toxicity testing is used to evaluate the agents' ability to induce DNA alteration, including gene mutations. To date, over 200 tests have been developed for detecting genotoxic effects, investigating mechanisms of mutagenesis, and predicting the carcinogenic potential. Some of these assays are listed in Table 108.1, which can detect different end points in genotoxicity, such as gene mutation, chromosomal damage, and DNA damage. For regulatory requirements of a chemical, drug, and biological product, a comprehensive assessment of their genotoxic potential is required.

Strategy and Regulation of the Genotoxicity Assessment

Genotoxicity assessment consists of a comprehensive test battery, including different end points included because of the multiplicity of mechanisms involved in genetic damage. Genotoxicity testing schemes are becoming simplified, and short-term assays have been widely used for detecting genotoxicity, investigating genetic effects, and supporting regulatory use. A limited test battery to genotoxicity testing (ICH core battery) for detecting gene mutation and CAs is preferable given the broad spectrum of potential events and the limits of single-test analysis for detecting all genotoxic mechanisms relevant in tumorigenesis (ICH, 2011). The standard test battery has some features: (1) assessment of mutagenicity in a bacterial reverse gene mutation test, which

has been shown to detect relevant genetic changes and the majority of genotoxic carcinogens in rodents and humans; (2) *in vitro* and/or *in vivo* assay in mammalian cells used for genotoxicity evaluation. Generally, several *in vitro* mammalian cell systems are widely used and can be considered sufficiently validated, such as the *in vitro* CA, *in vitro* MN, and MLA. These three assays are currently considered equally appropriate and therefore are interchangeable for measurement of chromosomal damage when used together with other genotoxicity tests in a standard battery for testing pharmaceuticals (ICH, 2011). While some alternative *in vitro* tests, such as *in vitro* cell transformation, DNA breakage and repair, UDS, and DNA adduct formation, are now primarily used in basic research or as supplemental methods to support or explain results from the core battery. The *in vitro* assays should be conducted both with and without the metabolic activation (S9) and include positive control as well as solvent/vehicle controls for each treatment. Weight of evidence (WoE) method has been set up to evaluate complex response patterns from a large test battery. Several additional *in vivo* assays, such as the comet assay, alkaline elution assay, transgenic mouse mutation assay, *in vivo* DNA covalent binding assay, and liver UDS assay also can be utilized in the ICH core battery or as follow-up tests to develop WoE in assessing results of *in vitro* or *in vivo* assays. Compared to an *in vitro* assay, the *in vivo* test plays a critical role in genotoxicity testing strategy. The value of *in vivo* results is directly related to the demonstration of adequate exposure of the target tissue to the test agent. Generally, negative results from appropriate *in vivo* assays (usually two), with adequate justification for the end points measured, and demonstration of exposure, are considered sufficient to demonstrate the absence of significant genotoxic risk. However, internationally agreed protocols are not yet in place for all *in vivo* assays, although considerable experience and protocol recommendations as well as published data exist for comet assays, alkaline elution assays, UDS assays, and DNA covalent binding measurements. Genotoxicity test batteries can detect carcinogens that are considered to act primarily via causing direct genetic damage, but they are not expected to detect non-genotoxic carcinogens. In addition, a positive result in any genotoxicity assay does not always mean that the agent poses a genotoxic/carcinogenic hazard to humans.

Genotoxicity Assays

In Vitro Assays

Bacterial Reverse Mutation Assay (Ames Test) The bacterial reverse mutation assay, also called as Ames test, is mostly widely used for detecting gene mutation induced by agents. The Ames test was developed by Professor Bruce Ames in the early 1970s. In this assay, the most often used bacteria

systems are *Salmonella typhimurium* and *Escherichia coli*. The major strains utilized in the Ames test consist of amino acid requiring strains of *S. typhimurium* TA97, 98, 100, 102, 1535, 1537, and 1538, which are used for detecting base-pair substitution or frameshift mutations in genes of the histidine (*his*) operon, and *E. coli* WP2 *uvr* A and WP2 *uvr* A pKM101, which are aimed to detect a base-pair substitution mutation in the tryptophan (*trp*) operon. These strains are mutants and are unable to grow and form colonies on a medium without histidine or tryptophan. The recommended set of bacterial strains (OECD, 1997; ICH, 2011) can detect base substitution and frameshift mutations. Test strains are treated with a range of concentrations of the test chemical or agent to determine whether the agent can cause point mutations. The revert mutations present in the test strains restore the functional capability of the bacteria to synthesize an essential amino acid. The revertant bacteria are detected by their ability to grow in the absence of the amino acid required by the parent test strain. This assay is performed both with and without the metabolic activation (S9). The most commonly used S9 fraction is a mixture of microsome and cytosol prepared from the livers of rodents treated with enzyme-inducing agents, such as Aroclor 1254 or a combination of phenobarbitone and β-naphthoflavone, which contain a variety of phase I and phase II enzymes. The choice and condition of the S9 may depend on the class of chemical being tested. There following are the two methods often used: the plate incorporation and preincubation methods. Briefly, suspensions of bacterial culture are exposed to the test chemical with and without S9. In the plate incorporation method, these suspensions are mixed with an overlay agar and plated immediately onto a minimal medium. In the preincubation method, the treatment mixture is incubated and then mixed with an overlay agar before plating onto a minimal medium. For both techniques, after 2 or 3 days of incubation, revertant colonies are counted and compared to the number of spontaneous revertant colonies on the solvent. The detailed information is described in OECD TG 471 (OECD, 1997d) and ICH S2 (R1) (ICH, 2011).

Mouse Lymphoma Forward Mutation Assay The mouse lymphoma (L5178Y/*Tk*^{+/−} -3.7.2C) forward mutation assay, referred to as MLA, is a mammalian gene mutation assay used within a standard test battery recommended by the OECD and ICH guideline. This assay was established by Donald Clive and colleagues in 1970s (Clive, 1973; Clive and Spector, 1975). The MLA detects a broad spectrum of genetic events, including mutations in the *Tk* gene that result from both gene mutations and chromosome damage, including chromosome loss. Therefore, the MLA is widely used in the core battery of genotoxicity tests. In addition, it is also a preferred *in vitro* mammalian gene mutation assay by the US EPA (Dearfield et al., 1991), US FDA Center for Food Safety and Nutrition (FDA, 2006), and ICH (ICH, 2011). The MLA

employs a strain ($Tk^{+/-}$ -3.7.2C) of L5178Y mouse lymphoma cells heterozygous at the Tk locus. When a chemical induces DNA damage leading to a mutational event (from $Tk^{+/-}$ to $Tk^{-/-}$), induced heritable loss of TK activity can easily occur. $Tk^{-/-}$ mutants can be detected by their inherent resistance to trifluorothymidine (TFT), which is incorporated into the DNA of TK-competent ($Tk^{+/-}$) cells resulting in cytotoxicity (Moore et al., 2003). In addition, $Tk^{-/-}$ mutants result in the loss of the salvage TK enzyme so that TFT is not incorporated into the cellular DNA, thereby enabling these cells to grow in the presence of TFT. This deficiency in the TK enzyme can result from a number of genetic events affecting the Tk locus, including gene mutations (point mutations, frameshift mutations, small deletions, etc.) and chromosomal events (large deletions, chromosome rearrangements, and mitotic recombination). Among these mutants, the induction of small-colony mutants is associated with chemicals inducing gross CAs, whereas the production of large mutant colonies is generally associated with chemicals causing point mutations (Moore et al., 2006; Moore et al., 2007). Chromosomal events lead to loss of heterozygosity (LOH). There are currently two equally acceptable methods for performing the MLA, namely, the soft agar and 96-microwell versions. This assay is also conducted both with and without S9.

Recently, the ICH S2 (R1) Guideline states several differences for testing pharmaceuticals, notably for the selection of the top concentration. The maximum top concentration of test article recommended decreases to 1 mM or 0.5 mg/ml from originally proposed 10 mM or 5 mg/ml, whichever is lower, when not limited by solubility in solvent or culture medium or by cytotoxicity (ICH, 2011).

Chromosome Aberration Assay Chromosome damage is a very important indicator of genetic damage relevant to environmental and clinical studies. Chromosomal mutation is related to changes in the chromosome structure (CAs) and changes in the number of chromosomes (numerical aberrations). Structural CAs have two types: chromosome and chromatid, which are induced by a chemical mutagenic agent through various molecular mechanisms. The structural aberrations may be a consequence of direct damage to DNA (e.g., DNA strand breaks, base damage, DNA cross-links) or indirect (e.g., inhibition of DNA topoisomerases I and II, generation of reactive oxygen species) and left unrepaired, or misrepaired to produce chromosome breaks or rearrangements. The CA test is widely used to screen for possible mammalian mutagens and carcinogens. In this assay, any cell lines, strains, or primary cell cultures, even human cells, may be used, such as Chinese hamster fibroblasts, human or other mammalian peripheral blood lymphocytes. Cell cultures are treated with the test substance both with and without S9. At predetermined intervals after the test substance exposure, cell cultures are treated with a metaphase-arresting substance

(e.g., colchicine), harvested, stained, and at least 200 metaphase cells are analyzed using microscopic analysis for the detection of CAs. The detailed requirement is described in OECD TG 473 (OECD, 1997c) and ICH S2 (R1) (ICH, 2011). For analysis of structural CAs at metaphase, there are categories described by Savage (Savage, 1976), e.g., chromosome-type aberrations (chromosome intrachanges and chromosome interchanges, including asymmetrical exchanges and symmetrical exchanges) and chromatid-type aberrations (chromatid break or terminal deletion, interstitial deletions, isochromatid deletions, inter-arm intrachanges, inter-arm interchange, triradials). Notably, the guideline ICH S2 (R1) currently decreases the top concentration for testing pharmaceuticals from the originally proposed 10 mM or 5 mg/ml to 1 mM or 0.5 mg/ml, whichever is lower, when not limited by solubility in solvent or culture medium or by cytotoxicity (ICH, 2011).

Micronucleus Assay The *in vitro* MN (MNvit) assay is a genotoxicity test newly adopted by the OECD for detecting the activity of clastogens and aneugens in divided cells after exposure to the test substance by analysis of MN in the cytoplasm of interphase cells (OECD, 2010). It provides a comprehensive basis for studying the chromosome damaging potential *in vitro*. In the TG 487, two methods, including with or without a cytokinesis blocker, actin polymerization inhibitor cytochalasin B (cyto-B) are both recommended to be used. The addition of cyto-B makes it easy to identify and analyze the MN frequency in cells because they have completed mitosis and therefore such cells are binucleate. For the method without a cytokinesis blocker, the cell population analysis is helpful to look at whether these cells have undergone mitosis. In addition, the MNvit assay also provides some value information on the mechanisms of chromosome damage, and MN formation are also provided using a cytokinesis blocker, immunochemical labeling of kinetochores, or hybridization with centromeric/telomeric probes (fluorescence *in situ* hybridization (FISH)). Theoretically, any cell type can be used in this assay in the presence or absence of cyto-B due to its robustness and effectiveness. The common use of rodent cell lines (CHO, V79, CHL/IU, and L5178Y) and human peripheral blood lymphocytes is highly recommended because of its extensively accumulating data from international validation studies (Aardema et al., 2006; Clare et al., 2006; Lorge et al., 2006) and the reports of the International Workshop on Genotoxicity Testing (IWGT) (Kirsch-Volders et al., 2000; Kirsch-Volders et al., 2003). This assay is conducted both with and without S9, but genetically engineered cell lines, which express specific human or rodent activating enzymes, may not need an exogenous S9 and may serve as the test cells.

In addition, the European Centre for the Validation of Alternative Methods (ECVAM) of the European Commission (EC) has also reevaluated the available data in a WoE

retrospective validation study, and the ECVAM Scientific Advisory Committee (ESAC) has endorsed the test method as scientifically valid. The use of the human TK6 cells (Corvi et al., 2008), HepG2 cells (Ehrlich et al., 2002), and primary Syrian hamster embryo cells (Gibson et al. 1997) has been described, although they have not been used in validation studies. Cell cultures are treated with the test substance both with and without S9 for 3–6 h, then the treatment medium is removed and replaced with fresh medium that may or may not contain cyto-B, and the cells are harvested 1.5–2.0 normal cell cycles later, stained, and the MN frequencies are analyzed in at least 2000 binucleated cells (with or without cyto-B) per concentration using a microscope, or validated flow cytometry or image analysis system.

Comet Assay The comet assay, also known as the SCGE assay, is widely used as one of the standard methods to assess DNA damage caused by a range of DNA-damaging agents. This assay was developed in the 1980s. The unique aspect of this method is its ability to detect DNA damage in individual cells. It can detect DNA single-strand breaks (SSBs) and alkali-labile sites under alkaline conditions ($\text{pH} > 13$), as well as DNA double-strand breaks (DSBs) under neutral conditions (Lin et al., 2014). The comet assay protocols have been adopted and optimized by many laboratories around the world. The comet assay is a rapid, simple, sensitive, and quantitative method for measuring DNA damage. Although it has some disadvantages, such as low throughput, relatively poor reproducibility (between users and laboratories), time consuming, and potentially biased image analysis (Brodsky et al., 1999), this assay has been accepted as a valuable tool for investigating DNA damage and repair by many laboratories around the world. Over the decades, the comet assay has become a basic tool to be used for *in vitro*, *ex vivo*, and *in vivo* systems and is increasingly being employed in a broad range of scientific fields, including the genotoxicity testing (Witte et al., 2007), human biomonitoring (Dusinska and Collins, 2008; Valverde and Rojas, 2009), and genetic ecotoxicology (Cotelle and Ferard, 1999). With its development, protocols for conducting *in vitro* and *in vivo* comet assays have been published by different expert panels, such as the IWGT (Tice et al., 2000; Burlinson et al., 2007), International Comet Assay Workshop (Hartmann et al., 2003), and by different laboratories (Speit and Hartmann, 2006; Liao et al., 2009; Burlinson, 2012). The *in vitro* comet assay is useful as an alternative to cytogenetic assays in early genotoxicity or photogenotoxicity screening of drug candidates (Witte et al., 2007). Theoretically, any cells can be used in the *in vitro* comet assay, e.g., mammalian cells, including cultured cells from different cell lines or isolated cells from the organism. Generally, the cell lines commonly used in the *in vitro* standard genotoxicity test battery are most widely employed in the *in vitro* comet assay (Tice et al., 2000).

In Vivo Assay

Chromosome Aberration Assay The *in vivo* CA test is commonly used for the detection of structural CAs induced by test chemicals in mammalian bone marrow cells, usually rodents, e.g., rats, mice, and Chinese hamsters, although any appropriate mammalian species may be used (OECD, 1997). Unlike the *in vitro* assay, this assay can assess the mutagenic hazard in humans extremely well because it considers the factors of *in vivo* metabolism, pharmacokinetics, and DNA repair processes. This assay is currently included in the stand test battery. Generally, animals are treated with the test substance by an appropriate route of exposure and are sacrificed at appropriate times after exposure. Concurrent positive and negative (solvent/vehicle) controls should be included for each sex in each test. Before sacrifice, animals are treated with a metaphase-arresting agent (e.g., colchicine), and then chromosome preparations are made from the bone marrow cells and stained. At least 100 metaphase cells for each animal are analyzed for CAs.

Micronucleus Assay The *in vivo* MN test is routinely used for detecting agent-induced cytogenetic damage to chromosomes or mitotic apparatus of erythroblasts in mammalian bone marrow and/or peripheral blood cells, usually from rodents (OECD, 1997). This assay can identify clastogens and aneugens that results in the formation of MN containing lagging chromosome fragments or whole chromosomes. Therefore, it is currently included in the stand test battery. Briefly, animals are treated with the test substance by an appropriate route of administration. The animals are sacrificed at appropriate times after exposure, the bone marrow is extracted or peripheral blood is collected at appropriate times after treatment, and slide preparations are made, and finally stained. These preparations are analyzed for the presence of MN. Although this assay is described in OECD TG 474, no standard treatment schedule is recommended as long as a positive effect can be demonstrated, and toxicity has been demonstrated or the limit dose has been used. Recently, systems for automated analysis, particularly, flow cytometric analysis, which has appropriately justified and validated, have become more acceptable alternatives to manual evaluation. In brief, the cell nuclei and MN are stained with fluorescence dye and then analyzed after the cell membrane and cytoplasm have been removed.

Comet Assay Recently, the *in vivo* comet assay has numerous published data and internationally acceptable protocols and even the application to various genotoxic testing strategies. However, there is no internationally agreed protocol of an *in vivo* comet assay. Scientific committees and regulatory agencies have been recommending the use of the *in vivo* comet assay to develop a WoE-based approach in genetic toxicology testing. An international collaborative trial on an

in vivo comet assay in 14 laboratories from Europe, Japan, and United States evaluated 15 chemicals in rat liver, and the results supported the notion that the liver comet assay is a reasonable alternative to liver UDS assay to detect the chemical-induced genotoxicity in liver.

The comet assay with specific modifications can also detect oxidative stress-induced DNA damage. The modifications include lesion-specific endonucleases, such as formamidopyrimidine glycosylase (FPG) and endonuclease III (Endo III), which can introduce strand breaks at the site of oxidative damage (Collins et al., 1993; Collins et al., 1996). Human 8-oxoguanine DNA glycosylase (hOGG1) has greater lesion specificity than FPG and EndoIII (Smith et al., 2006). In addition, some new or modified techniques have been developed for the *in vitro* comet assay, such as two-dimensional gel electrophoresis or two-tailed comet (2T-comet) assay (Klaude et al., 1996), comet-FISH (Santos et al., 1997), and CometChip (microwell array) technology (Wood et al., 2010; Kiraly et al., 2012). However, these new methods still need to be adequately validated to obtain reliable and reproducible results.

For registration of pharmaceuticals, it is required to conduct a comprehensive assessment of their genotoxic potential. The current generalized strategy consists of a battery approach for detecting the genetic end point relevant in tumorigenesis, including gene mutation and chromosome damage (aberration, chromosome loss or gain) using *in vitro* and *in vivo* assays. Although *in vitro* mammalian tests increase the sensitivity for detection of rodent carcinogens and broaden the spectrum of genetic events detected, they also decrease the specificity of prediction. Some agents are mutagenic *in vivo* but not *in vitro*; therefore, some *in vivo* test(s) are also included in the test battery, e.g., CA, MN, UDS. Recently, the ICH has included a second *in vivo* assay in Option 2 of the standard test battery for genotoxicity and recommended that the comet assay in liver could be one of the second *in vivo* assays (ICH, 2011). The US FDA has also released this guidance for industry in July 2012. In principle, the comet assay can be used in repeat dose toxicology assays with appropriate dose levels and sampling times. The *in vivo* comet assay is currently in final stages of validation, and it will likely be adopted by the OECD in the near future.

Liver Unscheduled DNA Synthesis The *in vivo* UDS test with mammalian liver cells is designed to identify chemicals that induce DNA repair in liver cells of treated animals. Although tissues other than the liver may be used, rat livers are preferred for this assay. This assay is commonly used to investigate genotoxic effects of chemicals in the liver. In this assay, the end point, DNA damage and subsequent repair in liver cells, is measured by determining the uptake of labeled nucleosides in cells that are

not undergoing scheduled (S-phase) DNA synthesis (OECD, 1986). In addition, the rodent *in vivo* liver UDS has been chosen as a preferred second assay in the standard test battery. This assay is often used to evaluate a DNA damage end point as a surrogate-like *in vivo* comet assay. For some test substances, the UDS assay is considered useful when they induce bulky DNA adducts or are positive in the Ames test. As with its *in vivo* counterpart, the OECD guideline (OECD, 1986) adopted in 1986 describes UDS procedures *in vitro* using primary cultures, human lymphocytes, or established cell lines, to detect DNA repair synthesis after excision and removal of a stretch of DNA containing the region of damage induced by agents. However, this *in vitro* TG will be deleted on 2 April 2014, and the assay is no more recommended.

Transgenic Rodent Mutation Assay The TGR gene mutation assay is used to detect gene mutations in any rodent tissue from which suitable DNA can be isolated. The regulatory genetic toxicology currently involves a wide range of *in vitro* mutation assays for detecting gene mutations and/or chromosomal alterations. *In vivo* assays are also the required components of many genetic toxicity testing strategies, in which current OECD TGs have been limited to investigate chromosomal damage (TG 474 and 475) and UDS in a very limited number of tissues. However, there are no OECD TGs *in vivo* to measure gene mutations, aside from the little-used mouse spot test for assessing heritable germ cell mutagenicity (OECD, 1986; Wahnschaffe et al., 2005), which will be deleted on 4 April 2014. For analysis of gene mutations *in vivo*, some non-transgenic mutation assays are described, but they are limited in use and no OECD TGs are described for these assays. The *in vivo* TGR mutation assays were originally accepted by the OECD on July 2011. The current version of the OECD guideline was updated and adopted on July 2013 (OECD, 2013) and is well characterized for *in vivo* tests for gene mutation. In the test battery, it is suggested to use an *in vivo* TGR mutation assay in place of a comet assay if an agent is positive *in vitro* in the MLA, is shown to induce predominantly large colonies and does not induce chromosome breakage in an *in vitro* metaphase assay. In this assay, the transgenic rats and mice are commonly used, which contain multiple copies of chromosomally integrated plasmid or phage shuttle vectors, and the transgenes contain reporter genes for detecting various types of mutations induced by agents. It is suggested that transgenes should respond to mutagens in a similar manner as endogenous genes, especially with regard to the detection of base-pair substitutions, frameshift mutations, and small deletions and insertions. The IWGT has recommended a protocol for implementing this assay (Heddle et al., 2000; Thybaud et al., 2003). The OECD guideline TG 488 is based on

these recommendations. Mutagenesis in the TGR mutation models is generally assessed as mutant frequency (OECD, 2013). However, further molecular analysis of the mutations can provide additional information. Transgenic rodent gene mutation assays available to support their use include *lacZ* bacteriophage mouse (MutaTM Mouse), *lacZ* plasmid mouse, *gpt* delta (*gpt* and Spi-) mouse and rat, *lacI* mouse and rat (Big Blue[®]). Moreover, the *cII* positive selection assay can be used for evaluating mutations in the Big Blue[®] and MutaTM Mouse models. In brief, the TGR assay includes treatment of the rodent with an agent over a period of time, and the unrepaired DNA lesions transform into stable mutations (expression time). After the animal is sacrificed, genomic DNA is isolated from the tissue(s) of interest and purified. The mutant colonies containing specific transgene are isolated using selective conditions and quantified. The mutations scored in the *lacI*, *lacZ*, *cII*, and *gpt* point mutation assays consist primarily of base-pair substitution mutations, frameshift mutations, and small insertions/deletions. Large deletions are detected only with the Spi- selection and the *lacZ* plasmid assays (Smith et al., 2009). The *in vivo* TGR assay for gene mutation is useful for further investigating a mutagenic effect detected by an *in vitro* system and to follow up the results of tests using other *in vivo* end points. It is anticipated that it may be possible to combine a TGR gene mutation assay with a repeat dose toxicity study (TG 407) in the future.

Rodent Pig-a Genes Mutation Assay The *Pig-a* gene mutation assay is based on the loss of function of the *Pig-a* gene, which leads to the absence of cell surface expression of specific proteins targeted to the surface by GPI anchors. The endogenous X-linked phosphatidyl inositol glycan, class A (*Pig-a*) gene, also called *Pig-a* gene, is involved in the synthesis of GPI anchors, which can gather multiple protein markers to the exterior surface of the cytoplasmic membrane (Kinoshita et al., 2008). In *Pig-a* mutant cells, there is a lack of GPI anchors and GPI-anchored markers. The marker-deficient mutants can be identified and enumerated using immunofluorescent staining and flow cytometric analysis. In addition, GPI anchor-deficient cells can also be characterized by their ability to expand in the presence of proaerolysin (proAER), a cytolytic toxin produced by the bacterium *Aeromonas hydrophila*. Proaerolysin binds GPI anchors present on wild-type cells and eventually leads to dead wild-type cells (Brodsky et al., 1999). However, ProAER does not bind to GPI-deficient *Pig-a* mutant cells, and the mutants can be selectively expanded in a growth medium containing proAER. Generally, *Pig-a* mutations can be detected in both erythrocytes and white blood cells by flow cytometric analysis. This assay has an opportunity to be discussed at the Working

Group of the National Coordinators of the Test Guidelines Programme (WNT), which was held in November in 2013.

Germ Cell Assays *In vivo* germ cell mutagenicity tests are used to assess potential heritable damage passed onto offspring, and the tests primarily include the mammalian spermatogonial CA test (OECD, 1997), mouse heritable translocation assay (OECD, 1986), mouse specific locus test, rodent dominant lethal test (OECD, 1984), spermatid MN assay, mammalian oocyte CA/aneuploidy test, UDS test in testicular cells, and TGR germ cell gene mutation assay (OECD, 2013).

In addition, some tests for detecting genotoxicity induction in somatic cells are also used to measure whether an agent has the capability to induce germ cell genotoxicity, e.g., the mammalian erythrocyte MN assay (OECD, 1997), mammalian bone marrow CA assay (OECD, 1997), and mouse spot test (OECD, 1986) are often used in predicting potential carcinogenicity.

Moreover, for assessing germ cell mutagenicity induced by chemicals, the United Nations Globally Harmonized System (GHS) classification of germ cell mutagenicity (<https://www.osha.gov/dsg/hazcom/ghs.html>) provides two different categories of germ cell mutagens: Category 1 chemicals are “known to induce heritable mutations or to be regarded as if they induce heritable mutations in the germ cells of humans.” Category 2 chemicals are those that “cause concern for humans owing to the possibility that they may induce heritable mutations in the germ cells of humans.” Among these categories, Category 1 has two subcategories: Categories 1A and 1B. The GHS recommends use of OECD TGs for genotoxicity testing and states that “if new, well validated, tests arise these may also be used in the total weight of evidence to be considered.”

Novel Assays The phosphorylation of histone H2AX at serine 139 (γ -H2AX) is considered one of the first steps of DNA damage response (Tanaka et al., 2007). It is used as a biomarker for detecting DNA DSBs induced by ionizing radiation or other genotoxic agents. The immunostained γ -H2AX can be measured using flow cytometry (Smart et al., 2011). In addition, single γ -H2AX foci can be visualized and counted under the fluorescence microscope. The expression of γ -H2AX in cells can be quantitatively analyzed using western blotting. It has been reported that γ -H2AX can be measured in different cells (somatic and germ cells) from *in vivo* animal studies, such as mouse bone marrow and testicular cells (Forand et al., 2004; Rube et al., 2008; Paris et al., 2011).

It is well known that mutagens, clastogens, and aneugens cause increased expression of the human *GADD45a* gene, which was originally identified and named by the Fornace laboratory (Fornace et al., 1992), and has been shown to

be associated with the response to genome damage. The *GADD45a-GFP* GreenScreen HC genotoxicity assay has been used to monitor genotoxin-induced transcription of the *GADD45a* gene (Hastwell et al., 2006; Walmsley, 2008). In this assay, the human lymphoblastoid cell line TK6 is used, which has wild-type p53 gene (Hildesheim et al., 2002), is the host for the reporter construct, in which the gene's expression is linked to the expression of green fluorescent protein (GFP). This assay is aimed to facilitate screening, which can be conducted in a microplate format (Knight et al., 2009). Data are collected through the use of the spectrophotometrical method or flow cytometry. To date, extensive validation has demonstrated that *GADD45a* assays have high sensitivity and specificity (Billinton et al., 2008; Jagger et al., 2009).

GENOTOXIC TESTING GUIDELINES

Overview

Genotoxicity tests are used to detect the genetic damage by various mechanisms in *in vitro* and *in vivo* systems. Several regulatory guidelines have been developed to provide various assays that are conducted for testing the genotoxicity. Most regulatory authorities have set their own requirements for detecting the genotoxicity that need to supply a series of genetic toxicity testing, e.g., US FDA, US EPA, and United Kingdom Environmental Mutagen Society (UKEMS). Some guidelines, such as the OECD Guidelines for the testing of chemicals, US EPA genetic toxicity TGs, and FDA Red Book, have provided various assays for detecting the genotoxicity. To date, most regulatory agencies and international authorities recommend a test scheme consisting of *in vitro* and *in vivo* methods to detect genotoxicity/mutagenicity induced by substances. The ICH recommends a standard battery test for pharmaceuticals to detect the genotoxicity. The ICH guidance optimizes the standard battery test for genetic toxicology and also provides the guidance on the interpretation of results (ICH, 2011). This guideline helps improve risk characterization for carcinogenic effects. In the sections below, some regulatory agencies or organizations are briefly described as to their own guidelines.

Regulatory Agency and Its Test Guidelines

OECD The OECD Guidelines for testing the genotoxicity induced by new and existing chemical substances, chemical preparations, and chemical mixtures consist of the most relevant internationally agreed testing methods used by the government, industry, and independent laboratories worldwide. They are used primarily in regulatory safety testing and chemical registration (Table 108.2).

US EPA In the US EPA, the Office of Chemical Safety and Pollution Prevention (OCSPP) has developed a series of harmonized TGs for use in the testing of pesticides and toxic substances. The EPA recommends these methods be used to generate data that are submitted to the EPA for supporting the registration. The OCSPP harmonized TGs for detecting genotoxicity are organized in Group Do Genetic toxicity test guidelines, from Series 870—Health Effects Test Guidelines (Table 108.3).

US FDA As mentioned previously, the FDA follows the ICH guideline for drug and biological product registration. The current guidance issued by the FDA for assessing the genotoxicity in drug registration includes S2 (R1) (Genotoxicity Testing and Data Interpretation for Pharmaceuticals Intended for Human Use). This newly released guideline applies to small-molecule, nonbiological pharmaceutical products that are intended to be used in humans.

As its responsibility, the FDA provides guidance to the industry and public for evaluating the safety of food and color additives. The current guideline, Redbook 2000 (CFSAN, 2007), known as "Toxicological Principles for the Safety Assessment of Food Ingredients" is the new name for "Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Food" originally published in 1982 ("Redbook I") and the draft revision published in 1993 ("Redbook II"). The Center for Food Safety and Applied Nutrition (CFSAN) of the FDA is responsible for revising and updating the Redbook in light of the developments in toxicological testing methods and comments from the scientific community and public. This guidance provides toxicological information submitted to the CFSAN, Office of Food Additive Safety (OFAS) regarding food ingredients. In Redbook 2000, it includes some genotoxicity tests in Chapter IV.C.1 Short-Term Tests for Genetic Toxicity listed in Table 108.4.

ICH

Genotoxicity testing is conducted for pharmaceuticals, industrial chemicals, and consumer products. The results from these tests are used to identify chemicals for heritable germ cell mutagenicity as well as carcinogenicity. Recently, ICH guideline S2 (R1) has been finalized under Step 4 in November 2011. This revised guideline replaces and combines the ICH guidelines S2A and S2B and optimizes the standard genetic toxicology battery to provide guidance on the interpretation of results. This guidance is the internationally agreed upon standard for follow-up testing and how to interpret positive results *in vitro* and *in vivo* in the standard genetic toxicology battery, including how to assess nonrelevant findings (ICH, 2011).

NONANIMAL ALTERNATIVE METHOD

With the development of nonanimal alternative methods, more *in vitro* methods are increasingly used for assessing the toxicity induced by substances. In general, alternative toxicity testing methods will be accepted after they have been scientifically validated and determined to be reliable (reproducible) and relevant for their intended purpose. The current OECD genotoxicity testing includes several

in vitro genetic toxicity assays adopted, and four of which are included in a standard test battery. There four *in vitro* assays include a mutagenicity test method based on bacteria: the bacterial reverse mutation test (Ames test) (OECD TG 471). The three commonly used methods are based on mammalian cells, and they are the *in vitro* mammalian CA test (OECD TG 473), *in vitro* mammalian cell MN test (OECD TG 476), and the *in vitro* mammalian cell gene mutation test (OECD TG 476). In addition, two *in vitro* mammalian cell

tests (*in vitro* sister chromatid exchange assay and DNA damage and repair, UDS) will be deleted on 2 April 2014.

To date, the criteria and processes for test method validation have been developed and implemented in Europe (under the auspices of the ECVAM), the United States (through the Interagency Coordinating Committee on the Validation of Alternative Methods, or ICCVAM), Japan (through the Japanese Centre for the Validation of Alternative Methods (JaCVAM), and internationally through the OECD. These organizations are responsible for the development and scientific regulatory acceptance of alternative testing methods. After undergoing these steps, e.g., research and development, pre-validation, and validation until regulatory acceptance, it usually takes at least 5 years. A lot of *in vitro* methods for genotoxicity testing are based primarily on bacterial and mammalian cells assays, and several of which are accepted by regulatory authorities. Aside from the standard *in vitro* mammalian cell genotoxicity tests described above, there are *in vitro* assays for detecting genotoxicity in primary germ cells; however, these are not standardized or validated, and there are no ongoing coordinated activities to address them at this time. The validation of comet assay and pre-validations of genotoxicity assays in 3D-skin model are coordinated by the JaCVAM and the European Cosmetic, Toiletry and Perfumery Association (COLIPA).

PERSPECTIVE

Some *in vitro* genotoxicity tests in cell lines for predicting carcinogenicity in rodents have shown the capability of high sensitivity, especially when combined in a standard battery. *In vitro* genotoxicity assays provide an integrated approach for assessing genetic damage. In the WoE approach, more weight is generally given to the positive results obtained by *in vivo* assays than *in vitro* assays. However, currently available genotoxicity assays are unable to detect all genotoxic carcinogens. Whichever assay is chosen, an *in vitro* assay or *in vivo* assay, it is critical to accurately identify the genotoxic carcinogens in the chosen assay. Numerous factors, such as experimental conditions or biochemical and physiological stresses, can affect the evaluation of genotoxicity in *in vitro* and *in vivo* assays, which can result in positive DNA damage response. In the future, it is important to investigate a correlation between *in vitro* and *in vivo* assays, even in human experiments. In addition, models that can be used in both *in vitro* and *in vivo* assay, as well as end points/tissues that can be evaluated in both animal and humans may contribute to a comprehensive understanding of the results and extrapolation to humans (e.g., MN and comet assay in peripheral blood). To understand the mode of action leading to the genotoxic response, the choice of assays and the data interpretation should take into account all available information. Computational prediction of genotoxicity (*in silico*

approaches) using molecular structure database, structure-activity relationship (SAR) or quantitative SAR (QSAR) models is useful and often used around the world by regulatory authorities as an adjunct to risk assessment, especially when no actual test data are available (Mahadevan et al., 2011). Generally, computer-based predictions using QSAR and *in vitro* testing are the first two steps for assessing genotoxicity/mutagenicity induced by substances. In addition, the development of toxicogenomics can contribute to screening carcinogenicity, and identifying new markers, and elucidating the mechanism. For industry perspective, several high throughput screening (HTS) assays or quantitative HTS have been established for the assessment of genotoxicity (Mahadevan et al., 2011), especially in early stage of drug development. In summary, genotoxicity testing is very useful, and a major challenge in the field of genetic toxicology is developing new or modified tests for the future that are able to efficiently detect genotoxicity with high specificity and sensitivity.

HUMAN RELEVANCE OF RODENT LEYDIG CELL TUMORS

THOMAS J. STEINBACH, ROBERT. R. MARONPOT, AND JERRY F. HARDISTY

INTRODUCTION

Rodents have been used extensively in virtually all fields of biomedical research and have been the primary species used in toxicologic and carcinogenic research. Over many years it has become obvious that some conditions and in particular some tumors in rodents have questionable relevance in humans. Some of these include peroxisome proliferator-activator receptor- α (PPAR- α) agonist-induced liver tumors, alpha 2u-globulin-induced renal tumors in male rats, and bladder tumors induced in rats by urinary calculi. In this chapter we review the human relevance of Leydig cell tumors (LCTs), which have been induced in rodents by a number of compounds. We will consider the similarities and differences between humans and rats in the physiology of the Leydig cell (LC) and the pathology of LCTs. Most importantly, we will examine the mechanisms of action that induce LCTs in rats and humans and present data on incidence, physiology, human endocrine disease, and comparative epidemiological studies that strongly indicate LCTs in rodents, in particular the rat, are of little relevance to human health.

DEVELOPMENT

The ontogeny of the LC can be reviewed in two basic ways: by following the stages of adult LC differentiation or by examining the two recognized generations of LCs, fetal and adult. Differentiation of the LC is typically broken down into four stages: stem LCs, progenitor LCs, immature LCs, and adult LCs. Stem LCs are spindle shaped and as a cell, which has not yet committed to a lineage of development, it does not

express the LC-specific markers such as luteinizing hormone receptor or steroidogenic enzymes such as 3 β -hydroxysteroid dehydrogenase. In the rat, at postnatal day 14 stem LCs begin to stain positive for 3 β -hydroxysteroid dehydrogenase and are identified at this point as progenitor LCs. These cells develop from about postnatal day 14 until day 28 and begin to produce androgen. (Reviewed in Chen et al., 2009) Gene expression changes most when stem LCs develop into progenitor LCs, whereas differences in gene expression from progenitor to immature LCs and from immature to adult LCs are minimal, suggesting these cells are relatively more similar (Stanley et al., 2011).

Starting at postnatal day 28, progenitor LCs transform morphologically to become more round. The immature LC has increased amounts of smooth endoplasmic reticulum and steroidogenic enzyme levels. Testosterone is not yet the major product produced by these cells because they possess high levels of androgen-metabolizing enzymes that produce 5 α -androstane-3 α , 17 β -diol. The immature LC population doubles once from postnatal day 28 to 56, at which point they develop into adult LCs. The androgen-metabolizing enzyme activity reduces while synthesis of testosterone increases. By day 90, testosterone production in an adult LC of a rat is 150 times than that of a progenitor, and five times than that of an immature LC (Shan et al., 1993).

Development of LCs can also be discussed in reference to the two generally recognized generations: fetal and adult. In the rat, the fetal LC begins to produce testosterone at about gestation day 16 and peaks on day 19 (Habert and Picon, 1984). In humans, testosterone peaks at the end of the 1st trimester (Reyes et al., 1974). The production of androgens is critical for masculinization of the fetus during what is termed

the “masculinization programming window.” In the rat this window is from 15.5 to 17.5 days of gestation while in the human it extends from 8 to 14 weeks of gestation. (Welsh et al., 2008) In addition to androgens, fetal LCs produce insulin-like growth factor 3, which is responsible for testicular descent (Zimmerman et al., 1999).

A number of factors that influence the differentiation of the fetal LCs have recently been identified and include: desert hedgehog, a cell signaling molecule secreted by Sertoli cells, and transcription factors such as GATA-4. Interestingly, in rodents, development of fetal LCs is not dependent on pituitary luteinizing hormone (LH) (until the hypothalamic–pituitary–gonadal axis begins functioning near birth). Primates, including humans, have a brief period of independence from hormonal stimulation but then fetal LCs become dependent on placental chorionic gonadotropins (Reviewed in O’Shaughnessy and Fowler, 2011; Svechnikov et al., 2010).

The adult LC forms mostly during puberty and produces the testosterone responsible for spermatogenesis, along with differentiation of other secondary sex characteristics. In both the rat and human there is decreased testosterone production associated with aging. In humans the decreased testosterone is associated with increased levels of LH and appears to be due to a decline in the number of LCs through degeneration. In rats, however, decreased testosterone is associated with declining LH levels and seems to be related to the inability of the LC to respond to LH stimulation (Reviewed in Chen et al., 2009; Cook et al., 1999).

STEROIDOGENESIS

The LC is responsible for producing virtually all of the steroids of the testis; testosterone being the major steroid

(Stocco, 1996). Although a number of pathways have been elucidated recently, the primary signaling method for steroidogenesis is initiated when LH binds to a G protein-coupled receptor, which in turn activates adenylate cyclase, producing cAMP (See Figure 109.1). Protein kinase A is activated by cAMP and results in phosphorylation of a number of proteins and transcription factors (Wang and Ascoli, 1990). One of the most important of these is steroidogenic acute regulatory protein (StAR), which is estimated to mediate 85–90% of steroid synthesis (Reviewed in Stocco et al., 2005). Steroidogenic acute regulatory protein and translocator protein, formerly known as peripheral-type benzodiazepine receptor, are components of a large, multi-protein complex known as the transducesome. This complex is responsible for transporting cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane (Reviewed in Rone et al., 2009). The translocation of cholesterol from the outer to inner mitochondrial membrane is the rate limiting step in the synthesis of all steroids (Miller, 2007; Manna 2009). Intracellular cholesterol is produced by three mechanisms: de novo synthesis in the endoplasmic reticulum; mobilization from the plasma membrane and uptake from circulating cholesterol esters; and mobilization from lipid droplets (Rone et al., 2009).

Mediated by StAR, free cholesterol is transported to the inner mitochondrial membrane, where it is metabolized into pregnenolone by the P450 cholesterol side-chain cleavage enzyme (CYP11A1) (Reviewed in Payne and Hales, 2004). The remaining reactions of steroidogenesis occur within the endoplasmic reticulum with small differences between rats and humans in the pathway (Cook et al., 1999). In rat pregnenolone is transformed to progesterone by the enzyme 3 β -hydroxysteroid dehydrogenase (3 β HSD). Next the P450

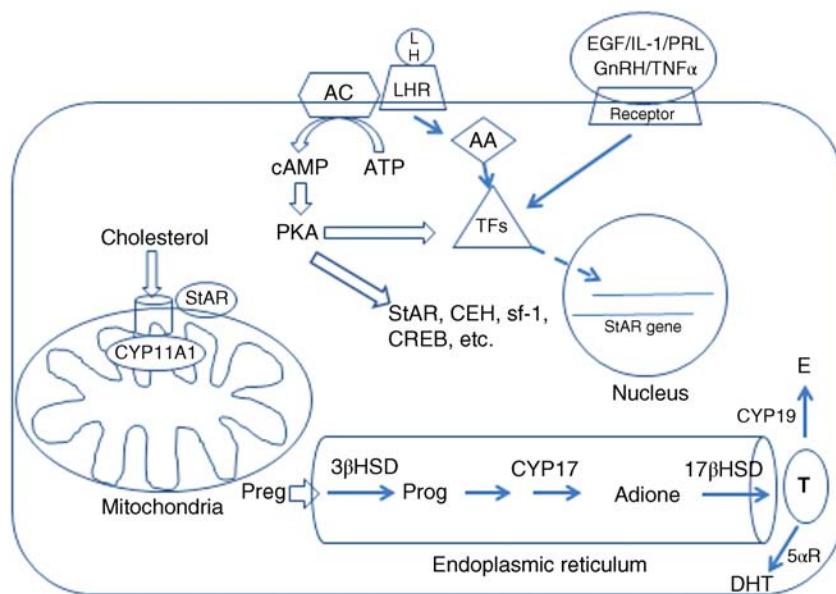

FIGURE 109.1 Mechanisms involved in the synthesis of testosterone.

enzyme, C₁₇_a-hydroxylase/C₁₇-20-lyase (CYP17), catalyzes two reactions converting progesterone first to hydroxyprogesterone and then to C19 steroid, androstenedione. In humans, CYP17 prefers pregnenolone as a substrate and converts it to 17 α -hydroxypregnenolone and then to C19 steroid, dehydroepiandrosterone (DHEA). Finally, 17 β -hydroxysteroid dehydrogenase (17 β HSD) converts the C19 steroid into testosterone (Payne and Hales, 2004). Testosterone can be further metabolized into estrogen by P450 aromatase (CYP19) (Payne and Hales, 2004) or into the more potent androgen dihydrotestosterone (DHT) (Cook et al., 1999).

As mentioned, cAMP-dependent activation of protein kinase A is essential for activation of StAR and other proteins and transcription factors involved in steroidogenesis, to include cholesterol esterase (CEH), steroidogenic factor-1 (sf-1), GATA-4, and cAMP response element-binding protein (CREB). However, there are other mechanisms by which steroidogenesis is regulated. In recent years research has focused on factors that influence and regulate StAR, since it is critical to the rate-limiting step of steroidogenesis. A number of factors can regulate StAR via cAMP-independent pathways. These include epidermal growth factor (EGF), macrophage-derived factors such as IL-1 and TNF α , hormones such as prolactin and gonadotropin-releasing hormone (GnRH), chloride ions, and calcium messenger systems. In addition, a protein kinase C pathway can be activated resulting in increased transcription and translation of StAR (Stocco et al., 2005; Manna et al., 2007). Leutinizing

hormone binding to its receptor can release arachidonic acid (AA) and metabolites of AA can regulate StAR gene expression (Wang et al., 1999).

PATHOLOGY

The mammalian testis is composed of a fibrous tunic that surrounds convoluted seminiferous tubules and supporting stroma. In a microscopic section the tubules make up the majority of the cellular structure present and contain mostly gametes in various stages of differentiation from spermatogonia to spermatozoa in addition to supportive cells, such as Sertoli cells. Surrounding the tubules is a small amount of connective tissue that contains blood vessels, nerves, and interstitial cells of Leydig (Figure 109.2). Normal LCs have a wide variation in morphology. They can be spindle shaped with little cytoplasm but are typically round and contain large amounts of lightly eosinophilic cytoplasm. In humans and the wild bush rat, the LC cytoplasm contains elongated, cigar-shaped structures known as crystals of Reinke. These crystals can be seen with light microscopy and are found only in adults. Their origin and function are unknown (Young and Heath, 2000).

In rodents, hyperplasia of LCs is characterized by aggregates of cells that focally or diffusely expand the interstitium between seminiferous tubules. Cells are typically round with centrally located nuclei and granular, eosinophilic cytoplasm. Occasionally, spindle cells with little cytoplasm and dark nuclei are also found (Boorman et al., 1990).

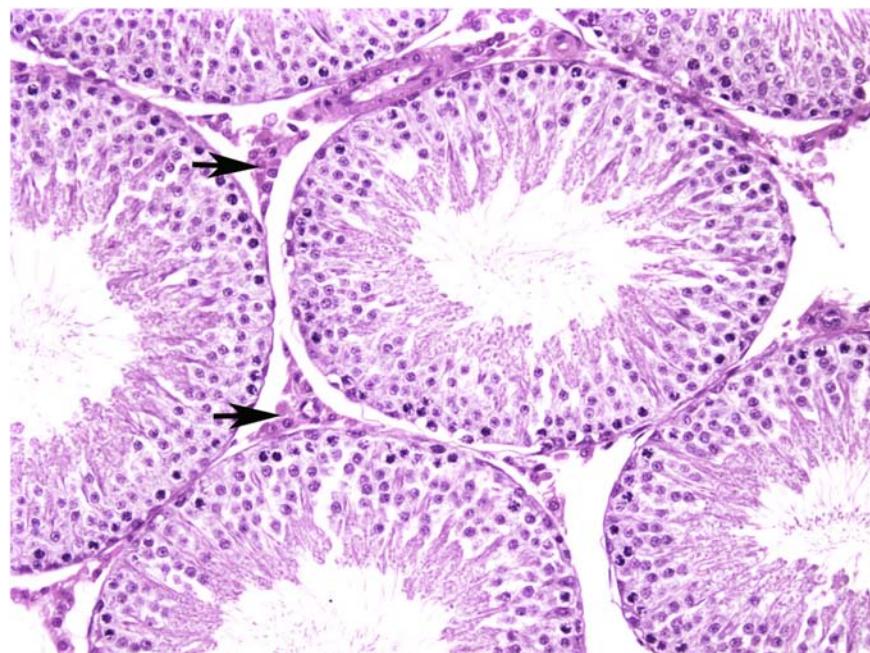

FIGURE 109.2 There are low numbers of Leydig cells (arrows) in the interstitium surrounding seminiferous tubules of this normal rat testis (H&E, 200 \times).

Leydig cell adenoma begins as hyperplasia and consists of one or more foci of expansive LCs that typically compress adjacent tubules. The distinction between hyperplasia and adenoma is difficult as cellular characteristics cannot distinguish between them. Most often size is used as a morphologic criteria to differentiate hyperplasia from adenoma. One recommendation from the National Toxicologic Program (NTP) is to use the size of adjacent tubules as a threshold. When the lesion grows larger than the diameter of the adjacent tubule, it is diagnosed as adenoma. In 2005 toxicologic pathology societies from around the world began an initiative to standardize nomenclature for proliferative and nonproliferative lesions in rats and mice. This initiative is termed the International Harmonization of Nomenclature and Diagnostic Criteria for Lesions in Rats and Mice (INHAND) (Mann et al., 2012). The INHAND focuses on specific organ systems. For the male reproductive system, the INHAND guidance differentiates hyperplasia from adenoma using a size of three seminiferous tubules, among other criteria (Creasy et al., 2012). This makes interpretation of incidence data in rodents difficult as published data on LC adenoma typically does not describe the methodology used in establishing the diagnosis of adenoma (Cook et al., 1999).

The incidence of LC adenoma in rodents is highly dependent on species and strain and increases with age. In mice it is typically low, <2.5%, whereas in Sprague-Dawley and Wistar rats it ranges from 4 to 7% (Cook et al., 1999). In Fisher 344 rats, however, the incidence of LC adenoma approaches 100% if the rat is allowed to live its life span (Boorman et al., 1990). LC tumors in rodents are almost always benign as malignancy is rarely reported (Boorman et al., 1990; Cook et al., 1999).

In contrast to rodents, LC tumors in humans are rare, comprising from 1 to 3% of all testicular neoplasms with an estimated incidence of 0.1–3 per million (Cook et al., 1999). Comparing the incidence of LCTs between rodents and humans is somewhat problematic. The data in rodents comes from toxicologic and carcinogenic studies, where rodents are subjected to complete histologic examination and small tumors, not evident grossly, are often discovered microscopically. In humans, testicular tumors are most often diagnosed by palpation and routine microscopic examination of testicular tissue does not occur. Advanced imaging techniques, however, have made possible the diagnosis of non-palpable testicular tumors. Recent data has shown that when ultrasound is used to diagnose testicular tumors, the incidence of LCT is significantly higher than previously reported (Leontharsberger et al., 2011). Regardless, even when considering detection bias, the incidence of LCT in rodents, especially in some strains, is markedly higher than in humans. Furthermore, LCTs in humans are found in all ages, from prepubertal boys to older men. Microscopically they resemble tumors in rodents except for the presence of Reinke crystals. While the majority of human LCTs are benign, a much higher

incidence, 10%, are considered malignant in humans. (Cook et al., 1999)

MECHANISM OF TUMOR INDUCTION

In the rat there are a number of plausible mechanisms for the induction of LC tumors. These include agonists of estrogen, GnRH, dopamine receptors, and PPAR- α . In addition, androgen receptor antagonists, and inhibitors of testosterone synthesis and the enzymes aromatase and 5 α -reductase can lead to LCTs. Most of these mechanisms are related to elevated levels of LH. It is well documented that prolonged elevated levels of LH induce LC hyperplasia and neoplasia in the rat (Neumann, 1991; Prentice and Meikle, 1995; Huseby, 1996). In addition, administration of testosterone to F344 rats lowers LH levels and blocks LCT formation (Chatani et al., 1990).

Because LH plays such a central role in LCTs of rats, it is useful to review the hypothalamic-pituitary-testis (HPT) axis to see how LH levels can influence the induction of LCTs. Figure 109.3, (adapted from Cook et al., 1999), highlights five mechanisms by which chemicals can disrupt LH levels and induce LCTs. These five mechanisms, and others, will be briefly reviewed in more detail and additional compounds known to induce LCTs in rats will be listed.

Flutamide is an androgen receptor antagonist. It competes with testosterone and DHT for binding at the androgen receptor (Simard et al., 1986). As a result, the androgen signal to the hypothalamus and pituitary is reduced, which stimulates an increase in LH secretion to counter the decreased androgen levels (Cook et al., 1993; Viguer-Martinez et al., 1983). Examples of other androgen receptor antagonists known to induce LCTs in rats include cimetidine (Leslie et al., 1981); procydine (Murakami et al., 1995); and bicalutamide (Iswaran et al., 1997).

In a similar manner, 5 α -reductase inhibitors, such as finasteride block the conversion of testosterone to DHT (Prahala et al., 1994; Rittmaster et al., 1992). Dihydrotestosterone has a higher binding affinity to the androgen receptor than does testosterone (DeGroot et al., 1995). Thus a decrease in DHT reduces the net androgenic signal to the hypothalamus and pituitary resulting in a compensatory increase in LH. Interestingly, 5 α -reductase inhibitors induce LCTs in mice and LC hyperplasia in rats (Cook et al., 1999).

Inhibition of testosterone synthesis also lowers the androgen signal resulting in increased LH levels. Interestingly, ketoconazole, which is the most widely known inhibitor of testosterone synthesis, did not induce LCTs but this seemingly was due to the design of the study, which exposed animals to lower levels and for shorter durations than similar bioassays (Cook et al., 1999). Examples of compounds that induce LCTs by inhibiting testosterone synthesis include lansoprazole (Fort et al., 1995); calcium

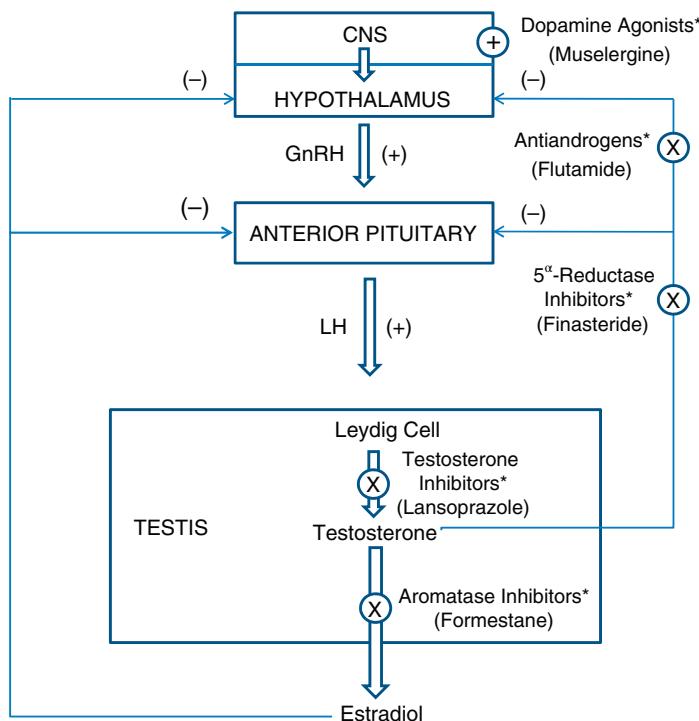

FIGURE 109.3 Regulation of the HPT axis and control points for potential disruption.

channel blockers such as metronidazole (Rustia and Shubik, 1979).

Formestane is an aromatase inhibitor and as such it blocks the conversion of testosterone to estradiol. Since estradiol provides negative feedback to the hypothalamus and pituitary (see Figure 109.3), inhibition of estradiol, in theory, would increase the levels of LH and induce LCTs. However, formestane induced LC hyperplasia in beagle dogs but not rodents (Junker-Walker and Nogues, 1994) and aminoglutethimide, the most well-known aromatase inhibitor, did not induce LC hyperplasia or LCTs (Salhanick, 1982; Shaw et al., 1988). The role of aromatase inhibitors in leading to LCTs, therefore, is equivocal.

Dopamine agonists such as muselergine decrease prolactin levels, which causes downregulation of LH receptors on LCs (Prentice et al., 1992). The decrease in LH receptors lowers the overall testosterone production and LH levels increase to compensate. An alternative mechanism was proposed based on work with oxolinic acid. Yamanda et al. suggested that dopamine agonists increase levels of GnRH and thereby increase LH levels (Yamanda et al., 1995). The exact mechanism has yet to be worked out.

In rats GnRH induces LCTs at low doses but not at higher doses. This is because the LC of the rat contains GnRH receptors and can stimulate the LC directly. Low levels of GnRH can also increase LH through direct stimulation of the pituitary (Figure 109.3). At higher doses, negative feedback inhibition from GnRH would lower LH levels and thus

LCTs. (Cook et al., 1999) Mice and humans do not have GnRH receptors on their LCs and are thus not susceptible to LCTs by GnRH agonists (Hunter et al., 1982).

Estrogen agonists induce LCTs in the mouse but almost never in the rat (Cook et al., 1999). However, PPAR- α agonists are known to lead to LCTs in rats. In at least some of the cases of PPAR- α agonists there is an increase in estradiol (but not LH or testosterone) that corresponds with the potency of the compound (Biegel et al., 2001). PPAR- α agonists also can reduce testosterone levels (Cook et al., 1992; Gazouli et al., 2002). As shown previously, compounds that lower testosterone can cause a compensatory rise in LH and lead to LCTs. Most likely, both elevation of estrogen and decreased testosterone play a role in induction of LCTs by PPAR- α agonists (Klaunig et al., 2003).

HUMAN RELEVANCE

It is clear from the forgoing discussion that many compounds induce LCT in rodents, especially rats. Since the rat is one of the primary species used in toxicologic and carcinogenic risk assessment, these findings may be of importance in establishing exposure thresholds or compound safety data. However, a number of factors, when examined closely, illustrate that the occurrence of LCTs in rats is not biologically relevant to humans. These differences are thoroughly discussed and referenced in Cook et al. (1999) and the reader is referred

there for a more in depth analysis. This discussion will focus on differences in comparative biology, tumor incidence, as well as cases of human genetic disease and data from epidemiology studies.

The biology of the rat and human differ in a number of important ways and some of those potentially have an impact on the relevance of LCTs in humans. These include differences in serum proteins, response to hCG, number of LH and GnRH receptors, sensitivity to prolactin, and LH-related aging changes.

The sex hormone-binding globulin is absent in the rat. It is produced in the liver in humans and binds to the majority of testosterone. This binding lowers the metabolism and clearance of testosterone in humans and dampens short-term changes in testosterone levels. In contrast, in the rat testosterone levels can be more rapidly altered and as a result, compounds that alter testosterone levels have a more dramatic effect in rats.

Rats and humans have been shown to respond differently to hCG, a hormone that has equivalent effects on LCs as does LH. *In vivo* and *in vitro* data show that hCG induces LC hyperplasia in rats while inducing hypertrophy in humans. In addition, testosterone secretion and the mitogenic response are up to 100-fold less in human LCs.

There are important differences between rats and humans in the receptors on LCs. Compared to humans, rats have over 10 times the number of LH receptors on their LCs. This spare capacity of receptors allows for a lower concentration of LH in rats that will induce a response in LCs. In addition, as mentioned, rats have GnRH receptors on LCs, while humans do not. It would appear, therefore, that induction of LCTs by GnRH agonists is not a mechanism applicable to humans. Likewise, unlike rats, humans do not express prolactin receptors on LCs. In the rat, dopamine agonists act by decreasing prolactin levels, which in turn lower the number of LH receptors on their LCs. The decrease in LH receptors results in a decrease in the testosterone levels and a compensatory increase in LH. Because humans lack prolactin receptors, dopamine agonists seemingly would not alter the number of LH receptors on human LCs and testosterone, and LH levels would remain unchanged. Therefore, it is unlikely that dopamine agonists would induce LCTs in humans.

Finally, rats and humans differ in how LH affects testosterone levels in aging. In both rats and humans testosterone levels decrease over time. However, in rats LH levels also decrease and this decrease in LH may be responsible for the decrease in testosterone. In contrast, LH levels remain unchanged in men with aging. Luteinizing hormone appears, therefore, not to be a factor in decreasing the level of testosterone in men with time.

As previously discussed, the incidence of LCT in rats and humans is markedly different. Depending on the strain, the incidence of LCT in rats ranges from nearly 100% in Fisher 344s to 5% in Wistar (Tucker, 1997) and 6.5% for Sprague-Dawley (McMartin et al., 1992) rats. In contrast, in humans

testicular cancer accounts for about 1% of all cancers in men and of these, only about 1% are of LC origin; making LCTs about 0.01% of all cancers in men (Cook et al., 1999). Consequently, the incidence of LCT in humans is in the order of 1.9 million-fold less than in F344 and 130,000-fold less than Sprague-Dawley rats (Cook et al., 1999).

There are two genetic endocrine diseases in humans that highlight the mechanistic differences in LCT induction between humans and rats. The first is androgen insensitivity syndrome, which is due to a defect in the androgen receptor. The second, familial male precocious puberty, is the result of a defect in the LH receptor. Reviewing the incidence of LCTs in individuals affected with these diseases further emphasizes that humans are clearly less sensitive to LCT formation than are rats.

In androgen insensitivity syndrome there is a genetic defect in the androgen receptor so that androgens are not recognized. The syndrome ranges from complete to partial insensitivity and phenotypically, affected individuals range from infertile males to females. Individuals with complete insensitivity and a cryptorchid testis have elevated levels of LH, but normal levels of testosterone. Testicular tumors, including LCTs, are more common in individuals with androgen insensitivity syndrome with some reports of LC adenomas as high as 2–3%. As a comparison, the incidence of LCT in rats when administered an androgen receptor antagonist, such as flutamide, is almost 100%. Administration of flutamide to rats can be thought of as a chemically induced form of androgen insensitivity syndrome. If humans were as sensitive to the formation of LCTs, then individuals with this syndrome would have a much higher incidence of LCTs, which they clearly do not. (Cook et al., 1999)

Familial male precocious puberty is the result of a genetic mutation of the LH receptor that results in constitutive activation. Affected individuals undergo puberty at about 4 years of age. They have testosterone production and LC hyperplasia but undetectable levels of LH. The continuous activation of LH receptors in individuals with familial male precocious puberty mimics the primary mechanism of LCT induction in rats, namely elevated LH levels. While LC hyperplasia is reported in cases of familial male precocious puberty, there have been no documented cases of LCTs despite a lifetime of LH-receptor activation. Once again, if humans were as sensitive to LH-induced LCT formation, individuals with familial male precocious puberty would have a much higher incidence of LCT (Cook et al., 1999).

Lastly, there have been a number of epidemiological studies conducted on compounds with human exposure for which there is comparative rodent study data available. Only three will be reviewed to illustrate the concept but for a more complete list refer to Cook et al. (1999). It must be emphasized that the epidemiological surveys relied on insensitive methods for the detection of LCT in humans but nonetheless the results are still helpful in underscoring the relative difference in LCT incidence between humans and rodents.

1,3-Butadiene is a ubiquitous product used in the plastics industry and because of its high exposure to humans, it has been extensively studied both in laboratory animals and humans. Sprague-Dawley rats exposed via inhalation had an increased incidence of LCTs (8% vs. 0% in controls) (Owen and Glaister, 1990). Using a large number of exposed workers, human epidemiological studies have failed to identify a risk of LCTs in men exposed to 1,3-butadiene (Divine and Hartman, 2001). Cadmium induces not only LCTs in rats but also adenomas in the prostate (Waalkes et al., 1988). However, a review of human exposure studies identifies increased risk of lung cancer but not prostate or LCTs (Verougastraete et al., 2003). Finally, trichloroethylene has wide human exposure as an industrial solvent and an additive in food, drugs, and consumer products. It causes marked increases in LCTs in Sprague-Dawley rats but a review of five cohort studies in humans did not identify trichloroethylene as a carcinogen (Cook et al., 1999).

CONCLUSION

In rats, LCTs are induced almost exclusively by elevated levels of LH. The exceptions seem to be LCTs induced by GnRH and dopamine agonists, which, as discussed, appear not to be applicable to humans since they lack the receptors (GnRH and prolactin) to induce LCTs. Therefore, when examining the relevance of LCTs induced in rats to human health, the question becomes what is the relative sensitivity in humans to LCT induction from elevated LH levels. As discussed, several lines of reasoning indicate that the high incidence of LCTs in rats is not relevant to humans. First, humans have a markedly lower incidence of LCTs compared to rodents, especially rats. Second, there are a number of comparative differences in the biology of the LC, especially the type and number of receptors that help explain the difference in rates of LCTs. Third, two endocrine diseases in humans do not produce LCTs at an incidence level expected, if the mechanism of LCT induction in human was similar to that in rats. And fourth, when compounds with both human epidemiological and rodent exposure data are compared, the results do not support a conclusion that rodent LCTs are relevant to human health.

REPRODUCTIVE TOXICOLOGY

JUDITH W. HENCK

INTRODUCTION

Adverse effects on the reproductive potential resulting from an occupational exposure to physical agents and chemicals in the workplace are important concerns for occupational medicine. Potential harm may occur to men and women, as well as to their progeny, due to an exposure prior to and during pregnancy and after birth. Adverse effects on the structural and functional components of male and female reproductive systems may lead to impaired fertility or infertility of exposed workers. According to the World Health Organization (2013), infertility is defined as: ". . . the inability to conceive a child. A couple may be considered infertile if, after two years of regular sexual intercourse, without contraception, the woman has not become pregnant (and there is no other reason, such as breastfeeding or postpartum amenorrhea). Primary infertility is infertility in a couple who have never had a child. Secondary infertility is failure to conceive following a previous pregnancy. Infertility may be caused by infection in the man or woman, but often there is no obvious underlying cause." Reduced fertility may be expressed as a reduction in the number of live births, reduced odds of conception, or increased time to pregnancy (Bellinger, 2005). One in six couples in the general population has trouble conceiving, with males and females equally responsible for infertility (Sikka and Wang, 2008). Adverse developmental effects may include death of the conceptus (embryo/fetus) or neonate, structural abnormalities, growth retardation (e.g., low birth weight), and functional deficits (e.g., in behavior, immune competence, ability to reproduce).

Reproductive hazards in the workplace have been investigated over the past several decades using workplace experience and epidemiology studies, as well as studies

in laboratory animals. The complexity of the male and female reproductive systems renders this work challenging. Completion of the mammalian developmental cycle is dependent upon the following functions: gametogenesis (production of male and female germ cells); libido; transport of the germ cells to facilitate fertilization; transport, formation, and cleavage of the zygote; implantation of the embryo in the uterus; formation of a functional placenta; embryogenesis and organogenesis; fetal development and maturation; delivery, lactation, and maternal care; postnatal survival and adjustment of the neonate; growth and maturation; and sexual maturation (Johnson, 1986). The cycle then begins again with gametogenesis in the offspring. Each of these stages can potentially be disrupted by specific toxicants in humans as well as laboratory animals. Physical agents and toxicants may adversely affect various morphologic structures of the reproductive tract, as well as the hormonal balance required to maintain reproductive homeostasis. In addition, exposure of women to reproductive hazards may not only affect reproductive well-being, but also development of the conceptus if pregnancy occurs; in this circumstance exposure to toxicants may impact two individuals, rather than one.

Interpretation of data from exposure to hazardous chemicals and physical factors in the workplace may be confounded by a number of factors, including age and ethnicity, and lifestyle factors such as smoking, diet, alcohol and recreational drug use, stress, noise, and work shifts. It is often difficult to ascertain the dose/exposure. In an occupational setting, exposure levels are generally higher and more closely monitored than for environmental exposure, so individual exposure can be more reliably estimated (Schrag and Dixon, 1985). However, this is still often a difficult process, rendered more

complex by the fact that workers may be exposed to more than one putative toxicant, making it difficult to ascribe reproductive effects to a single physical agent or chemical. The nature and magnitude of reproductive toxicity are often dependent on the exposure levels, yet these are difficult to assess in an occupational setting. Although studies in laboratory animals have the ability to closely control and monitor exposure, they are often conducted at exposures in excess of those encountered in an occupational setting and must therefore be interpreted in that context. In female reproductive and developmental toxicity, maternal age may be a confounding factor in the evaluation of cumulative exposure to an agent such as ionizing radiation, since older women would be expected to have higher cumulative exposure than younger women (Whelan, 1997). Paternal exposure may contribute to developmental toxicity, and it may be difficult to separate maternal from paternal influences.

Often only limited information on potential human reproductive effects exists, and it may then be necessary to rely on data from laboratory animal species to inform risk assessment. Many examples exist in the scientific literature of chemicals that induce reproductive and/or developmental toxicity in humans and in one or more laboratory animal species, and the predictive value of laboratory animals has proven to be useful in the safety assessment. In most cases, more data exist in laboratory animals than in humans. Important questions related to laboratory animal studies include, how well do laboratory species predict human reproductive and developmental toxicity for a given physical or chemical agent, and, are relevant end points available in animal models? Possible sources of interspecies differences include genetic variability, metabolism, intracellular pathways of toxicity, membrane biochemistry and receptors, pharmacokinetics, and specific organ function (Working, 1988). It is important to have an understanding of these differences and recognize potential limitations in species extrapolation. In case of male reproductive toxicity, many of the same end points can be employed in humans and research animals, including measurements of sperm count and concentration, motility, and chromosome morphology (Wyrobek et al., 1983). Conversely, the number of sperm per ejaculate in humans is much less than that of laboratory species—while this means greater fertility for the laboratory species, it also renders them relatively insensitive indicators of human reproductive risk (Working, 1988). With regard to developmental toxicity, the following pre- and postnatal considerations are important in evaluating laboratory animal predictivity: (1) divergent differentiation of structure, function, and physiology across species; (2) lack of understanding of species differences in functional ontogeny; and (3) lack of common end points and milestones across species (Morford et al., 2004). It is important to keep in mind that developmental effects do not occur at the same chronological age across species; structural and functional damage

demonstrates stage specificity that is dependent on developmental age.

Despite these potential limitations, human occupational and environmental experience, epidemiology studies, and often many laboratory animal studies with a given toxicant have identified physical and chemical reproductive issues, resulting in the development of health and safety regulations and guidelines designed to protect workers from reproductive hazards. The following sections describe the effects of known occupational and/or environmental toxicants on male and female reproduction, as well as on offspring development. While the agents and chemicals discussed do not comprise a comprehensive list, they are well-known examples of reproductive toxicants that may be encountered in an occupational setting. A given physical or chemical agent may appear in more than one section, highlighting the potential of some toxicants to adversely affect male and female reproduction and development. Descriptions of the occupational uses and potential environmental routes of exposure are given in the first section in which the chemical appears.

ENDOCRINE DISRUPTION

Over the past two decades, scientific and public attention has been drawn to the public health impact of chemicals known to modulate the action of hormones. These chemicals are referred to as endocrine disruptors and defined as: "... an exogenous agent that interferes with the production, release, transport, metabolism, binding, action, or elimination of natural hormones responsible for the maintenance of homeostasis and the regulation of developmental processes." (Kavlock et al., 1996) Reports of male reproductive tract issues have increased over the last several decades, including increased risks of testicular cancer, and congenital anomalies such as cryptorchidism and hypospadias, and declining sperm production (Oliva et al., 2001). Skakkebæk et al. (2001) have suggested that the rapid increase of reproductive disorders is due to environmental or lifestyle factors, rather than genomic structural defects. These effects have been linked to the widespread use of endocrine active chemicals. One of the lines of evidence creating this link is that the male reproductive issues of current concern in humans, with the exception of testicular cancer, can be experimentally produced in animals by pre- and perinatal exposure to chemicals known to target the endocrine system (Skakkebæk et al., 2001). Initial concerns involved chemicals that mimic estrogen or are antiestrogens; more recently chemicals that are androgens or antiandrogens, and those that can affect thyroid function, have been investigated. The Scientific Consensus Report from the International Programme on Chemical Safety (IPCS, 2002) states the following major areas of concern surrounding endocrine disrupting chemicals:

(1) adverse effects in certain wildlife, fish, and ecosystems; (2) increased incidence of certain endocrine-related human diseases; and (3) endocrine disruption resulting from an exposure to certain environmental chemicals observed in laboratory animal experiments. Wildlife effects to which this report refers include eggshell thinning and altered gonadal development with severe population decline in birds of prey exposed to the pesticide dichlorodiphenyltrichloroethane (DDT), altered reproductive development of fish exposed to pulp and paper mill effluents, and impaired reproductive and immune function with population decline of Baltic seals exposed to the DDT metabolite DDE (IPCS, 2002). Although adverse health consequences were initially identified in environmentally exposed wildlife and domestic animal species with relatively high exposures to organochlorine compounds (Kavlock et al., 1996), recent attention has turned to reports in humans of declining sperm counts; increased incidence of hypospadias, cryptorchidism, and testicular cancer; altered sex ratios; and increased breast cancer incidence. Chemicals that target the endocrine system are capable of inducing adverse effects on adult reproductive function; however, the developing organism can be particularly vulnerable due to the importance of hormones in directing differentiation in many tissues and the enhanced potential for changes to be irreversible (Dyer, 2007). Developmental effects associated with these chemicals include congenital abnormalities such as hypospadias and cryptorchidism, testicular cancer, reduced semen quality, and neurobehavioral alterations (Barlow et al., 1999).

Organochlorine chemicals, including internationally banned polychlorinated biphenyls (PCBs) and the pesticides DDT and its metabolites, and dieldrin, were considered to act as estrogens and therefore were postulated to induce or promote breast cancer (Stockholm Convention, 2001). Although reviews of the literature have concluded that the existing data do not support a causal relationship between organochlorine exposure and breast cancer, they also do not provide sufficient information to refute the hypothesis (Barlow et al., 1999). Hoyer et al. (1998) reported results from a 17-year retrospective study that showed an increase in breast cancer with dieldrin, but not with PCBs or total DDT. Estrogenic compounds have also been shown to impact the male reproductive function. Chlordanone, a pesticide with estrogenic activity, has been reported to decrease sperm count and sperm motility in exposed workers (Sheiner et al., 2003; Jensen et al., 2006). Endocrine toxicants/disruptors that act via hormone receptors typically have a much lower binding affinity for hormone receptors compared to endogenous ligands and therefore less biologic activity; however, potency could be increased by factors such as metabolic persistence and serum protein binding affinities (Barlow et al., 1999).

Vinclozolin and its metabolites are examples of antiandrogenic endocrine toxicants. Vinclozolin is used

commercially as a fungicide for fruits, vegetables, ornamental plants, and vines. It is formulated as a dry flowable and extruded granular material and is applied using various techniques such as aerial application, dip treatment, and use of thermal foggers. Experiments in laboratory animals have demonstrated that *in utero* exposure of male rats at a key stage of development alters testis development and impairs adult spermatogenic capacity and reproduction. Cowin et al. (2010) established that these adverse effects, including reductions in anogenital distance, increased testicular germ cell apoptosis, reduction in the number of elongated spermatids, and postpubertal prostatitis, are hormonally regulated via antagonism of the androgen receptor and are reversed by a high dose of testosterone administered at the time of puberty. Anway and Skinner (2006) have additionally provided evidence that vinclozolin may act transiently at the time of embryonic sex determination via an epigenetic mechanism to promote a spermatogenic cell defect and subfertility in males. According to the U.S. Environmental Protection Agency (EPA), antiandrogenic effects would be expected in humans since the androgen receptor is conserved across species (U.S. EPA, 2000a). However, human consequences of vinclozolin exposure are unknown.

Research on chemicals considered to be endocrine disruptors has led to the ban or restriction of some commercially available compounds such as the pesticides DDT and methoxychlor (MXC) and the plasticizer bisphenol A (BPA). While the subject of endocrine disruption still tends to be controversial, one idea for which there is universal agreement is that further research is required to understand its potential causes and consequences, and how the risk can be minimized for humans and animals. In many instances the functional effects of low exposure are not clear and do not provide sufficient evidence as to the possible effect on the reproductive system. Trends in the incidence of adverse effects attributed to targeting of the endocrine system, such as cryptorchidism and hypospadias, as well as potential declines in semen production and quality, do not appear to be consistent and tend to demonstrate geographical variation (Barlow et al., 1999). One area that requires better understanding is the potential consequences of low levels of exposure to synthetic endocrinologically active compounds, compared to those known to occur naturally (Safe, 2000). Also, further study is required to evaluate complex endocrine alterations induced by mixtures of chemicals. Evidence from rat studies suggests that low dose mixtures of chemicals that alter endocrine activity may have adverse effects on the male reproductive system, whereas low doses of the agents administered singly do not (Kortenkamp, 2008). The potential interaction of lifestyle factors such as diet, physical activity, and obesity with endocrine disruption, as well as disease states such as diabetes, all merit additional investigation.

MALE REPRODUCTIVE SYSTEM

The male reproductive system comprises many different cell types and is under multilevel hormonal control and autonomic nervous system input. The complexity of the structural and functional aspects provides a large number of targets for toxicants, and indeed, a substantial number of chemically diverse compounds are known to affect the male reproductive system. Specific toxicants are known to selectively target structural and/or regulatory components of the male reproductive system.

Male germ cells are produced in the testes within the seminiferous tubules. These are long, convoluted tubules lined by epithelial cells that contain differentiating populations of germ cells, from the most immature form known as spermatogonia, through increasing stages of maturation of cells known as spermatocytes and spermatids. Spermatogonia are considered to be the stem cells of the seminiferous tubules. A certain proportion of spermatogonia undergo a series of mitotic divisions to increase in number. They then move into meiotic prophase and proceed through various stages of spermatocyte maturation while becoming increasingly larger and undergoing DNA replication in preparation for meiosis. Two meiotic divisions then occur to produce haploid spermatids in preparation for fusion with the haploid female germ cell, the oocyte. Further maturation results in elongated spermatozoa, which are eventually released into the seminiferous tubule lumen (the process of spermiation) for transport to the epididymis, where final differentiation into mature sperm cells occurs (Foster and Gray, 2008). The functional morphology and actions of the sperm can also be affected by a reproductive toxicant. Motility is required for fertilization, and the energy needed is produced through specialized metabolic pathways that operate within the sperm. Agents such as mercury and lead may have a combined effect on both the dynamics of the sperm cell membrane and the epididymis.

Sperm complete their maturation in the epididymis, and the secretory and absorptive functions of the epididymal epithelium are required to maintain viable sperm (Harbison, 1998). Mature sperm must undergo a process known as capacitation following release from the epididymis and once within the oviduct of the female. This process is necessary for successful fertilization: the sperm acquires the ability to bind to the oocyte and undergo the acrosome reaction, which is a calcium-dependent process that occurs as a consequence of the interaction of capacitated spermatozoa with receptors on the zona pellucida of the oocyte. Acrosomal enzymes are thought to facilitate this process (Perreault, 1997). Interference with capacitation or the acrosomal reaction by xenobiotics can potentially have deleterious effects on fertility.

The cycle in which immature germ cells become mature sperm capable of fertilizing the female oocyte is known as the spermatogenic cycle; duration is species dependent,

requiring approximately 74 days for completion in humans and 60 days in rats (Johnson et al., 1997). Cells of these various maturational stages can be selectively targeted by the reproductive toxicants. A large functional reserve of male germ cells exists in various mammalian species, and the size of this reserve pool is species dependent. Millions of cells may be produced daily due to the constant cell turnover; these large numbers may confer an advantage—there may be an increased chance of reversibility for toxic insult to the germ cells.

Additional cell types within the testis are also vulnerable to reproductive toxicants. The Sertoli cells provide nutritional and architectural support to the developing germ cells. They also serve as components of the blood–tubule barrier, which separates blood and interstitial components from the adluminal compartment, comprising Sertoli cell secreted products and germ cells. The blood–tubule barrier is considered to create a specialized environment that is believed to foster development of spermatocytes and spermatids (Richburg and Boekelheide, 1997). Modifications of the blood–tubule barrier by toxicants can lead to exposure of developing germ cells and selective destruction. Leydig cells within the testis produce testosterone, the primary hormone responsible for differentiation and development of the male reproductive tract, masculinization of the male at puberty, sperm production, secondary sex characteristics, and sexual behavior (Kelce, 1997). Chemicals that affect testosterone production can act directly on the Leydig cell or indirectly by disruption of the hypothalamic–pituitary–gonadal axis (H-P-G), which exerts hormonal control on testosterone production via regulatory feedback systems.

Testicular function is closely regulated by a series of closed-loop feedback systems involving the central nervous system (CNS), hypothalamus, pituitary, and testicular and germinal cell compartments (Sokol, 1997). Hormones important to this regulatory system, known as the H-P-G axis, include gonadotropin releasing hormone (GnRH) from the hypothalamus, which stimulates the release of the pituitary gonadotropins follicle stimulating hormone (FSH) and luteinizing hormone (LH). FSH and LH stimulate gonadal steroid secretion (testosterone and estrogen) for the maturation and maintenance of spermatogenesis.

Reproductive toxicants may also affect the transport and maturation of the sperm in the epididymis, transport of sperm in the female oviduct for the purpose of fertilization of the oocyte, and accessory glands such as the prostate and seminal vesicles, which provide secretions necessary for the survival and transport of sperm. In addition to the effects on reproductive system structure and function, exposure of males to specific mutagenic reproductive toxicants can result in embryonic death through a dominant lethal effect. This involves a genetic lesion of the germ cell that does not impair fertilization of the oocyte but is lethal to the resulting embryo, causing death before or soon after implantation.

(Henck, 1997). Some chemicals require metabolic activation to produce an adverse effect. The testes have sufficient enzymatic capacity to produce harmful concentrations of some metabolites. Metabolism of *n*-hexane, acrylamide, 1,2-dibromo-3-chloropropane (DBCP), glycol ethers, and phthalates in the testes appears to contribute to their toxicity (Harbison, 1998).

Physical Agents

Radiation

The testicular tissue is highly sensitive to ionizing radiation. Radiation doses in the range of 0.11–0.15 Gy (=joule/kilogram) may temporarily decrease sperm count, while 2–5 Gy may result in long-lasting or permanent azoospermia and sterility (Sheiner et al., 2003; Jensen et al., 2006). At higher doses (>15 Gy), the Leydig cells may be affected; in addition, whole body irradiation can damage the H-P-G axis, affecting the reproductive capability (Sikka and Wang, 2008). The energy associated with X-rays and other types of radiation can cause chemical rearrangement of DNA, which may affect its ability to duplicate and direct cellular events. Some of the early stages of cell division are most susceptible to breakage of the DNA strands caused by gamma irradiation. The observable outcome of these types of breakage is malformation in the chromosomes of the germ cells. Some of the somatic cells found in the testis may be damaged in a similar manner and may be sloughed from the tubules in which spermatogenesis occurs. In this case, the result is the collection of clumps of cellular debris in the duct system that carries the sperm.

In animals, paternal exposure to gamma radiation produces an alteration in type B spermatogonia, expressed in progeny as a proliferation disadvantage in chimera assays (Warner et al., 1991). Direct X-irradiation of the testes has been shown to retard testicular growth and reduce spermatogenesis in male rats (Jensh and Brent, 1988). Breeding activity and the percentage of positive inseminations were also slightly reduced, although a significant percentage of male offspring were fertile. Head or thorax irradiation did not adversely affect testicular growth or spermatogenesis, indicating that adverse reproductive effects of X-irradiation on the testes and adverse reproductive outcome may not be mediated through the effects of X-irradiation on other parts of the body.

The sensitivity to DNA damage induced by radiation differs during different stages of spermatogenesis. Assessment of double-stranded DNA damage in various cells suggests that spermatogonia and preleptotene spermatocytes were more sensitive to gamma irradiation than other cell types. However, all did show an increase in double-stranded DNA damage. This type of damage can affect postfertilization processes as

well. X-irradiation of sperm cells produced a large number of DNA lesions in fertilized eggs at the first cleavage metaphase. The frequency of chromosome aberrations observed in eggs fertilized with sperm recovered from X-irradiated early spermatid to late spermatocyte stages was higher than in the eggs fertilized with irradiated sperm recovered from spermatozoa to late spermatid stage. Thus lesions produced in spermiogenic cells were effectively repaired in the cytoplasm of the fertilized eggs (Matsuda et al., 1989).

Recently, concerns have been raised about potential effects of radio frequency electromagnetic radiation (RFEMR)—the type of radiation employed in cell phone communication. In response to an abstract indicating that regular mobile phone use can negatively impact human semen quality, Aitken et al. (2005) exposed mice to RFEMR employed by electrical devices such as cell phones and wireless devices, such as speakers and baby monitors. Following exposure for 7 days, DNA damage to caudal epididymal spermatozoa was assessed. No adverse effects were observed on sperm number, morphology, or vitality; however, genotoxic effects on spermatozoa were observed, indicating that this is an area of study that requires further investigation.

Heat

Production of sperm requires a temperature 3–4 °C lower than normal body temperature. Decreased sperm count due to excessive heat has been reported for pathologies such as varicocele and cryptorchidism, as well as fever, in patients restricted to wheelchairs, in professional truck drivers, and in workers in the ceramics industry (Sheiner et al., 2003). Although sedentary work position is associated with increased scrotal temperature, it has not been associated with decreased sperm count (Jensen et al., 2006).

Solvents

Solvents are used to dissolve, dilute, and disperse materials that are insoluble in water; they are used as degreasers, are constituents of paints, varnishes, lacquers, inks, aerosol spray products, dyes, adhesives, fuels, and fuel additives, and are intermediates in chemical syntheses (Bruckner et al., 2008). Their small molecular size and lack of charge make inhalation a major route of exposure, and they are readily absorbed across the lungs, gastrointestinal tract, and skin. Virtually all solvents can cause adverse effects, including reproductive toxicity, as described subsequently.

Bromopropanes 2-Bromopropane (2-BP) is a solvent that was intended to be a replacement for ozone-depleting chlorofluorocarbons (CFC). Exposure of electronics factory workers in Korea via inhalation to 2-BP in a cleaning solution resulted in hematopoietic disorders in men and women, as

well as azoospermia or oligospermia, and reduced sperm motility (Park et al., 1997). Reduced sperm production also occurred in rats exposed to 2-BP by inhalation for 9 weeks, as well as decreases in the weight of male reproductive organs, numbers of epididymal sperm, percent motile sperm, and the incidence of sperm with normal shape (Ichihara et al., 1996). Severe atrophy of the seminiferous tubules was observed in these rats, with reductions in all types of germ cells; Sertoli cells were unaffected. Administration of high subcutaneous doses of 2-BP to rats for 1–5 days resulted in reductions in stage 1 spermatogonia after one injection and reductions in spermatogonia at other developmental stages after multiple injections (Omura et al., 1999).

Based on observations of toxicity in Korean electronics factory workers, an alternative to 2-BP was sought to replace CFC. The selected alternative was 1-bromopropane (1-BP), which was thought to be less toxic due to its reduced mutagenic potential (Ichihara, 2005). However, 1-BP was found to be a potent neurotoxicant in laboratory animals and subsequently, in humans. Studies in rats also indicate that 1-BP is a reproductive toxicant. Rats exposed to 1-BP by inhalation for 12 weeks demonstrated reduced weights of epididymides, prostate, and seminal vesicles; reduced epididymal sperm count and motility; increased tailless sperm and sperm with immature head shape; retained, elongated spermatids; and reduced plasma testosterone (Ichihara et al., 2000). The authors concluded that the primary effect of 1-BP on reproduction in rats was to induce failure of spermiation. It is of interest that this primary effect differs from that of the structurally similar compound 2-BP, which targets spermatogonia; the reason for this difference in targets is unknown. To date there have been no reports of human reproductive toxicity with 1-BP, so the human impact remains uncharacterized.

Glycol Ethers Glycol ethers are used as solvents for surface coatings (latex paints and varnishes), paint thinners, strippers, inks, metal cleaning products, liquid soaps, and household cleaners and are also used as jet fuel anti-icing additives and in semiconductor fabrication. Some glycol ethers and their oxidative metabolites are known to induce reproductive, developmental, hematologic, and immunologic toxicity, and a few have tested positive in rodent cancer bioassays (Bruckner et al., 2008). There appears to be an inverse relationship between the length of the alkyl chain and reproductive and developmental toxicity in monoalkyl glycol ethers and their metabolites; low molecular weight compounds such as 2-methoxyethanol (2-ME) and 2-ethoxyethanol (2-EE) are considered more toxic than ethylene glycol ethers, which are more toxic than propylene glycol ethers (U.S. Environmental Protection Agency, 1984). For this reason, industrial use has shifted away from low molecular weight compounds such as 2-ethylene glycol monomethyl ether (EGME) and 2-ethylene glycol monoethyl ether (EGEE) toward those with more favorable toxicity profiles such as ethylene, diethylene,

and triethylene glycol butyl ethers and propylene glycol monomethyl ether (Bruckner et al., 2008). Human occupational exposure can occur by inhalation, ingestion, and dermal absorption; glycol ethers are rapidly absorbed by all routes of exposure (Correa et al., 1996).

Male reproductive toxicity has been associated with glycol ethers in humans and laboratory animals. Glycol ethers target the spermatocytes, resulting in reduced sperm counts and potential infertility. Painters exposed to 2-EE and 2-ME demonstrated a reversible spermatotoxicity characterized by oligospermia and azoospermia, and reduced numbers of sperm/ejaculate were identified in foundry workers exposed to glycol ethers (Bruckner et al., 2008). Veulemans et al. (1993) found an association between impaired fertility and the detection of 2-ethoxyacetic acid (a metabolite of 2-EE and considered a biomarker of glycol ether exposure) in urine of male fertility clinic patients diagnosed as infertile or subfertile. There was no correlation with sperm quality measures, which the authors postulated might be due to a latent period between the exposure and observed effects on fertility.

In laboratory animals, glycol ethers appear to target spermatocytes, the product of the first meiotic division of spermatogenesis. Exposure of male rats to EGME for 2 or 4 weeks resulted in severe degenerative changes in the testes, including atrophy of seminiferous tubules and formation of multinucleated giant cells, abnormal sperm head morphology, degeneration of pachytene spermatocytes, and reduced numbers of germ cells (Watanabe et al., 2000). In a continuous breeding study with EGME in mice, Lamb et al. (1984) identified decreased sperm motility and count, an increased percent of abnormal sperm, and infertility. Creasy and Foster (1984) determined that primary spermatocytes undergoing pachytene development constituted the initial and major site of morphological damage in rats given oral doses of EGME or EGEE and that within this population, differential sensitivity was demonstrated depending on the precise stage of meiotic maturation. They also determined that spermatocytes in later stages of cell division, late-stage spermatids, and spermatogonia could be affected, but only if the dose was increased and exposure prolonged.

Trichloroethylene and Perchloroethylene Trichloroethylene (TCE) and perchloroethylene (PERC) are commercially important solvents used primarily in metal degreasing, as paint and stain removers and chemical intermediates, and in the textile cleaning industry (Forkert et al., 2003; Carney et al., 2006). These solvents are volatile chemicals, and the highest human exposures occur via inhalation. From an environmental perspective, ingestion is also an important route of human exposure, as TCE and its metabolic products, including PERC, are known to be common water supply contaminants (World Health Organization, 2005).

Both TCE and PERC are well absorbed from the lungs and gastrointestinal tract and metabolized primarily by hepatic cytochrome P450 2E1 (Bruckner et al., 2008). They share a common major metabolite, trichloroacetate. Studies in laboratory animals and human experience with TCE have led to the conclusion that toxicity is attributable to metabolites, which include TCE oxide, chloral, and dichloroacetyl chloride; chloral is metabolized to chloral hydrate to form trichloroethanol (TCOH) and trichloroacetic acid (TCA). The latter two metabolites are used as biomarkers of human exposure (Forkert et al., 2002). Eight mechanics exposed to TCE occupationally and diagnosed with clinical infertility were found to have TCE and metabolites in seminal fluid but not in urine, suggesting a potential association between TCE and impaired fertility (Forkert et al., 2003). Trichloroethylene metabolites, chloral and TCOH, were also identified in the seminal fluid of mice exposed to TCE by inhalation, indicating similar metabolic disposition to that of humans. Cytochrome P450 2E1 was found to be localized in the epididymal epithelium and testicular Leydig cells in mice, with higher levels in the former. This corresponded to higher levels of chloral formed in microsomal incubations in the epididymis compared to the testis (Forkert et al., 2002). After 4 weeks of TCE exposure, structural damage, manifested as sloughing of epithelial cells, occurred in the epididymal epithelium of mice, but no morphologic changes were apparent in the testis, indicating that TCE metabolism in the epididymis resulted in adverse reproductive effects (Forkert et al., 2003).

Other Industrial Chemicals

Acrylamide Acrylamide is a white crystalline powder used in the production of polyacrylamide polymer, gels, and binding agents; water-compatible polyacrylamides are used in water treatment, mineral processing, pulp and paper production, and in synthesis or compounding of dye materials, soil conditioners, and cosmetics. Human exposure can occur from foods (formed during frying and baking of starch-rich foods), smoking, drinking water, and from dermal contact with products that contain residual acrylamide (Centers for Disease Control, 2009). The primary adverse effect observed from a chronic occupational exposure to acrylamide is neurotoxicity. However, there are no confirmed reports in humans of acrylamide-induced testicular damage. Animal studies indicate a need for caution, in that they have identified adverse male reproductive effects, including germinal cell injury and dominant lethality. Adult and prepubertal mice demonstrated transient testicular damage after oral dosing with acrylamide (Sakamoto et al., 1988). The transient nature of the testicular effects of acute acrylamide treatment may explain the transient fertility reduction and increased pre- and postimplantation loss observed when acrylamide-treated male rats were mated with untreated females (Sublet et al.,

1989). The reproductive effects of chronic, low level exposure to acrylamide have not been assessed in animal studies. Clearly, such studies might have more relevance to occupational situations in which humans are exposed repeatedly to low levels of acrylamide (Harbison, 1998).

Binding of acrylamide to sperm DNA and to the unique sperm cell protein protamine has been observed in mice, raising questions of the potential for genotoxicity (Sega et al., 1989). Binding of acrylamide to DNA was found to be greatest in late spermatid to early spermatozoal stages and declined in later stages of spermatogenesis. *In vivo* experiments with several strains of mice suggested that acrylamide has the potential to induce gene mutations; glycidamide, the epoxide metabolite of acrylamide, is also mutagenic (Sega et al., 1989). Acrylamide is genotoxic to germ cells, affecting all stages of development with the exception of spermatogonia, and a positive dominant lethal response has been demonstrated in multiple studies conducted by the oral, parenteral, and dermal routes of administration (Dearfield et al., 1995).

Boric Acid Boric acid is a male reproductive toxicant that specifically affects the process of spermiation, which is the interaction of Sertoli cells with elongated spermatids, the most mature testicular form of germ cells, and results in their release into the lumen of seminiferous tubules (Chapin and Ku, 1994). The element boron does not exist naturally but rather exists in combination with oxygen as, for example, boric acid or borate salts such as borax (Moore, 1997). Water-soluble forms of boron are widely distributed in surface and ground waters from natural sources and industrial contamination, and borates are known to be essential micronutrients for plants, thus introducing boron into the food supply (Murray, 1995; Moore, 1997). Industrial applications of boric acid and borax include the manufacture of glass products such as glass fiber insulation, as well as enamels, ceramics, fire retardants, insecticides, fertilizers, laundry bleaches, wood preservatives, cosmetics and personal care products, and dietary supplements. Human exposure to boron can occur by consumption of contaminated water and bottled drinking water, dietary consumption of crops and other foodstuffs, and inhalation of boron compounds during mining, manufacturing, and other industrial processing (Moore, 1997).

Few reports assessing the effects of boron on reproduction exist. One small report of workers exposed to boric acid suggested that it produced adverse effects on sperm parameters and fertility, while a larger study of borate-exposed miners revealed no adverse paternal effects from occupational exposure. Thus, data are considered insufficient to judge whether boron is a male reproductive toxicant in humans (Moore, 1997). However, studies in laboratory animals have demonstrated male reproductive toxicity. High dose boric acid has been shown to produce testicular

lesions in adult rats, mice, and dogs. The specific effect has been described as inhibition of spermatiation, followed by testicular atrophy. In rats, Ku et al. (1993) determined that the effect on spermatiation could be separated from testicular atrophy based on the dose, with the effect on spermatiation occurring first and at lower doses, and indicating that separate mechanisms may be operating. While effects on spermatiation have been shown to be reversible in rats treated with boric acid, atrophy was not, and there was no return of spermatogenesis, despite the presence of a normal-sized population of dividing spermatogonia (Chapin and Ku, 1994).

Phthalates Phthalates (phthalate esters) are plasticizers added to plastics to impart flexibility and resilience or as solubilizing and stabilizing agents. They are found in a variety of products, including adhesives, detergents, lubricating oils, vinyl floors, food wraps, personal-care products, medical products, and toys. They are not chemically bound to the plastics to which they are added and can therefore be readily released into the environment (Kavlock et al., 2002). Human exposure can occur through ingestion, inhalation, dermal contact, and by intravenous or parenteral routes (medical devices and materials containing phthalates), and human milk can be a source of exposure for infants (Centers for Disease Control, 2009).

There are numerous forms of phthalates, and many of these forms have been evaluated for toxicologic potential. Male reproductive toxicity is the primary effect observed in laboratory animals. Phthalates are considered to be endocrine disruptors and have been studied extensively in laboratory animals. Although several forms were initially proposed to be estrogenic, based on *in vitro* data, they were found to not have estrogen activity in *in vivo* assays. Rather, the male reproductive toxicity attributed to the phthalates is similar to that induced by antiandrogenic compounds, although not identical to known androgen receptor antagonists such as flutamide (Mylchreest et al., 1999; Wolf et al., 1999). In a multigenerational study in which rats were exposed to diethylhexyl phthalate (DEHP) and its primary metabolite monoethylhexyl phthalate (MEHP), Parks et al. (2000) determined that exposure during the critical period of male differentiation resulted in reduced testosterone, decreased anogenital distance, and Leydig cell hyperplasia. *In vitro*, DEHP and MEHP displayed no affinity for the androgen receptor at concentrations up to 10 µM, and *in vivo*, female offspring in the same study were unaffected by prenatal exposure, indicating that perturbation of estrogenic activity was not a mechanism of action. These authors concluded that inhibition of testicular testosterone during sexual differentiation is a likely cause of DEHP- and MEHP-induced malformations in androgen-dependent tissues of males. In rats, di-*n*-butyl phthalate (DBP) is toxic to the Sertoli cells of the testis and impairs spermatogenesis by inducing widespread exfoliation of the seminiferous epithelium

(Mylchreest et al., 1999). Neonatal and pubertal rats are more sensitive to phthalate-induced testicular toxicity than are adult rats (Dostal et al., 1988).

In a review of DBP, reduced anogenital distance and increased incidence of undescended testes were reported to occur in offspring of treated rats; adult rats treated subchronically with oral doses demonstrated testicular lesions, epididymal hypospermia, and decreased sperm motility and concentration (Kavlock et al., 2002). Wolf et al. (1999) conducted a comparative developmental toxicity study in rats of several chemicals known or suspected to be antiandrogenic, which included DEHP and DBP. Reduced anogenital distance was observed, and in addition, hypospadias, cryptorchidism, ventral prostate agenesis, and testicular and/or epididymal atrophy or agenesis also occurred with each, although the effects were considerably greater with DEHP.

The relevance of these findings to human males has yet to be determined; at present human health effects from low environmental exposures of phthalates is unknown (Centers for Disease Control, 2009). A National Toxicology Program (NTP) panel expert panel reviewed human studies of phthalate exposure and found that small numbers of subjects and possible confounding factors provided insufficient evidence that DEHP exposure during pregnancy, childhood, or adulthood is causing harm (Kaiser, 2005).

Metals

Cadmium The occurrence of cadmium in the environment is widespread—it occurs naturally in the environment at low levels but can be present at higher levels due to industrial emissions from non-ferrous mining and metal refining, smelting, battery manufacture, and electroplating operations. It is found in the food chain, surface waters, soil, and ambient air and is also found in nickel/cadmium batteries, pigments (cadmium yellow), and plastics (Dyer, 2007; Massányi et al., 2007; World Health Organization, 2012). Exposure to cadmium may occur concurrently with lead and other heavy metals. Tobacco smoke is one of the most common sources of cadmium exposure because the tobacco plant concentrates cadmium (Klaassen, 2006). Cadmium absorbed through smoking has relatively high bioavailability. It has been postulated that negative effects of smoking on semen quality are the result of the observed trend for cadmium in tobacco smoke to accumulate in the genital tract of smokers (Benoff et al., 2000).

In the environment, exposure to high concentrations of airborne particles that may contain cadmium have been associated with decreased semen quality, particularly in metal workers compared to other occupations; however, dose-response relationships and/or causal mechanisms remain to be defined (Benoff et al., 2000). Cadmium is classified as a human carcinogen, with the most convincing association to lung cancer; it is also a multi-tissue animal

carcinogen (Waalkes, 2003). An increased risk for human prostate cancer has also been reported; however, given the complex etiology of this disease, it is considered difficult to ascribe the cause in a small proportion of cases to a single factor (Waalkes, 2003). In addition, cohort studies in cadmium-exposed workers have not confirmed this association (Thompson and Bannigan, 2008). It should be noted, however, that the human prostatic epithelium could potentially be a target of the oncogenic effects of cadmium, based on *in vitro* evidence that human prostate epithelial cells can be malignantly transformed by cadmium (Nakamura et al., 2002). Cadmium has been shown to induce testicular tumors and preneoplastic lesions in rats at doses lower than those required to induce testicular toxicity. However, high doses of cadmium have been shown to result in substantial reduction in circulating levels of testosterone and resultant atrophy of the testis and prostate (Waalkes et al., 1997), which would likely counter a proliferative stimulus from cadmium (Waalkes, 2003).

Cadmium accumulates preferentially in reproductive organs and has been shown to adversely affect a number of cell types within the male reproductive system. Adverse effects appear to depend on the dose, route of administration, and duration of exposure. In laboratory animals, cadmium has been reported to induce irreversible necrosis of the testicular tissue, decreased spermatogenesis, testicular hemorrhage and edema, and endothelial cell damage in testicular blood vessels following oral or parenteral administration of single high doses (Thompson and Bannigan, 2008). Potential mechanisms of action include (1) indirect insult resulting from vascular disruption and (2) direct injury to spermatogenic cells (Zenick et al., 1982).

Cadmium is considered to be a Sertoli cell toxicant, primarily disrupting the blood–tubule barrier (Richburg and Boekelheide, 1997); the mechanism of action is considered to be through adverse effects on cell adhesion. Disruption of the blood–tubule barrier can result in the reduction in germ cell numbers and potential infertility. Daily subcutaneous administration of high doses of cadmium to rats for 6 weeks resulted in its accumulation in the testes, primarily in the spermatogonia and spermatocytes, with subsequent reduction of these cell types (Aoyagi et al., 2002). A study by Zenick et al. (1982) demonstrated that subchronic administration of more environmentally relevant oral doses (up to 69 parts per million (ppm) in the drinking water for 70–80 days) to rats did not result in testicular toxicity or adverse outcomes to offspring of treated males. Additional studies conducted with chronic low level cadmium administered parenterally have failed to reveal histologic damage, even with a cumulative dose higher than acutely toxic doses, possibly due to the induction of metallothionein synthesis and subsequent cadmium binding on repeated exposure (Zenick et al., 1982).

Cadmium has also been shown to induce benign Leydig cell tumors in rats. Following acute high doses of cadmium, hemorrhagic necrosis of the testis and chronic degeneration with subsequent loss of androgen production are followed by a high incidence of testicular interstitial cell tumors (Waalkes, 2003). Danielsson et al. (1984) found that cadmium accumulates in the interstitial tissues of the testis, supporting potential effects on hormone production by the Leydig cells and/or on blood supply. Loss of androgen production is thought to lead to overstimulation of remnant testicular cells by the LH (Waalkes et al., 1997). Rat testes are extremely sensitive to cadmium-induced tumorigenesis, and the mechanisms by which this occurs are likely of little relevance in humans (Waalkes, 2003).

Lead Although progress has been made in reducing environmental lead concentrations by removing or reducing sources such as leaded gasoline, lead-based paints, lead-soldered cans, and lead plumbing pipes (Goyer, 1996), lead is still considered to be a ubiquitous environmental contaminant (Dyer, 2007). Dietary intake is a common means of human exposure; however, humans are also exposed to lead aerosols occupationally and in the environment. Exposure to lead and cadmium may occur concurrently. Although the primary target of lead-induced toxicity is the CNS, lead is also known to affect the male reproductive system and preferentially accumulates in the reproductive organs. The mechanism of action of lead-induced male reproductive toxicity is not clear, but may involve both direct effects on the reproductive organs and effects on the endocrine control of reproduction. Evidence from an occupational exposure of humans to inorganic lead leading to blood lead concentrations $\geq 40 \mu\text{g}/\text{dl}$ resulted in impaired male reproductive function characterized by reductions in sperm count and increased sperm death, reduced sperm volume, density, and motility, adverse effects on sperm morphology, and decreased secretory function of the prostate and seminal vesicles (Apostoli et al., 1998). The most prevalent effects were on sperm count and concentration. In the environment, exposure to high concentrations of airborne particles that may contain lead have been associated with decreased semen quality, particularly in metal workers compared to other occupations; however, dose-response relationships and/or causal mechanisms remain to be defined (Benoff et al., 2000). High levels of lead in humans have been associated with decreased fertility and a reduced ability to undergo the acrosome reaction (Benoff et al., 2003; Dyer, 2007).

Major risk factors for lead-induced toxicity include age, nutrition, housing and socioeconomic factors, and smoking. Tobacco smoke is considered a major source of airborne environmental lead exposure (Benoff et al., 2000), and blood lead concentrations are reported to be elevated in smokers. Reports indicate that men with marginal semen quality may become infertile by smoking. Inconsistent effects on male

reproduction have been produced in laboratory animal experiments. Certain species and strains of laboratory animals are resistant to lead-induced reproductive toxicity, while others are highly sensitive (Apostoli et al., 1998). In sensitive rat strains, atrophy of the seminiferous tubules; reduced populations of spermatogonia, spermatocytes, and Leydig cells (with decreased testosterone); vacuolization of Sertoli cells; reduced sperm motility; prostate hyperplasia; and infertility have been reported to result from lead exposure. An additional effect reported in mice is reduced implantation resulting from male exposure. The reason for the difference in response among various species and strains has not been fully characterized but is thought to be due to pharmacokinetic differences in lead accumulation in the testes or to differences in function of the blood–tubule barrier (Apostoli et al., 1998).

Lead exposure may result in adverse hormonal effects. A negative effect of increased blood lead concentration on the outcome of *in vitro* fertilization was attributed to altered sperm function. This study reported an increase in spontaneous acrosome loss and a decreased ability to undergo the progesterone-stimulated acrosome reaction (Benoff et al., 2003). The question of whether lead disrupts the H-P-G axis in human males remains unanswered—some studies provide evidence while others do not. Studies in laboratory animals have shown that disruption of the H-P-G axis may actually be a primary mechanism of action for adverse effects on male reproduction. Several molecular targets have been proposed to account for the symptoms of lead poisoning; most of these targets fall into the following two primary categories: proteins that naturally bind calcium or those that bind zinc (Godwin, 2001). Interference with calcium homeostasis may play a role in lead-induced reproductive toxicity and presents a plausible association between lead and hormonal disruption in particular. Calcium has an important role in the regulation of GnRH and sperm function; as a second messenger it facilitates the transfer of extracellular hormone signals to the cell interior. Potential disruption of pulsatile GnRH release may also disrupt the release of FSH and LH (Krsmanović et al., 1992). In addition, calcium is required for sperm motility and for the steps leading to fertilization (Sokol, 1997). Blood lead levels >40 µg/dl were shown to markedly decrease serum and intratesticular testosterone in rats treated for 30 days with lead acetate, resulting in reduced spermatogenesis and impaired fertility (Sokol et al., 1985). In this study, decreased testosterone and gonadal function were associated with reduced FSH but no effect on LH, indicating that normal hormonal feedback mechanisms were impaired, and leading to the conclusion that primary targets of lead toxicity in these rats were the hypothalamus and pituitary. This effect on the H-P-G axis was reversible. McGivern et al. (1991) investigated the hypothesis that lead exposure during development would disrupt H-P-G function in adulthood. They exposed pregnant

female rats to lead acetate from gestation day 14 through parturition, considered a period of rapid differentiation of the H-P-G axis. Male offspring had reduced sperm count, less territorial scent marking and masculine behavior, azoospermia, enlarged prostate, and enlarged volume of the sexually dimorphic nucleus of the preoptic area of the hypothalamus, demonstrating disruption of hormonal feedback regulation.

Pesticides

Exposure to pesticides has been associated with male reproductive toxicity, particularly with regard to high level and/or extended duration industrial and end-use contact. Several recent epidemiology studies have evaluated exposure to a variety of pesticides and, although these studies are typically small, they have identified associations between pesticide exposure and decreased sperm concentration, motility, and morphology. Concomitant exposure to several different pesticides may also present an issue. Swan et al. (2003) measured metabolites of eight current-use, persistent pesticides to serve as potential biomarkers of pesticide exposure and found an association with semen quality in farmers from an area in the United States with high pesticide use relative to farmers from an area with low pesticide use. In contrast, a review conducted by Perry (2008) that evaluated low level occupational and environmental exposure to a variety of pesticides concluded that epidemiologic evidence is thus far equivocal due to the small number of published studies. This review evaluated sperm parameters, DNA damage, and numerical chromosome aberrations in epidemiologic studies of pyrethroids, organophosphates, phenoxyacetic acids, cabamates, organochlorines, and pesticide mixtures. Some pesticides have been definitively associated with male reproductive toxicity, however, and are described subsequently.

1,2-Dibromo-3-chloropropane The identification of infertility due to testicular failure in workers involved in the manufacture of DBCP is considered a sentinel event of major importance in occupational medicine due to a large number of cases of impaired fertility in workers exposed during the manufacturing process (Teitelbaum, 1999). 1,2-Dibromo-3-chloropropane was extensively employed as a nematocide on a global basis beginning in the 1950s. Reports of infertility in male workers engaged in the manufacture of DBCP began to emerge in 1977, leading to an eventual ban by the U.S. EPA in 1979 (ATSDR, 1995). It is still used in other countries, indicating that there is still some risk from industrial exposure. In addition, an exposure can occur from ingesting contaminated drinking water or food or from inhalation exposure to hazardous waste sites with improper disposal (ATSDR, 1995; Teitelbaum, 1999).

Workers exposed to DBCP during its manufacture were azoospermic or mildly to severely oligospermic; there was a positive correlation between duration of the occupational

exposure and the extent of reduction in sperm production (Whorton et al., 1977; Potashnik et al., 1978; Whorton and Milby, 1980). The effects occurred in conjunction with elevated FSH and LH but in the absence of an effect on testosterone (Whorton et al., 1977). Follow-up of these exposed workers, as well as other cohorts exposed to DBCP during manufacturing, revealed a tendency toward reversibility of fertility effects and hormonal alterations in oligospermic men but not in azoospermic men (Whorton and Milby, 1980; Potashnik, 1983). Potashnik (1983) found that reversibility was also inversely related to previous exposure time and was most likely to occur in the presence of normal FSH values. In an evaluation of the largest cohort of DBCP-exposed workers to date, Slutsky et al. (1999) reported adverse reproductive health effects, including infertility, in men from 12 countries primarily exposed through application of DBCP, rather than through manufacturing. Azoospermia and oligospermia were still present in a high percentage of these workers many years after their direct exposure had ceased, suggesting that these conditions were permanent in these men (Slutsky et al., 1999).

1,2-Dibromo-3-chloropropane is also a male reproductive toxicant in a variety of laboratory animal species, which was actually demonstrated prior to the reports of human male infertility (Babich and Davis, 1981; Teitelbaum, 1999). Inhalation exposure of rats, rabbits, guinea pigs, and monkeys, as well as oral administration to rats, resulted in atrophy and degeneration of the testes accompanied by abnormal sperm development, reduced sperm counts, and degeneration of seminiferous tubules; at high oral doses, male rats exhibited severe reduction in both production and mobility of sperm cells (Babich and Davis, 1981). A direct effect on sperm was suggested by a study in which male rats given a single subcutaneous injection of DBCP were observed to be infertile within 2–7 days (Kluwe et al., 1983). These authors suggested that DBCP may cause nearly immediate infertility via a direct effect on post-testicular sperm, and that a possible mechanism of this infertility is inhibition of glucose metabolism in ejaculated sperm. Inhalation exposure of male rats to DBCP resulted in a dominant lethal effect, in that increased resorptions occurred in unexposed females mated to exposed males; this effect tended to reverse following termination of the exposure (Rao et al., 1983).

The metabolic pathways for DBCP following ingestion may involve epihalohydrins, other reactive epoxides, or 2-bromoacrolein as intermediates (World Health Organization, 2003). Of particular interest for reproductive toxicity is epichlorohydrin, which is also known to be a male reproductive toxicant in humans and laboratory animals and has recently been used as an experimental model to evaluate the relationship of impairment of sperm motility to fertility. Fertility in untreated female rats mated with males treated with epichlorohydrin for 19–22 days was found to be impaired due to inhibition of fertilization, rather than a

dominant lethal effect (Toth et al., 1991). Reduced fertility was further correlated with impairment of sperm motility end points. Experimental evidence also suggests that DBCP may impair sperm motility and fertilizing ability, but verification is required (Perreault, 1997).

Ethylene Dibromide Ethylene dibromide (EDB), also known as 1,2-dibromoethane, is a component of some pesticides. It is an alkylating agent and is mutagenic and carcinogenic (Ratcliffe et al., 1987). Occupational exposures have been associated with decreased sperm count, decreased production of seminal fluid, and fewer motile and morphologically normal sperm cells. One study reported reduced fertility, but this has not been reproduced (Jensen et al., 2006).

Related animal data have also shown male reproductive effects in a variety of species. Spermicidal effects, characterized by lysis of the chromatin of elongating spermatids, were evident in both rams and bulls; abnormal sperm were found in the ejaculate of bulls but not in rams (Amir, 1991). Abnormal sperm were not found in the ejaculate of rams and may have been phagocytized in the epididymis, illustrating an apparent species difference in response. Reduced litter size was observed following mating of male rats and mice treated with EDB to untreated females, indicating a potential dominant lethal effect (Ratcliffe et al., 1987). Ethylene dibromide was found to potentiate germ cell dominant lethal mutations induced by ethyl methane sulfonate (EMS), which correlated with glutathione depression. In rodent assays, EDB exposure depressed glutathione levels in the caput and cauda epididymis but not in the testes. Depression of glutathione levels in reproductive tissues correlated with potentiation of EMS-induced dominant lethal mutations and with increased binding of EMS to sperm heads, likely the cause of observed postimplantation fetal deaths (Teaf et al., 1990).

FEMALE REPRODUCTIVE SYSTEM

The female reproductive system consists of multiple anatomic and chemical components and is under strict neuroendocrine control. The large number of anatomical and chemical components provides multiple targets for physical and chemical injury. In the mammalian female reproductive system, all germ cells (ova, oocytes) are produced prior to birth. Approximately 400,000 oocytes and their surrounding primary follicles are produced by the time of birth in each human ovary (Foster and Gray, 2008). If damage to the germ cells occurs during embryo–fetal development, replacement is not possible, resulting in impaired fertility or infertility. This adverse effect is often not recognized until adulthood, when the woman tries to conceive and is unsuccessful. Many ovarian follicles undergo atresia after

birth through the normal process of the menstrual cycle, so numbers are constantly decreasing, until they are exhausted after approximately three decades, and menopause ensues. If the oocyte population is diminished, these events may be accelerated, resulting in premature menopause (reproductive senescence). Alterations in the age of sexual maturation or reproductive senescence can potentially alter the reproductive capacity (Mattison et al., 1983).

The impact of occupational and industrial exposure on the female reproductive system is less well known than for males. One of the main reasons for this lack of data is that it is difficult to identify and analyze reproductive impairment in women. There is little reason to suspect impairment unless the woman has shown evidence of infertility or a prolonged inability to maintain a pregnancy. Germ cell production in a woman is difficult to monitor, and possible indicators, such as amenorrhea (lack of menstruation) or irregular menstruation, occur frequently enough and for such a variety of reasons that linking these and industrial exposure is difficult (Harbison, 1998). Pregnancy failure also occurs spontaneously, and it is therefore difficult to ascertain if the cause is due to maternal or embryonic deficiencies or abnormalities, or to an external environmental influence.

Toxicants are known to affect female reproduction primarily by disruption of the ovarian function through direct effects on the ovary or by interference with the H-P-G axis, which exerts neuroendocrine control over the female reproductive processes. The major functions of the ovary are to produce the female germ cell (oocyte) and to serve as an endocrine organ for the production of female hormones, in particular estrogen and progesterone. During fetal development, oogonia (stem cells for oocytes) proliferate and then enter meiotic cell division. At this time the supportive follicle complex is formed, which consists of the oocyte, granulosa cells, basement membrane, and thecal cells; this is the smallest functional unit of the ovary (Mattison et al., 1983). Beginning at puberty, in a cycle of specific duration depending on species (approximately 28 days for humans, 4 days for rats), ovarian follicles are recruited and selected by FSH (from the anterior pituitary) to grow and attain additional granulosa cell layers, in preparation for ovulation and, ultimately, fertilization. This cycle continues throughout the reproductive life of the female. One of the primary functions of the granulosa cells is to produce the hormone estrogen. The ovarian follicle grows through increasing stages of complexity, from primary to secondary to antral to preovulatory, and these stages can be variously affected by ovarian toxicants (Hoyer, 2005). Destruction of oocytes in small primordial follicles causes infertility since these follicles cannot be replaced, while destruction of more mature growing or antral follicles only temporarily disrupts reproductive function because they can be replaced from the existing pool of primordial follicles (Hoyer, 2005). Chemicals that selectively damage large growing or antral follicles

are known to cause transient, reversible reproductive system dysfunction (Yu et al., 1999). If fertilization occurs, granulosa cells undergo further differentiation, begin to produce the hormone progesterone, which is important in maintaining pregnancy, and ultimately become cells of the placenta. If ovulation does not occur, the ovarian follicle (including the oocyte) regresses through a process known as atresia, which is considered to occur through apoptosis (i.e., programmed cell death). Follicular atresia occurs throughout the reproductive lifetime of the female; since the number of oocytes is predetermined prior to birth the supply is eventually depleted, leading to the ovarian failure of menopause. Because menopause has been linked to a variety of disease states, premature onset induced by toxicants can potentially have a severe impact on women's health (Hoyer, 2005).

Key regulatory hormones for female reproduction are the same as those which govern the male reproductive cycle: GnRH stimulates the release of FSH and LH. Follicle stimulating hormone is responsible for the recruitment and selection of the dominant ovarian follicle for subsequent ovulation and potential fertilization; the growing follicle is then stimulated to release estrogen. Luteinizing hormone is important in ovulation and in formation of the corpus luteum, which releases progesterone and is crucial in the maintenance of pregnancy. Exposure to chemicals that act to mimic or antagonize the actions of endogenous estrogen can disrupt the balance of this feedback system and result in adverse consequences for reproduction and the maintenance of pregnancy.

Consideration of female reproductive toxicology may also involve consideration of the relationship between mother and conceptus (i.e., the developing embryo/fetus) and potential adverse outcomes. The mother may transfer chemical agents, including active metabolites, to the conceptus by a variety of mechanisms, adversely affecting development. Transport of male and female germ cells to the site of fertilization in the oviduct (fallopian tube) and the transport of the fertilized egg to the site of implantation and development in the uterus are also functions that can be disrupted by reproductive toxicants. Atrophy of the oviduct or uterus can prevent transport and exocrine support of the germ cells and embryo. Formation of the corpus luteum and the subsequent complex processes required for implantation of the embryo may also be affected by toxicants, as well as formation of the placenta to nourish and remove wastes from the conceptus. Hormonal control of the duration of pregnancy may be shortened or lengthened by toxicants, resulting in potential adverse effects on the fetus. Following birth, milk production and secretion may be affected by toxicants. Thus, a variety of targets exist for physical and chemical agents to disrupt female reproduction and development of the conceptus, pointing to the need for additional research to identify mechanisms of action to help mitigate potential risks to women in the workplace.

Physical Agents

Ionizing Radiation Precautions are taken in the health care setting to minimize the risk of ionizing radiation exposure in women and potentially, the conceptus. Ionizing radiation is a known risk factor for ovarian toxicity and for fetal death, malformation, and growth retardation. Much of what is known about the effects of ionizing radiation on the female reproductive tissues comes from patients receiving low therapeutic doses for cancer treatment, female health workers exposed occupationally, and victims of higher environmental exposures, including survivors from the atomic bomb detonations in Hiroshima and Nagasaki, and the Chernobyl reactor accident. Therapeutic and environmental exposures have been associated with ovarian failure, premature menopause, and infertility. Depletion of primordial follicles appears to be the primary manifestation of ovarian toxicity. Adverse effects on female gonadal function occur at all ages, with the degree and persistence of damage depending on the dose, irradiation field, and age (older women are more susceptible) (Meirrow and Nugent, 2001). The estimated radiation dose at which half of ovarian follicles are lost in humans is 4 Gy (Wallace et al., 1989); permanent ovarian failure is estimated to occur at 20 Gy in women <40 years of age, and at 6 Gy in older women (Lushbaugh and Casarett, 1976; Meirrow and Nugent, 2001). Dose-responsive loss of primordial follicles has also been observed in mice, with a range of increasing doses producing partial to total loss (Gosden et al., 1997). With regard to occupational exposure to low levels of ionizing radiation, evidence suggests that exposure of female health-care workers to ionizing radiation within prescribed limits and prior to conception does not constitute a risk factor for reproductive health (Figà-Talamanca, 2006).

Concerns have been expressed about potential effects of RFEMR on female reproductive health, due to the prevalence of these emissions in the environment. However, no definitive conclusions have been reached. Although exposure to video display terminals is suspected to have a slight association with the risk of miscarriage, it is unclear whether the effect is due to electromagnetic frequency or to work-related conditions such as ergonomic factors, work stress, and long working hours (Figà-Talamanca, 2006).

Ergonomic Factors/Occupational Stress A current area of interest in women's health is the impact of various occupationally related ergonomic factors and stress. In addition to exposure to various physical and chemical agents in the workplace, such factors as heavy physical work, prolonged standing or sitting, climbing stairs or ladders, cold, shift work, and irregular work schedules may also represent occupational risk factors (McDonald et al., 1988; Nurminen et al., 1989; Marbury, 1992; Figà-Talamanca, 2006). Heavy physical work is considered to be a risk factor for

spontaneous abortion, as well as low birth weight and premature delivery. Fenster et al. (1997) found that standing at work for more than 7 h was associated with an increased risk of spontaneous abortion only in women with a history of two or more spontaneous abortions. The risk of spontaneous abortion was found to increase when physical strain occurred early in pregnancy (Figà-Talamanca, 2006). Noise-induced stress has been associated with potential interference with the endocrine system and an increased risk of miscarriage in humans and laboratory animals. However, in a study conducted by Nurminen (1995), threatened abortion was not associated with noise exposure alone; when combined with shift work, the risk was enhanced twofold. Additional risks attributed in this study to noise in shift work included pregnancy-induced hypertension and shorter duration of pregnancy. Effects on gestational age have also been reported to occur from a combination of stressors, rather than a single stressor, with women in the highest exposure category having the greatest risk (Marbury, 1992).

Overall, stress is known to interfere with the endocrine system, which may be manifested by menstrual disorders and altered cycle length. However, studies of work-related stress have not provided definitive evidence that stress is an independent factor in female reproductive toxicity. It is often difficult to establish the cause-and-effect relationship, since the negative reproductive effect may be a source of stress in itself (Figà-Talamanca, 2006).

Solvents

Exposure of women to solvents in occupational settings has been associated with adverse reproductive effects. In a study of the relationship between spontaneous abortion, stillbirth without congenital defect, and working conditions, McDonald et al. (1988) found that exposure to solvents was associated with an increased risk of spontaneous abortion and stillbirth. Often exposures in the workplace occur to a mixture of solvents, so it can be difficult to attribute adverse effects to a single chemical. However, accidental contamination with specific solvents, coupled with laboratory animal data, has helped to establish the biological plausibility.

Bromopropanes 2-Bromopropane (2-BP) exerts adverse effects on both male and female reproductive systems. In addition to adverse effects on the hematopoietic (pancytopenia) and male reproductive systems, inhalation exposure of electronics factory workers in Korea to 2-BP resulted in increases in circulating FSH and LH, secondary amenorrhea, and hot flashes in women (Kim et al., 1996). Subsequent inhalation studies in rats demonstrated ovarian dysfunction, which was attributed to the destruction of the primordial follicle and its oocyte due to induction of apoptosis (Yu et al., 1999). Following the identification of toxicity associated with 2-BP, 1-BP was introduced to the workplace as a CFC replacement. As

mentioned previously, 1-BP was found to be a potent neurotoxicant in laboratory animals, as well as a male reproductive toxicant (Ichihara, 2005). Female reproductive toxicity has also been identified in rats with 1-BP but not in humans. Exposure to 1-BP in a multigeneration study resulted in prolongation of the estrous cycle, decreased ovarian weight, reduced numbers of corpora lutea, and increased numbers of ovarian cysts (Yamada et al., 2003). 1-Bromopropane disrupted ovarian follicular development in these rats by targeting antral and developing follicles. Similar to the situation with males, the target is different for 1-BP and 2-BP; 2-BP targets the oocyte of the primordial follicle, whereas 1-BP disrupts follicular development (Ichihara, 2005). The reason for the difference in target between the two forms of bromopropane has not been established.

Glycol Ethers Although glycol ethers are primarily recognized as male reproductive toxicants and developmental toxicants, limited evidence also suggests that they can adversely affect the female reproductive system. Studies of women employed in the semiconductor industry reported an increased risk for spontaneous abortion and subfertility; prolonged time to conceive has also been reported, which may be associated with evidence of prolonged menstrual cycles (Schenker et al., 1995; Correa et al., 1996; Hsieh et al., 2005).

In vitro evidence supports the potential for glycol ethers to alter ovarian function in humans. Almekinder et al. (1997) exposed cultured rat luteal cells to EGME and its proximate metabolite methoxyacetic acid (MAA) and observed cellular hypertrophy and increased progesterone production. *In vivo*, EGME has been observed to elevate serum progesterone and suppress estrous cyclicity, inhibit ovulation, and increase corpora lutea size by inhibiting luteolysis in rats (Davis et al., 1997). Exposure of cultured human luteinized granulosa cells to the same concentration of MAA to which rat luteal cells were exposed also resulted in increased progesterone production (Almekinder et al., 1997), suggesting a potential risk for human exposure. Studies in several laboratory animal species exposed to glycol ethers have reported increased embryo mortality (Hardin et al., 1986; Scott et al., 1989). Studies at lower doses in which rats have been allowed to deliver their offspring have demonstrated an association between glycol ethers and prolonged gestation (Nelson and Brightwell, 1984; Toraason and Breitenstein, 1988).

Other Industrial Chemicals

Vinylcyclohexene and Related Compounds 4-Vinylcyclohexene (VCH) is a dimer of 1,3-butadiene. Occupational exposure can potentially occur via inhalation during the production of 1,3-butadiene, VCH or 4-vinylcyclohexene diepoxide (VCD), as well as during the production of butadiene-based rubber, extrusion of electrical cable insulation, flame retardants, insecticides, and plasticizers

(IARC, 1994a). 4-Vinylcyclohexene is considered by the International Agency for Cancer Research IARC (IARC, 1994a) to be possibly carcinogenic to humans, based on laboratory animal data. 4-Vinylcyclohexene diepoxide has been extensively studied as a model for ovarian toxicity. Ovarian tumors were produced in mice in a lifetime study in which VCH was administered orally and were preceded by observations of ovarian and uterine atrophy (Hoyer and Sipes, 2007). Ovarian effects were not observed during a lifetime study in rats, and subsequent research determined that the species difference in response was due to greater conversion to mono- and di-epoxide metabolites in mice, which were also shown to induce ovarian toxicity. The ovarian toxicity of VCH has been well characterized in *in vitro* and *in vivo* experimental models and has been attributed primarily to the active metabolite VCD. The mechanism of action is a direct effect on the ovaries, with selective destruction of small pre-antral follicles. 4-Vinylcyclohexene diepoxide (VCD)-induced follicle loss is via apoptosis and results in acceleration of the natural process of ovarian follicle atresia (Hoyer and Sipes, 2007).

Vinylcyclohexene diepoxide, in addition to being an active metabolite of VCH, is also used industrially as a reactive diluent for other diepoxides and for epoxy resins derived from BPA and epichlorohydrin (IARC, 1994b). It is also considered by the IARC to be possibly carcinogenic to humans based on results from lifetime studies in which skin application resulted in benign and malignant skin tumors in mice and rats and, in one study, ovarian and lung tumors in mice (IARC, 1994b). Nonneoplastic lesions in these studies included ovarian follicular atrophy and tubular hyperplasia in mice.

Species specificity with regard to toxicant-induced ovarian atrophy is also demonstrated by 1,3-butadiene in that the mouse is the most sensitive species, likely due to pharmacokinetic differences (Christian, 1996). Mice demonstrate greater bioavailability of 1,3-butadiene, greater production of toxic intermediates, and a lower capacity for detoxification of these intermediates (U.S. EPA, 2002). Metabolic activation appears to be required for ovarian toxicity, and mice are more sensitive than rats to ovotoxic effects of the mono- and diepoxides of 1,3-butadiene (U.S. EPA, 2002). No human data are available to indicate that adverse female reproductive effects have resulted from occupational exposure to 1,3-butadiene, or to VCH or VCD.

Metals

Cadmium Cadmium, a metal widely dispersed throughout the environment, has been linked to a range of detrimental effects on human reproduction and development. While adverse effects primarily involve male reproduction and development of children exposed in utero or after birth, evidence also points to potential disruption of the female

reproductive system. Cadmium is considered to be an endocrine disruptor in that it either enhances (low doses) or inhibits (high doses) the biosynthesis of progesterone, a hormone linked to normal reproductive cyclicity in females, as well as the maintenance of pregnancy (Henson and Chedrese, 2004). A decrease in basal secretion of progesterone, as well as FSH and LH, occurred following treatment of rats with a single high dose of cadmium chloride, indicating an effect on the hypothalamic-pituitary-ovarian axis (Paksy et al., 1989). Cadmium effects on the female reproductive system appear to be species specific. A single subcutaneous injection of cadmium chloride in hamsters, four mouse strains, and two rat strains prior to and after sexual maturity revealed that hamsters had the greatest sensitivity to cadmium-induced ovarian toxicity (Rehm and Waalkes, 1988). Lesions in hamsters included ovarian hemorrhagic necrosis, with damage to small arteries of developing follicles and interstitial stroma, resulting in failure to ovulate. The most severe ovarian lesions occurred in immature hamsters, mature hamsters at high doses, and shortly before ovulation at all doses; these lesions were, however, reversible. In this study rats also demonstrated dose- and age-dependent toxicity in the ovaries, uterus, and cervix, while mice were more resistant to cadmium-induced toxicity. Massányi et al. (2007) evaluated the structures of ovary, oviduct, and uterus in rabbits after a single intraperitoneal dose or after 5 months of oral dosing with cadmium chloride. Ovarian effects included a decrease in the relative volume of growing follicles, increased stroma, and increased numbers of atretic follicles. Edema was observed in the oviduct and was considered related to the disintegration of vascular walls. Increased stroma in the uterus was considered a sign of edema caused by damage of blood vessel walls and subsequent diapedesis.

Effects on the uterus and mammary gland have also been observed in laboratory animals treated with cadmium. *In vitro*, cadmium was estrogenic in the MCF-7 human breast cancer cell line; effects on gene expression were considered to be mediated by the estrogen receptor independent of estradiol. Cadmium also induced the growth of MCF-7 cells and demonstrated signs of estrogenicity *in vivo* (Garcia-Morales et al., 1994). A single intraperitoneal injection of cadmium chloride induced an increase in uterine wet weight, promoted growth and development of mammary glands, and induced hormone-regulated genes in ovariectomized rats (Johnson et al., 2003). Female offspring of pregnant rats given intraperitoneal injections of cadmium on gestation days 12 and 17 displayed an earlier onset of puberty and increased mammary gland development (Johnson et al., 2003). Increased urinary cadmium concentrations were associated with uterine fibroids in a German cohort of infertile women (Gerhard et al., 1998).

Cadmium is known to accumulate in human ovaries. Ovarian biopsies conducted by Varga et al. (1993) revealed

a linear increase in cadmium between 30 and 65 years of age, particularly in smokers versus nonsmokers. The increase in cadmium levels in ovaries of smokers is not unexpected, as tobacco smoke is a major source of cadmium contamination. Enhanced cadmium concentrations and lower progesterone levels have also been reported in follicular fluid and in placentas of smokers compared to nonsmokers (Piasek et al., 2001). Recurrent miscarriage and uterine fibroids have been directly linked with increased cadmium excretion in women.

Lead Exposures to high levels of lead have been associated with spontaneous abortion in women. Although the evidence has in general been equivocal for low to moderate level lead exposures due to the small size of most studies, a prospective study conducted in Mexico City identified a dose-response relationship between the risk of spontaneous abortion and blood lead levels (Hertz-Pannier, 2000). This study revealed that blood lead levels in the range of 10 ± 25 mg/dl could have adverse effects on pregnancy.

Lead is known to accumulate in the granulosa cells of the ovary and has been shown to affect follicular development and maturation. Morphological changes in the ovaries of mice treated with lead acetate were described as atresia and included a significant effect on small and medium follicles at low doses, with an effect on antral follicles at a higher dose (Junaid et al., 1997). Treatment of female rats with lead acetate for 15 days resulted in a reduction in binding of LH and FSH to granulosa cells, which altered steroidogenic enzyme activity and induced cytotoxicity (Nampoothiri and Gupta, 2006). Lead was shown to accumulate in the uterine epithelium of mice given an intraperitoneal injection of lead chloride and to disrupt morphology, potentially through interference with the activity of ovarian steroid hormones on the endometrium (Wide and Nilsson, 1979). In a subsequent study, implantation of the blastocyst was inhibited in mice given a single intravenous injection of lead chloride (Wide, 1980). This effect was counteracted by a combination of estrogen and progesterone, suggesting that implantation failure could indeed be due to an effect of lead on uterine responsiveness to ovarian steroids.

Mercury Mercury is found in such diverse items as thermometers, traditional blood pressure meters, switches, mirrors, fluorescent lamps, and dental amalgam fillings. In addition, mercury catalysts are used in the oxidation of organic materials, and inorganic mercury is used in the pulp and paper industry as a fungicide. The most common forms of mercury to which humans have been exposed are elemental (metallic) mercury vapor, methylmercury, mercuric chloride, and phenylmercuric acetate (Seegmiller, 1997). Of these, mercury vapor has been evaluated to the greatest extent with regard to female reproductive toxicity. Reports of menstrual cycle abnormalities, including painful menstruation and changes in

bleeding patterns and menstrual cycle duration, have been attributed to mercury vapor (Rowland et al., 1994). In particular, adverse effects on reproduction have been reported for female dental practitioners due to inhalation of elemental mercury vapor from dental silver amalgam fillings. A study by Rowland et al. (1994) indicated that women with exposure to 30 or more amalgams per week and with poor mercury hygiene (i.e., following practices that did not minimize exposure to mercury) showed evidence of reduced fertility, while women exposed to low levels of mercury were actually more fertile than unexposed controls.

Studies of various forms of mercury in laboratory animals, often at high doses that resulted in systemic toxicity, identified disturbances of the menstrual/estrous cycle, inhibition of ovulation, and/or infertility (Davis et al., 2001; Schuurs, 1999). In a study designed to evaluate the impact of systemic toxicity on female reproductive effects in rats, Davis et al. (2001) exposed rats to low levels of mercury vapor and found subtle changes in estrous cyclicity and corpora luteal morphology, but no adverse effects on fertility, leading these authors to suggest that reproductive effects noted in occupationally exposed women might be secondary to systemic and/or neurotoxic effects of mercury. In a review by Schuurs (1999), reproductive effects in women exposed to elemental mercury in a smelting plant, a mercury vapor lamp factory, and in dental practices were associated with mercury concentrations that likely exceeded the threshold limit value (TLV) of 25 µg Hg⁰/m³ for women.

Some adverse effects of mercury may be mediated through the H-P-G axis. Mercury was found to accumulate in the anterior pituitary of rhesus monkeys implanted with amalgam fillings (Danscher et al., 1990) and was associated with hormonal disorders in a German cohort of women evaluated for effects of heavy metal exposures (Gerhard et al., 1998).

In animals, exposure to metallic mercury vapor prolongs the estrous cycle. Mercury also can have toxic effects on placental function. *In vitro* studies using normal, full-term human placentas reported that inorganic mercury inhibited placental amino acid transport (Iioka et al., 1987). In the rat conceptus, metallic mercury inhibited placental uptake of essential trace elements (Danielsson et al., 1984), amino acids, and nucleosides but did not directly affect the utilization of amino acids or nucleosides.

Pesticides

Organochlorine Pesticides Pesticide exposure in women has been associated with adverse reproductive outcomes such as infertility, delay in conception, spontaneous abortions, congenital defects, and premature delivery (Figà-Talamanca, 2006). Organochlorine pesticides in particular can substitute for estradiol, resulting in disruption of female reproductive function. One example of an organochlorine pesticide that has been extensively studied in laboratory animals is MXC, which was intended as a replacement for DDT, but has now

been banned in the United States and the European Union due to its toxicity, bioaccumulation, and endocrine disruption activity (U.S. EPA, 2004). Human exposure can occur by air, soil, and water resulting from contamination with MXC. Methoxychlor is considered to be an environmental estrogen; the metabolite 2,2,bis(p-hydroxyphenyl)-1,1,1-trichloroethane (HPTE) is the active estrogenic form (Cummings, 1997). In an evaluation of a variety of short-term *in vivo* methods used to detect estrogenic activity in compounds known to have affinity for the estrogen receptor (although to a much lesser extent than estradiol), MXC advanced the age at vaginal opening (i.e., resulted in precocious puberty), disrupted the estrous cycle, and increased uterine weight (Laws et al., 2000). It has also been shown to induce adverse effects on fertility, early pregnancy, and early *in utero* development in laboratory rodents. Female mice given oral doses of MXC for 2 or 4 weeks developed persistent vaginal estrus (indicative of accelerated reproductive senescence), reduced ovarian weight, and an increase in the number of atretic ovarian follicles (Martinez and Swartz, 1991). These factors could be expected to result in reduced fertility. In rats, infertility has been demonstrated with long-term MXC exposure, while the adverse effect of short-term exposure during early pregnancy has been shown to block the decidual response of the uterus, which is necessary for successful implantation of the blastocyst (Cummings and Gray, 1989). Methoxychlor administration during days 1–3 of pregnancy resulted in a dose-dependent decrease in blastocyst implantation, while administration during days 4–8 resulted in resorption of embryos, decreased uterine weight, and a reduction in serum progesterone without affecting the number of corpora lutea or implantations, or ovarian weight (Cummings and Gray, 1989). Resorption following post-implantation dosing was considered to be a manifestation of normal decidual development. Although MXC has been thoroughly studied in laboratory animals, as per Cummings (1997), the significance of female reproductive toxicity with respect to human health remains to be determined.

One of the most well-known and well-studied organochlorine pesticides is DDT. Although DDT has been banned in many countries due to adverse effects induced in wildlife populations, it is still used in some countries and also persists in the environment. The metabolite 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene (DDE) is considered to be ubiquitous, is found in tissues of humans worldwide, and is consistently found in follicular fluid and serum of women (Tiemann, 2008). While DDT does not bind to the estrogen receptor, several contaminating isomers do, with the most potent being *o,p*-DDT (Das et al., 1997). Estrogenic DDT isomers induce estrogenic effects on female reproductive parameters similar to those of MXC.

γ -Hexachlorocyclohexane (lindane) is also found in air, water, and soil samples worldwide and has been shown to

cause reproductive failure in laboratory animals characterized by the absence of implantation sites when given to mice during early pregnancy, total resorption of fetuses when given in mid-pregnancy, and neonatal death when given in late pregnancy (Tiemann, 2008).

DEVELOPMENTAL TOXICITY

Occupational exposure to toxicants can potentially impact the development through indirect exposure of the parents and subsequent transfer of the chemical and/or metabolites via the placenta or breast milk to the conceptus (embryo/fetus) or to the neonate. Neonates and young children who are still in the process of developing may be exposed directly to industrial chemicals in the case of contamination of air, water, foodstuffs, soil, or even contaminated clothing worn by parents. Adverse effects on development may also be induced through inheritance of genetic damage of the germ cells of one or both parents. The primary manifestations of developmental toxicity are embryo/fetal death, malformations (birth defects), growth retardation, and developmental delay. Adverse fetal outcomes may also include preterm delivery, altered sex ratio, and childhood cancer. The study of the induction of adverse structural changes during development is known as teratology; a physical or chemical agent that induces such effects is known as a teratogen. The association of blindness and deafness in children with maternal exposure to the rubella virus (German measles) and the linkage of limb abnormalities with thalidomide exposure were among the first examples of environmental factors identified as causing congenital defects. The overall incidence of birth defects in the United States is approximately 3%. Birth defects are defined as structural malformations with a significant impact on the health and development of a child and account for 20% of infant mortality in the United States (Parker et al., 2010). It is estimated that less than half of all human conceptions result in the birth of a completely normal healthy infant, and that the cause of birth defects is unknown in 65% of cases (Rogers and Kavlock, 2008), underscoring the need for continued research. For the purpose of discussing teratogenicity, human development can be divided into the following three stages: the preimplantation stage, the later embryonic stage, and the fetal stage. At any time after fertilization, the developmental process may be disrupted. Injury to the fertilized egg during the gastrula stage usually results in cell death. Damage involving minor cell death can be repaired, but major cell death cannot, and the result is abortion of the pregnancy. If the organism survives generally no structural deformity is seen. This is based on flexibility, or totipotency, of the cells, which allows them to follow various paths and replace lost cell lines. Spontaneous abortion in these early stages usually goes unrecognized and therefore rarely is associated with an exposure. The first

8-week period of organogenesis, the time of the most and the fastest growth, also is the period of greatest susceptibility to environmental influences, and most teratological effects are induced during this period. Exposure during the fetal period is most likely to result in a reduction in cell size and number. From 8 weeks to term, the fetus, generally considered less vulnerable than the embryo but more susceptible than the child or adult, can be subjected to adverse influences that lead to physical growth retardation and functional abnormalities. Some developmental processes that are not completed until after birth, such as physical growth and maturation of the nervous system, may be adversely affected by exposure during this period (Harbison, 1998).

Developmental toxicity is a subject of great concern with regard to environmental and occupational exposure, as well as pharmaceutical development, and has been well studied in laboratory animals due to the difficulties inherent in obtaining human data. Wilson (1977) proposed six scientific principles that sought to explain the roles played by critical periods of development, genotype, dose-response relationships, the various manifestations of abnormal development, access of agents to the developing tissues, and mechanisms critical to the understanding of developmental toxicity. These principles are highly valued in the risk assessment of potential developmental toxicants and can help to explain phenomena such as enhanced or diminished susceptibility during development relative to adults, responses that differ depending on developmental stage, and the role of key metabolic pathways and hormonal influences. As an example, during development, windows of vulnerability exist: these are periods during which toxic insult to specific organs and tissues can result in structural or functional damage. The age at which these windows occur and the duration of the insult required to induce damage are species specific, increasing the complexity of cross-species comparisons (Morford et al., 2004).

In addition to effects on the structure, adverse effects on function may also be induced during development and are generally manifested after birth. This is especially important for organs and tissues that have a protracted duration of development, including the postnatal period. These include the CNS and the immune, reproductive, and urinary systems. Developmental neurotoxicology, also known as behavioral teratology, is a subset of developmental toxicology, which has received a great deal of study.

An important consideration in evaluation of developmental toxicity in humans and laboratory species is maternal toxicity. Maternal factors that can affect development include genetics, disease state, nutrition, stress, and placental toxicity (Rogers and Kavlock, 2008). In addition, toxicity of a given physical or chemical agent to the maternal animal, inducing such outcomes as excessive weight loss and compromised organ-specific structure or function, can impact the development of the conceptus. Maternal effects could potentially

exacerbate developmental toxicity or directly cause developmental changes.

Exposure of the mother to a carcinogen during pregnancy can result in a phenomenon known as transplacental carcinogenesis. Fetal tissues are thought to be privileged targets of neoplastic change induced by carcinogens due to the massive cell proliferation and differentiation taking place during embryogenesis (Alexandrov et al., 1990). A well-characterized example of transplacental carcinogenesis in humans and laboratory animals is the synthetic estrogen, diethylstilbestrol (DES). Diethylstilbestrol was prescribed as a drug for prevention of miscarriage and for the treatment of various hormone-dependent cancers and late complications of pregnancy; it was also used as a growth promoter in livestock (Seegmiller, 1997). Daughters of women who used DES to prevent miscarriage developed a rare form of cancer of the vagina or cervix, clear cell adenocarcinoma, which was first detected when they reached puberty. Investigative studies in mice have determined that exposure to DES during critical periods of reproductive tract differentiation permanently alters estrogen target tissues, resulting in increased susceptibility for tumor development postnatally (Newbold et al., 2006).

Physical Agents

Ionizing Radiation Exposure of the conceptus to ionizing radiation is a known risk factor for embryonic/fetal death, malformation, and growth retardation, with adverse effects dependent on the dose and developmental stage of exposure. Exposure of parents before conception may cause genetic damage to male or female germ cells and lead to abortion, stillbirth, and possibly cancer (Goldberg et al., 1998). A review by Brent (1980) described this stage-specific susceptibility. Prior to the blastocyst stage, the embryo is most sensitive to the lethal effects of ionizing radiation and insensitive to teratogenicity and growth-retarding effects. During early organogenesis, the conceptus is sensitive to growth retarding, teratogenic, and lethal effects but can recover from growth retarding effects during the postpartum period. In the early fetal period, sensitivity is diminished to teratogenicity but is retained to CNS effects and growth retardation. Exposure during later fetal stages does not result in malformations, but the fetus can respond with permanent cell depletion of various organs and tissues if the exposure is sufficiently high.

The CNS is particularly vulnerable to *in utero* exposure to ionizing radiation; adverse neurologic effects such as microcephaly, mental retardation, lower intelligence scores, poor school performance, and seizures have been reported in survivors of the Nagasaki and Hiroshima nuclear bombings during World War II, who were exposed to ionizing radiation *in utero* (Yamazaki and Schull, 1990). The most critical period for these effects seemed to be 8–15 weeks after fertilization, which corresponds to the developmental stage

when neuronal production is increased and immature neurons migrate to their cortical sites of function. Sensitivity to radiation is quite constant across all mammalian species during each developmental period. The animal and human data have been critically contrasted in a review article by Schull et al. (1990).

In a review on counseling of pregnant women regarding risks associated with diagnostic radiation, Brent (2009) stated that the various manifestations of radiation exposure during development have a no-observed-adverse-effect level (NOAEL), and that almost all diagnostic radiological procedures provide exposures below the NOAEL for these effects.

Solvents

Ethanol Ethanol is present as an additive in gasoline, a solvent in industry, and in many household products and pharmaceuticals. Human exposure can occur in these contexts, as well as through the consumption of intoxicating beverages. Ethanol is eliminated from the body by urinary excretion and exhalation; it is metabolized to acetaldehyde by alcohol dehydrogenase and can interact with other solvents metabolized in this way. It induces cytochrome P450 2E1, which can enhance metabolic activation and potentiate the toxicity of a considerable number of other solvents and drugs (Bruckner et al., 2008).

Fetal alcohol spectrum disorder (FASD) describes a constellation of effects that may occur in offspring of mothers who consume alcohol during pregnancy. Effects range from mild to severe and include fetal alcohol syndrome (FAS), which is at the most extreme end of the spectrum (Riley et al., 2011) and is considered the most common nonhereditary, preventable form of mental retardation (Bruckner et al., 2008). The prevalence of FAS in the United States and some Western European countries is estimated to be as high as 2–5% (May et al., 2009). Diagnostic criteria for FAS include maternal alcohol exposure during gestation, a specific pattern of craniofacial malformations (including short palpebral fissures and abnormalities in the premaxillary zone), pre- and/or postnatal growth retardation, and evidence of neurodevelopmental abnormalities, including decreased cranial size at birth, structural brain abnormalities, and/or neurological function deficits (Stratton et al., 1996). Peak maternal blood alcohol level is the most important determinant of the likelihood of FAS and severity of effects. Alcohol-related birth defects (ARBD) can also occur in which physical abnormalities of the skeleton and certain organ systems are not accompanied by the standard craniofacial malformations (May et al., 2009). These congenital anomalies can include atrial or ventricular septal defects, digit and limb anomalies, and aplastic kidneys (Stratton et al., 1996).

Developmental neurotoxicity, or alcohol-related neurodevelopmental disorder (ARND), has been shown to occur concomitantly with, or in the absence of, physical defects

(including growth retardation and CNS malformations), on a continuum ranging from mild to severe. Functional consequences include a neonatal abstinence syndrome, mild to severe cognitive deficits, hyperactivity, distractibility, deficits in attention and reaction time, learning and memory disabilities, and state lability in infants. Ethanol exposure is considered to affect brain development via numerous pathways and at all stages, from neurogenesis to myelination (Riley et al., 2011).

There is a good deal of congruence between human and animal disorders resulting from maternal ethanol exposure. Developmental neurotoxicity, manifested as deficits in learning, inhibition, attention, regulatory behaviors, and motor performance, was found to be affected in both humans and laboratory animals following moderate levels of ethanol exposure during development (Driscoll et al., 1990). Although the dose required to produce an effect differed among species, blood alcohol levels were quite similar. The majority of studies conducted in humans and laboratory animals involve ingestion of relatively high doses of ethanol to mimic consumption of alcoholic beverages. While these studies provide important information, their relevance to industrial exposure is limited, since this type of exposure is typically via inhalation or dermal absorption, producing substantially lower blood alcohol levels. In a review of occupational ethanol exposure, Irvine (2003) concluded that there is no evidence that industrial exposure to ethanol is a developmental toxicity hazard.

Glycol Ethers Some glycol ethers and their metabolites, including EGME, EGEE, 2-ME, 2-EE, and 2-MAA, are developmentally toxic in laboratory animal species and have been shown to produce malformations in a variety of organ systems (Andrew and Hardin, 1983; Hardin et al., 1986; Scott et al., 1989). Embryo mortality, as well as hydrocephaly, exencephaly, cardiovascular malformations, craniofacial anomalies, malformations of the digits and ribs, dilatation of the renal pelvis, and/or minor skeletal variations, occurred in several animal species exposed to EGME, EGEE, 2-ME, or 2-MAA, with some species specificity observed with respect to adverse effects. Functional changes have also been observed following an in utero exposure. Female rats treated with EGME or EGEE in a study in which they were allowed to deliver their offspring exhibited a slight prolongation of gestation, but no other indications of maternal toxicity (Nelson and Brightwell, 1984). Offspring from these females displayed neurobehavioral changes and regional brain alterations of several neurotransmitters. Gestation was also prolonged in rats treated with 2-ME during gestation (Toraason and Breitenstein, 1988). Electrocardiograms evaluated from offspring of these females revealed persistent, aberrant QRS waves, suggestive of an intraventricular conduction delay. These changes occurred in the absence of morphologic anomalies of the heart.

Maldonado et al. (2003) reviewed four glycol ether-related epidemiology studies. Facial malformations (e.g. oral clefts), CNS malformations, neural tube defects, and varying degrees of mental retardation in children of mothers exposed to glycol ethers occupationally were attributed to this exposure. However, these authors concluded that there were methodological issues with all four studies; in addition, the attribution of malformations to glycol ether exposure lacked biological plausibility since the glycol ethers to which the women were exposed in general have not been shown to be teratogenic in animal models. This appears to be an area requiring further research to determine potential concordance of human and animal data that may impact the risk assessment of glycol ethers.

Toluene Toluene is present in paints, lacquers, thinners, cleaning agents, glues, and gasoline, which is the largest source of atmospheric emissions of toluene and exposure to the general population (Bruckner et al., 2008). Inhalation is the primary route of human exposure, although skin contact also occurs frequently. Toluene exposure occurs in individuals who inhale gasoline, glue, and spray paint to obtain a sense of euphoria, which occurs at an exposure of at least 500 ppm (Wilkins-Haug, 1997). The term “fetal solvent syndrome” describes the sequelae from in utero exposure, which include microcephaly, developmental delay, growth deficiency, and craniofacial defects similar to those associated with FAS (Pearson et al., 1994; Wilkins-Haug, 1997; Bruckner et al., 2008). Pearson et al. (1994) suggested that a common mechanism of action may explain the craniofacial teratogenicity induced by toluene and by ethanol.

Developmental effects were observed in a two-generation study in mice reported by Roberts et al. (2003). In this study, male or female mice were exposed by inhalation to concentrations as high as 2000 ppm toluene for 80 days prior to mating, during mating, and for females, through gestation and lactation; parental animals were evaluated for effects on fertility, and their F₁ generation offspring were evaluated for survival, growth, development, behavior, and ability to produce the F₂ generation. A separate cohort of females was exposed to toluene during gestation, and their fetuses were evaluated for developmental anomalies. F₁ offspring were subsequently directly exposed to toluene for 80 days after weaning. There were no effects on fertility or reproductive performance of males, females, or the F₁ generation, or on maternal or offspring behavior. Body weights were reduced in F₁ offspring of females exposed to toluene, as well as their F₂ offspring; body weights were unaffected in offspring of exposed males. Decreased fetal body weight and skeletal anomalies were observed in the F₁ and F₂ generation fetuses of exposed females.

Additional human studies have reported reduced fertility and increases in spontaneous abortion in women exposed to toluene in an industrial setting, but the interpretation of these

studies has been confounded by unknown exposure levels, timing of exposure, and duration of exposure, as well as presence of other solvents, small sample size, and lifestyle factors such as smoking and alcohol consumption (Wilkins-Haug, 1997; Roberts et al., 2003).

Other Industrial Chemicals

Bisphenol A Bisphenol A (BPA) is used in the production of polycarbonate plastics used in food and drink containers, as well as in epoxy resins used as lacquers to coat metal products such as food cans, bottle tops, and water supply pipes. The production volume of this chemical is considered to be high. The primary source of exposure to humans is assumed to be ingestion of food or drink that has been in contact with a material containing BPA, although direct contact can also occur (Chapin et al., 2008). It is estimated that the highest intake is in infants and children. Bisphenol A has been the subject of much discussion and study due to widespread human exposure, evidence of reproductive and developmental toxicity in laboratory animals, and its status as an estrogenic compound.

Early development appears to be the greatest period of sensitivity to adverse effects in laboratory animals. Adverse developmental effects include fetal and neonatal death and decreased growth rate. Additional effects reported in rats and mice include delayed puberty in males and females, as well as altered mammary gland development in females leading to the development of preneoplastic lesions and increased susceptibility to neoplastic development, and increased susceptibility to prostate carcinogenesis (Diamanti-Kandarakis et al., 2009). Evidence for disruption of the H-P-G axis in rats exposed to BPA *in utero* has also been presented, as well as effects on brain structure and function, including behavior anomalies (Richter et al., 2007).

A NTP report on BPA, based on findings from the expert panel of the Center for the Evaluation of Risks to Human Reproduction (CERHR), found no direct evidence for health effects in humans. Although the NTP expressed minimal concern regarding developmental effects identified in laboratory animals that included an earlier age for puberty in females, and some concern regarding effects on the brain and behavior, it concluded that additional research is needed to better understand if findings from laboratory animals are of any significance to human health. New information continues to emerge based on extensive ongoing research, particularly about potential low dose effects, and recent statements of support for further clarification of BPA-associated risks have been issued by the U.S. Food and Drug Administration (FDA) and the Endocrine Society (Diamanti-Kandarakis et al., 2009; U.S. FDA, 2013).

Halogenated Hydrocarbons Polychlorinated biphenyls (PCBs) are known to be developmental neurotoxicants,

based on reports of children exposed in utero or during lactation due to maternal consumption of contaminated fish or rice oil, or to background environmental levels (Barlow et al., 1999). High levels of contamination with PCBs and polychlorinated dibenzofurans (PCDFs) reported in Yucheng, Taiwan, and Yusho, Japan, were associated with low birth weight, preterm delivery, and developmental effects in children (Whelan, 1997). Infants developed an ectodermal dysplasia syndrome, which included toxicity to skin and teeth; CNS toxicity may potentially be part of this syndrome (Peterson et al., 1993). Adverse effects occurred in children of mothers who were rendered clinically ill by exposure to PCBs; these effects included effects on motor and mental function, as well as developmental and behavioral problems. Children of mothers exposed to lower levels of PCBs in the United States exhibited smaller birth and neonatal size; weak reflexes; were less responsive to stimuli; had more jerky, unbalanced movement, and more startles; were hypotonic; had deficits in gross and fine motor coordination; and had poorer visual recognition and memory performance. These effects were presumed to occur in the absence of maternal toxicity (Tilson et al., 1990). Schantz et al. (2003) have reported that despite the decline in levels of PCBs in exposed cohorts, negative impacts on cognitive functioning are still being reported. The geometry of PCBs is such that a large number of substitutions can be made on the dual benzene rings, leading to a total of 209 theoretically possible congeners, only a few of which persist in the environment (Ulrich and Stahlmann, 2004). Although many studies have been conducted with PCBs in laboratory animals, they have typically evaluated commercially available mixtures of congeners, different from the environmental congeners to which humans are exposed and having potentially different toxicity profiles. Schantz et al. (2003) have suggested that more complete information is needed for relevant congeners to allow for more informed scientific and risk assessment decisions.

Polychlorinated diphenyl ethers (PBDEs) are used as flame retardants, with human exposure occurring from treated surfaces and contaminated food. A prospective epidemiology study identified a positive association between congenital cryptorchidism and levels of PBDEs (Main et al., 2007). Newborn boys evaluated in this study were from an area of considerable production rates of PBDEs, resulting in increased levels of concern. It is anticipated that further investigation will occur that may also take into account other potential environmental contaminants.

Dioxins are polyhalogenated compounds that are considered to be ubiquitous environmental pollutants. The most widely studied of these is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). The spectrum of adverse effects induced by this class varies with specific compounds and also tends to be species dependent. Developmental toxicity in mammals includes decreased growth, structural malformations,

functional alterations, and prenatal mortality; at low exposure levels, structural malformations are not common (Peterson et al., 1993). Functional alterations are the most sensitive signs of developmental toxicity and include adverse effects on male reproductive structures and reproductive behavior in rats and neurobehavioral deficits in monkeys. The ectodermal dysplasia syndrome described for PCBs and PCDFs has also been observed in humans as a result of exposure to high levels of TCDD in Seveso, Italy, as well as in rats and monkeys exposed to TCDD *in utero* or via lactation (Yasuda et al., 2005). Altered sex ratio was also reported in births following the Seveso incident, with an excess of females compared to males (Yoshimura et al., 2001).

A specific pattern of structural malformations has been reported in mice exposed to TCDD *in utero*, which includes cleft palate; hydronephrosis and thymic hypoplasia have also been observed. These changes occur in the absence of maternal toxicity and embryo/fetal toxicity. Mice appear to be highly susceptible to TCDD-induced teratogenesis, as other species demonstrate maternal and embryo/fetal toxicity but are not as susceptible to malformations (Couture et al., 1990). In contrast, mice are not as sensitive to TCDD-induced developmental reproductive toxicity as compared to rats and hamsters. *In utero* exposure of male rats to low doses of TCDD resulted in reduction in numbers of sperm per cauda epididymis, daily sperm production, and sperm transit rate through the cauda epididymis when evaluated as adults (Faqi et al., 1998). These rats also had increased numbers of abnormal sperm, increased mounting and intromission latencies (measures of male sexual behavior), and, at the highest dose tested, reduced testosterone. Decreases in daily sperm production did not occur in mice exposed to TCDD during gestation and lactation; the only effect common to rats and mice was a reduction in epididymal sperm numbers (Theobald and Peterson, 1997). Reduction in anogenital distance has been reported in male rats exposed to TCDD *in utero* but not in male hamsters (Birnbaum, 1995). Reproductive alterations have also been reported in female rats and hamsters exposed to TCDD during gestation and lactation and include cleft phallus/clitoris, hypospadias, and/or delayed/incomplete vaginal opening (Birnbaum, 1995).

Trichloroethylene and Perchloroethylene Ingestion of TCE in drinking water has been associated with cardiac malformations in children exposed *in utero*. A study conducted in 1973 noted that congenital heart disease appeared to be increased in a small area of the Tucson Valley in Arizona; a subsequent study of a similar area found that the groundwater was contaminated with TCE, and to a lesser extent, dichloroethylene (DCE) and chromium. Follow-up of offspring from parents living in this area at the time of contamination prior to or during the first trimester of pregnancy revealed a significant association, but not a cause-and-effect relationship, between parental exposure and an increase in congenital heart disease

(Goldberg et al., 1990). Cardiac malformations were also observed in fetuses from rats administered TCE or DCE directly to the uterus during gestation days 7–22 (Dawson et al., 1990). Cardiac malformations, including atrial and ventricular septal defects and defects of aortic, pulmonary, and mitral valves, were observed with both TCE and DCE. Cardiac malformations were also observed in a study by Smith et al. (1989), in which oral intubation on gestation days 6–15 resulted in interventricular septal defect and levocardia. Subsequently, Johnson et al. (1998) studied TCE metabolites TCA, monochloroacetic acid, trichloroethanol, carboxy methycystine, trichloroacetaldehyde, dichloroacetaldehyde, and dichlorovinyl cystine given in drinking water to rats throughout pregnancy. Cardiac malformations of the same nature as those observed with TCE and DCE were observed with TCA only. Interventricular septal defect and levocardia were observed following oral gavage administration to rats on gestation days 6–15 (Smith et al., 1989).

A number of studies in laboratory animals have evaluated effects of TCE, PERC, and metabolites on development using a variety of routes of administration and developmental periods of exposure. In addition to the cardiac malformations associated with TCE, DCE, and TCA, impaired embryo/fetal survival and growth were the most commonly observed adverse effects. Human studies have yielded equivocal effects, but there is some evidence of association between TCE exposure and intrauterine growth impairment (National Research Council, 2006).

Prenatal exposure to TCE has also been associated with postnatal functional impairment. Peden-Adams et al. (2006) evaluated the immune function in mice exposed to TCE from gestation day 0 through 3 or 8 weeks of age. Trichloroethylene caused increased hypersensitivity responses and increased numbers of thymic CD4+ and CD8+ cells at 8 weeks of age, suggesting that TCE is a developmental immunotoxicant. A cross-species comparison of PERC identified developmental neurotoxicity as an additional adverse effect and concluded that neurotoxicity was the most sensitive end point for inhalation exposure, while growth retardation was the most sensitive end point for oral exposure (Beliles, 2002). This review concluded that with regard to reproductive and developmental toxicity of PERC, in most cases there was concordance between rodent and human effects.

Hexachlorobenzene Hexachlorobenzene (HCB) was formerly manufactured as a fungicide; however, due to adverse human health effects that occurred from a contamination incident in Turkey, it is currently not in use for this purpose in most countries. At present it is found as a by-product or a contaminant from production of other chlorinated products such as industrial solvents and pesticides (Ando et al., 1985; Goldey and Taylor, 1992). The major route of human exposure to HCB is through the diet. Following absorption,

HCB accumulates in the adipose tissue and persists for many years since it is highly lipophilic and resistant to metabolism (Weisenberg, 1986). It is transferred to the human fetus and newborn through the placenta (Weisenberg, 1986) and breast milk (Watanabe et al., 1990). It crosses the blood–brain barrier and is known to be a developmental neurotoxicant. Watanabe et al. (1990) studied several neurotoxicant chemicals with pre or postnatal exposure and determined that blood–brain barrier transfer, which varies with lipid solubility, is a major factor in developmental neurotoxicity. Goldey and Taylor (1992) treated female rats with HCB for 4 days, and 2 weeks later mated them with untreated males. Offspring tested at various times during the postnatal period were hyperactive and demonstrated age-dependent changes in the acoustic startle response. The amplitude of the startle response was decreased on postnatal day 23 but increased on postnatal day 90; the reason for difference in response at these ages is unknown.

Mortality rates were high among children of lactating mothers in Turkey who ate bread contaminated with HCB. According to one report, all children born to mothers with porphyria, an effect of high dose HCB, died (ATSDR, 1990). Children nursed by mothers exposed to HCB showed pink sores on their skin and experienced weakness, convulsions, and annular erythema. Maternal blood and breast milk concentrations of HCB were unknown. Estimates of HCB consumption in bread during this period were 0.05–0.2 g/day (Ando et al., 1985).

Vinyl Chloride Vinyl chloride, also known as vinyl chloride monomer, is used primarily to produce the polymer polyvinyl chloride, which is a widely used plastic. Exposure of pregnant mice, rats, and rabbits to high concentrations of vinyl chloride resulted in no malformations; however, fetotoxicity, characterized by reduced survival, decreased body weight, and induction of anatomical variations occurred in mice and/or rats exposed during development (John et al., 1977). Vinyl chloride is mutagenic in most major short-term tests (California Environmental Protection Agency, 2000) and is known to induce a rare cancer of the liver in humans (U.S. EPA, 2000b). It is also a liver carcinogen in rats, mice, and hamsters when administered at high concentrations by inhalation to adult animals in lifetime studies. In these studies, tumors of the liver, nasal cavity, kidneys, Zymbal's gland, and blood vessels were attributed to vinyl chloride exposure. Maltoni et al. (1981) determined that *in utero* exposure of rats to vinyl chloride during a critical phase of development also induces tumors of the kidneys, Zymbal's gland, and blood vessels. A review by Rice (1981) concluded that vinyl chloride is a transplacental carcinogen in rats when administered at high concentrations to pregnant animals. The mechanism of action involves metabolic conversion of vinyl chloride to reactive intermediates such as chlorooxirane in the maternal and fetal tissues.

Several studies have reported significantly higher rates of developmental effects, such as fetal loss and congenital malformations, in communities containing vinyl chloride polymerization facilities. However, these studies did not show any significant correlation between developmental effects and proximity to vinyl chloride facilities or occupational exposure of either parent (Infante, 1976; Thériault et al., 1983; Rosenman et al., 1989; ATSDR, 1995). The apparent contradiction in these findings may be explained by confounding factors such as other industrial emissions.

Metals

Arsenic Arsenic is a metalloid that is ubiquitous in the environment and is also used commercially. Although both inorganic and organic forms exist in nature, the inorganic forms are considered to be more toxic (Golub et al., 1998). Exposure of humans to inorganic forms of arsenic occurs primarily in drinking water, as well as in food and from environmental contamination. Sources of environmental arsenic include glass and copper smelters, coal combustion, and uranium mining (Dyer, 2007). Inorganic forms of arsenic include trivalent (arsenite) and pentavalent (arsenate) forms, which are readily absorbed from the gastrointestinal tract (Waalkes et al., 2003; Dyer, 2007). These forms of arsenic have been most commonly used in laboratory animal experiments.

Arsenic is considered to be a human carcinogen: Chronic exposure of adults to high concentrations of at least several hundred µg/l may cause cancer of the skin, urinary bladder, lung, liver and prostate, and possibly of other tissues (Brown and Ross, 2002; Waalkes et al., 2003). Evidence also exists that arsenic is a transplacental carcinogen. Examination of a cohort of individuals from Chile who were exposed *in utero* or during early childhood to high concentrations of arsenic in contaminated drinking water revealed an increase in mortality as young adults from both malignant and nonmalignant lung disease (Smith et al., 2006). The ability of arsenic to induce transplacental carcinogenesis has been confirmed in mice, with tumors occurring at multiple sites. Offspring of female mice given sodium arsenite daily during gestation days 8–18 had dose-related increases in the incidence and multiplicity of liver tumors and adrenal tumors; the incidences of ovarian tumors and lung carcinoma were also increased (Waalkes et al., 2003). In addition, proliferative lesions were increased in the uterus and oviduct. The tumor spectrum induced by arsenic is considered to resemble that of estrogenic carcinogens and is associated with estrogen-linked genes (Liu et al., 2008). In addition, limited *in vitro* studies with MCF-7 breast cancer cells, as well as estrogen binding assays and receptor activation assays, suggest that arsenic may have an estrogenic activity (Dyer, 2007).

Arsenic has also been associated with spontaneous abortion and stillbirth in cases of human exposure to high levels,

although interpretation of these case reports is complicated in some instances by potential exposure to other environmental contaminants (Golub et al., 1998). Developmental toxicity has been demonstrated in hamsters, mice, rats, and rabbits. Adverse effects included malformation, death, and growth retardation and were dependent on the dose, route of administration, developmental period of exposure, and form of arsenic tested; agents that chelate arsenic were found to protect against developmental toxicity (Golub et al., 1998).

Cadmium Cadmium is embryotoxic and teratogenic in laboratory animals. Ovarian cadmium has been associated with failure of progression of oocyte development from the primary to the secondary stage and failure to ovulate. It is also known to disrupt movement of the secondary oocyte into the oviduct, where combination with the spermatozoa normally would result in fertilization (Thompson and Bannigan, 2008). Decreased implantation of the resulting embryo has been found to result from cadmium exposure at doses that fail to disrupt early development of the embryo in vitro. Higher doses inhibit progression to the blastocyst stage and can cause degeneration and compaction in the blastocyst, with apoptosis and breakdown in cell adhesion followed by implantation failure. Cadmium has been shown to accumulate in embryos, beginning at the four-cell stage. Damage to trophoblast cells surrounding the early embryo, including inhibition of trophoblastic invasion, reduced steroidogenesis, and adjusted handling of nutritive metals such as calcium and zinc, can lead to necrosis of the placenta. While little cadmium crosses the placenta, it is known to concentrate in the placental tissue (Piasek et al., 2001; Satarug and Moore, 2004).

As mentioned previously, a predominant source of cadmium in the environment of non-polluted areas is tobacco smoke, and it has been reported that placentas from smokers have double the cadmium concentration of nonsmokers. Placental cadmium resulting from maternal exposure to industrial wastes or tobacco smoke has been associated with reduced progesterone biosynthesis by the placental trophoblast (Piasek et al., 2001). Recurrent miscarriage and uterine fibroids were linked to increased cadmium in a German cohort of infertile women (Gerhard et al., 1998). Maternal exposure to cadmium has been associated with low birth weight and an increased risk of spontaneous abortion, and cadmium has been reported to accumulate in high concentrations in the placenta (Henson and Chedrese, 2004). In perfused human placentas, the secretion of human chorionic gonadotropin (hCG), a hormone vital to early pregnancy maintenance, was reduced by exposure to cadmium (Wier et al., 1990).

Although placental transfer of cadmium is limited, a wide range of abnormalities has been reported in laboratory animals, which are dependent on the stage of developmental exposure, species, strain, dose, and route of administration (Schoeters et al., 2006). These abnormalities include

craniofacial, neurological (including neural tube closure), cardiovascular, gastrointestinal, and genitourinary, as well as limb anomalies. During critical periods of development, prenatal exposure to cadmium at doses that cause no overt maternal toxicity may have postnatal, adverse behavioral sequelae that persist into adulthood (Ali et al., 1986). Limb deformities were also seen at dosages that did not cause a reduction in fetal body weight (Soukupova and Dostal, 1991). While human malformations have not been reported with cadmium, maternal exposure has been associated with low birth weight and increased preterm deliveries (Satarug and Moore, 2004). The smaller size of the infants was attributed to early delivery.

Lead Lead is considered to be a human developmental toxicant. Animal studies indicate that effects from lead absorption in developing offspring are seen at lower doses than those needed to cause overt toxicity in the adult, suggesting a more vulnerable fetus (Sikorski et al., 1989; Levallois et al., 1991; McGivern et al., 1991). Lead can potentially be transferred to a developing child via the placenta or breast milk. Occupational risks include abortion, stillbirth, postnatal death, and congenital malformations. Early fetal loss may be one of the most sensitive measures of lead reproductive toxicity (Sweeney and LaPorte, 1991). Lead is also a human developmental neurotoxicant. Lead-based paint remains the most common source of lead exposure for children <6 years of age, with a 2–4-point IQ deficit for each µg/dl increase in blood lead within the range of 5–35 µg/dl (Liu et al., 2008). Blood lead concentrations as low as 10–15 µg/dl in children have been associated with hyperactivity, poor fine motor control, decreased gestational age, low birth weight, poor academic achievement, and intelligence deficit (Suzuki and Martin, 1994). Prenatal lead exposure has also been associated with reduced intellectual development in children, with a critical period occurring around 28 weeks of gestation (Schnaas et al., 2006). Lead crosses the placenta and accumulates in fetal tissues in an amount proportional to maternal blood lead levels (Goyer, 1996). It has been measured in the human fetal brain as early as the end of the first trimester (13 weeks) (Goyer, 1990). Absorption and retention of lead may be significantly increased in later stages of pregnancy (Donald et al., 1986).

Acute lead encephalopathy, characterized by a swollen, edematous brain with proteinaceous exudates around blood vessels, petechial hemorrhage, and capillary necrosis may be produced at higher concentrations and is more severe in children than in adults; motor peripheral neuropathy may be seen as a functional consequence (Suzuki and Martin, 1994). Fetuses may be even more sensitive to cell-specific effects in the nervous system than are children. One of the proposed mechanisms of lead-induced neurotoxicity is swelling of the brain due to altered capillary permeability; immature endothelial cells may be less resistant to this effect, permitting lead

to reach newly formed brain cells (Goyer, 1990). Intracellular lead can affect binding sites for calcium, which in turn can impact functions such as neurotransmitter release. Other potential mechanisms include indirect effects on cognitive development through lead-associated alterations in birth weight and gestation (Dietrich et al., 1987).

Effects on survival and development of offspring have been reported following maternal and paternal exposure to lead. Chronic paternal blood lead levels of >40 µg/dl or 25 µg/dl have been associated with increased risk of spontaneous abortion or reduced fetal growth, while maternal blood levels of approximately 10 µg/dl have been associated with increased risks of pregnancy hypertension, spontaneous abortion, and reduced offspring neurobehavioral development, with somewhat higher levels associated with reduced fetal growth (Bellinger, 2005). Delayed growth and pubertal development have been reported in girls and are likely related to disruption of the H-P-G axis (Dyer, 2007). There is currently insufficient evidence to provide a definitive association between parental lead exposure and structural malformations.

Mercury Methylmercury is a well-known human teratogen, having first been documented in 1952 following contamination of Minamata Bay, Japan, and subsequent ingestion of contaminated seafood. Methylmercury poisoning was thereafter referred to as Minamata disease. Subsequent contaminations have occurred in Niigata, Japan; Sweden; the former Soviet Union; Iraq; and the United States. Methylmercury primarily targets the CNS; it is readily absorbed by the gastrointestinal tract, crosses the placenta, concentrates in the fetus, and ultimately crosses the fetal blood–brain barrier (Seegmiller, 1997). Clinical signs of toxicity resulting from *in utero* exposure included cerebral palsy, malnutrition, blindness, delayed speech development, severe hearing impairment or deafness, motor impairment, tremors, convulsions, abnormal reflexes, mental retardation, abnormal electroencephalograms (EEGs), excessive crying and irritability, and pathologic changes in the CNS (Suzuki and Martin, 1994). Most methylmercury-exposed mothers with affected infants showed no symptomatology.

Rates of spontaneous abortion among wives of 152 workers occupationally exposed to mercury vapor were reported to be higher than rates in wives of 374 control (unexposed) workers in the same plant (Cordier et al., 1991). The authors speculated that the mechanism of toxicity could include direct effects of mercury on the male reproductive system and indirect toxicity to the mother or embryo through transport of mercury from the father. Subsequent investigations of pregnant women occupationally exposed to metallic mercury in dental offices found that elevated mercury levels could be found in their placentas and fetal membranes, but these exposures were apparently not sufficient to cause developmental toxicity because there was no increase in spontaneous abortion rates and no defects found in the

offspring. A questionnaire administered among men and women working in a dental environment found no differences in the rates of spontaneous abortions or congenital malformations (Brodsy et al., 1985).

Placental transfer of mercury varies according to the chemical form of the mercury compound (Messite and Bond, 1988). For example, methylmercury readily crosses the placenta, while inorganic mercury does not. In addition, mercury metabolism in fetuses appears to be much different from metabolism in mothers, possibly because of different blood circulation (Harbison, 1998). Despite these differences, laboratory animal data have demonstrated adverse effects on the reproduction and development with all chemical forms of mercury tested; these effects include impaired implantation of the embryo, spontaneous abortion, stillbirths, decreased birth weight, congenital malformations, and behavioral effects on exposed offspring (Messite and Bond, 1988; Rowland et al., 1994; Schuurs, 1999).

DEVELOPMENTAL TOXICOLOGY

THOMAS A. LEWANDOWSKI

This chapter will deal with adverse effects of workplace chemical exposures on child development, starting from effects after the point of conception up through adulthood. However, one should not make too strong a distinction between the effects of exposures occurring before or after conception (i.e., reproductive versus developmental toxicology) because exposures of both female and male workers prior to conception, which do not prevent conception may nonetheless have implications for later child development (Hooiveld et al., 2006; Cordier, 2008). Thus the reader is advised to consider both reproductive and developmental toxicology when evaluating potential workplace exposures.

It is also worthwhile to define some of the terms used in this subfield of toxicology. A *teratogen* is a chemical that causes malformation (birth defects, terata) in the developing organism. Not all developmental toxicants are teratogens. Some may cause death of the embryo or fetus without producing any observable defect. Alternatively, chemicals may also produce decreases in fetal body weight, a particularly sensitive indicator of developmental toxicity. All of these effects may be attributed to *developmental toxicants*. Developmental toxicologists are particularly concerned with agents that exert a selective or greater toxicity to the developing organism relative to the adult. That is, the agent causes effects on the developing organism at doses below those associated with parental toxicity. This narrower definition is necessary because at doses that are maternally toxic, one cannot tell whether the chemical is acting specifically on the fetus or affecting maternal health to such an extent that fetal health is indirectly compromised. The focus on agents that are

selectively toxic to the fetus is appropriate because general occupational exposure limits are set to protect the health of working adults and thus address the potential for indirect harm due to maternal systemic toxicity.

PRENATAL EXPOSURES

The potential impact of workplace exposures on reproduction and development is a significant concern. Approximately 75% of all women will become pregnant at least once during their working life (Alpert and Cawthorne, 2009) and 80% of all pregnant women who work will do so up until the last month of their pregnancy. It was at one time believed that the placenta effectively isolated the fetus from potentially harmful maternal chemical exposures. It is now known that the placenta is only a limited barrier and in fact may actively transport or metabolize many chemicals, potentially allowing them to accumulate in fetal tissues (Myllinen et al., 2005). Indeed for some chemicals (e.g., mercury, dioxins, chlorinated pesticides), the fetus may constitute an important sink for maternal exposures. On the other hand, maternal metabolism may significantly attenuate a chemical dose before it reaches the fetus, potentially preventing fetal exposure from reaching adverse effects levels (Figure 111.1). The nature of maternal/fetal dosimetry is unfortunately chemical specific and not easily predicted. The increasing availability of physiologically-based toxicokinetic (PBTK) models of chemical disposition during pregnancy (summarized by Corley et al., 2003) may help to resolve this particular challenge in developmental toxicology.

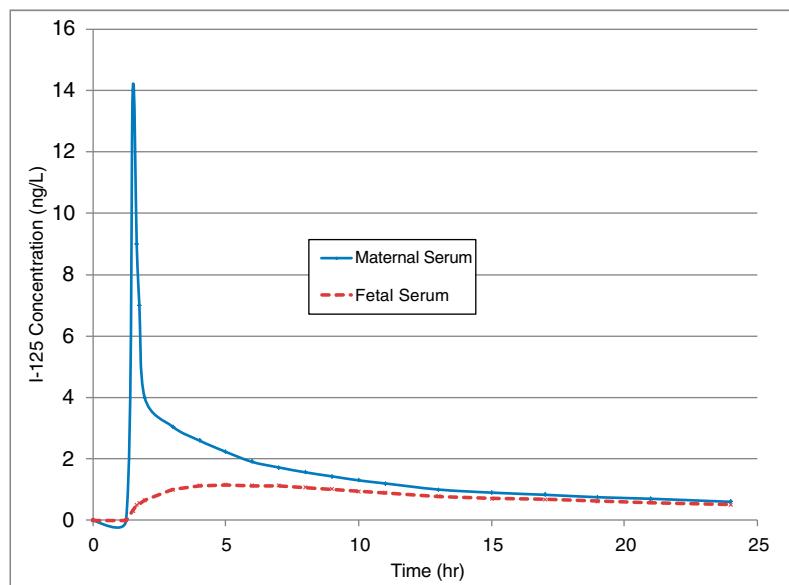

FIGURE 111.1 Effect of maternal metabolism on fetal exposure. *Source:* Data taken from the study of Clewell et al. (2003) involving radioiodine exposure.

PRENATAL DEVELOPMENT AND WINDOWS OF SUSCEPTIBILITY

The process of human development is truly an amazing process. The daughter cells of a fertilized egg, after attaching themselves to the uterine wall (thereby becoming an embryo), will undergo rapid division, rearrangement and migration, producing a fetus (at 8–9 weeks postfertilization in humans) with all of the developing tissues in their proper proportions and locations in the body. These activities are under the control of various chemical signals encoded in the embryo's DNA, which direct details such as the location and orientation of the developing limbs and the positioning of different brain regions. A large number of scientific studies have shown that if some event occurs to interfere with one of those signals, a specific birth defect related to the signal's intended target is likely to ensue. Due to the specifically timed nature of embryonic development, there exist “windows of susceptibility” when particular tissues may be affected by chemical exposure (Wilson, 1965; Rodier, 1977; Adams et al., 2000). For example, research has shown that the industrial solvent 2-methoxyethanol produces brain malformations in rats when administered on the seventh and eighth day of gestation but paw malformations when administered on gestational day 11 (Clarke et al., 1992; Terry et al., 1994). In general, chemical exposures early in development (in the first week of pregnancy) will likely result in either no effect or complete loss of the embryo, exposures during the period of main organ formation (called organogenesis, approximately weeks 3–8 in humans) may lead to visible gross deformities, and exposures during the latter part of pregnancy may result in reduced

infant size, functional deficits or prematurity but not in gross malformations (Figure 111.2). As shown in Figure 111.2, for many tissues the key period of organogenesis occurs before the end of the first trimester, a key time point when pregnant women often choose to disclose their pregnancy status. It is thus important to encourage employees to inform health and safety personnel of their pregnancy (or intended pregnancy) as early as possible.

POSTNATAL EXPOSURES

The period of concern for developmental toxicity does not cease at birth. In addition to whatever chemical body burden the child receives prior to birth, the child may receive exposure via breast milk if the mother elects to breastfeed her infant. Most advisory agencies recommend that mothers breastfeed their infants for at least the first 6–24 months of life (e.g., WHO, 2003). Highly lipophilic (i.e., fat soluble) chemicals, including some pesticides and chlorinated compounds may concentrate in breast milk at levels higher than in maternal serum (Wang and Needham, 2007). Certain inorganic chemicals (e.g., iodide, thiocyanates, perchlorate) may accumulate in breast milk and may be associated with higher levels of exposure to the neonate (Azizi and Smyth, 2009). It is important to note that for the first few months of life, milk constitutes the sole source of dietary exposure for the child and the child's consumption rate of milk is high relative to his/her body weight.

Throughout the entire period of childhood, children may also experience exposures due to chemicals brought into the

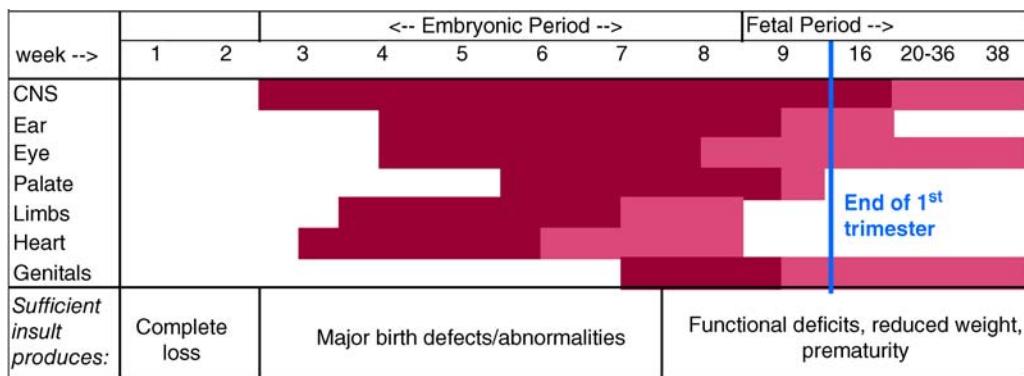

FIGURE 111.2 Windows of in utero susceptibility to chemical agents. Darker shading represents the period of greatest vulnerability. Adapted from Moore and Persaud, 1973.

home from the workplace on contaminated clothes or equipment. Because children have unique physiological and behavioral traits (e.g., proportionally higher inhalation rates, crawling and mouthing behaviors), they may be more at risk from these exposures than an adult. Although the use of dedicated work clothing left at the job site is now common in some fields, this so-called para-occupational exposure may be important in jobs where the risks of developmental toxicity are less well recognized or in cases where chemical exposure patterns are highly variable.

POSTNATAL SUSCEPTIBILITIES

From birth to the late teens the child's body grows and matures, becoming increasingly adult like. It would be incorrect, however, to assume that the progression is strictly linear. The pattern of growth and development during childhood is complex and varies among different organ systems. Of particular concern for chemical exposure, children are born with limited metabolic capacity for many chemicals compared to an adult and chemical half-life may therefore be considerably increased. The maturation of the child's metabolic capacity is substrate specific but is amenable to a few generalizations. Children are born with much less Phase I enzyme metabolic capacity (e.g., lower cytochrome P450 activity levels) than the adult, although for many enzymes children reach adult levels around age 2 (Alcorn and McNamara, 2002, 2003; de Zwart et al., 2004). Phase II (conjugating) enzyme metabolism may be slower to develop (particularly glucuronidation), although compensatory pathways (e.g., sulfation) may partially offset this metabolic limitation (Alcorn and McNamara, 2002).

TESTING FOR DEVELOPMENTAL TOXICITY

Much of the data used in assessing developmental and reproductive toxicity (DART) concern for workers comes from

standard toxicity tests conducted in animals rather than studies in humans. While data from observational studies of exposed workers are highly relevant to the worker scenario, these studies are typically limited in number and are usually complicated by simultaneous exposures to multiple chemicals. Because animal testing forms the basis for many developmentally-based occupational exposure limits, it is worth describing how such tests are performed. Standard test protocols used in Western countries used to assess potential reproductive and developmental toxicity are summarized in Table 111.1.

Animal studies are used to identify no observed adverse effect levels (NOAELs) or lowest observed adverse effect levels (LOAELs), which are then divided by uncertainty factors (accounting for interspecies differences and sensitive subgroups) to arrive at an acceptable exposure level (Threshold Limit Value (TLV), WEEL, etc.). Studies in other species (fish, insects, birds) may also be available for particular compounds; however, these studies are generally not used to establish safe human exposure levels due to the greater degree of interspecies differences and the lack of standardized testing protocols. As noted above, studies that report DART effects at levels only above those causing general toxicity in the parental animals may lead one to conclude that the chemical in question does not cause selective developmental toxicity and risks are adequately controlled using an exposure limit based on preventing maternal toxicity.

SPECIFIC AGENTS

Metals

A number of metals have long been implicated as potential DART agents, most notably lead and mercury. Exposure to lead is possible in a number of industries, including metal smelting, lead mining and processing, battery reclamation, repair industries (due to soldering activities) and construction (e.g., due to exposure to existing lead-based paint) (ATSDR, 2007). Exposure to lead resulting in high blood lead levels

TABLE 111.1 Standard Animal Tests for Assessing DART Effects

Test	OECD Guideline Number	Typical Test Species	Exposure Design	Endpoints Considered
One generation reproduction toxicity study	415	Rats, mice	At least 1 spermatogenic cycle (e.g., 56 days in mice, 70 days in rats)	Litter size, litter weight, gross anomalies, microscopy of reproductive organs
Two generation reproduction toxicity study	416	Rats, mice	Exposure of first parental generation prior to mating, exposure of the first generation of offspring from birth through weaning of the second generation	Litter size, litter weight, gross anomalies, microscopy of reproductive organs, analysis of all three generations
Prenatal developmental toxicity study	414	Rat, rabbit	Exposure from implantation to just before birth (delivery by caesarean section)	Litter size, litter weight, maternal reproductive organs, skeletal and soft tissue malformations
Reproduction and developmental toxicity screening study	421	Rat	54 days (males and females) both exposed pre and postmating	Newborns examined 4 days post-birth; assesses reproductive success, fetal development and birth
Combined reproductive, developmental and repeated dose toxicity study	422	Rat	Combination of OECD 421 and OECD 408 (28-day repeated dose study for assessing general toxicity)

(>80 µg/dl) in children produces overt toxicity in the form of encephalopathy, anemia, and renal tubular damage (ATSDR, 2007), although such effects are extremely rare today. Beginning in the 1970s, studies suggested that children with blood lead concentrations well below this level (e.g., 30 µg/dl and below) had apparent deficits on various psychological tests, including IQ, attention, and behavior (notably Needleman et al., 1979). As a result of these studies, major efforts have been undertaken to reduce children's lead exposure and have met with considerable success. The most recent CDC blood lead data indicate a geometric mean of 1.9 µg/dl in children aged 1–5 (Jones et al., 2009). There is currently debate concerning the existence of a threshold for lead neurodevelopmental toxicity. Defining a threshold is difficult because at exposure levels associated with blood lead values <10 µg/dl, effects are subtle and only detectable on a population level (CDC, 2007).

Regarding occupational exposures, lead is known to cross the placenta and children born to mothers with elevated blood lead levels show elevated blood lead concentrations compared to children born to unexposed mothers (Goyer, 1990). The potential for *in utero* lead exposure is the primary basis for the Occupational Safety and Health Administration (OSHA) lead standard. It should be noted, however, that because children display a higher GI absorption capacity for lead compared to adults (O'Flaherty, 1998; Leggett, 1993) and also exhibit hand-to-mouth behaviors, significant postnatal exposure to

lead dust can occur if the material is brought into the home from the workplace (i.e., para-occupational exposure). In investigating potential occupational lead poisoning cases, the industrial hygienist should also be aware of potential worker exposures via the use of lead containing folk remedies, cosmetics, lead glazed dishware, or hobby materials, all of which can provide substantial exposures (ATSDR, 2007). For reference, the average blood lead level in pregnant women in the United States in the time period between 2003 and 2008 has been reported as 0.69 µg/dl (Jones et al., 2010).

The organic forms of mercury (notably methylmercury) are most strongly connected with neurodevelopmental problems (Aschner et al., 2010; Davidson et al., 2004; Castoldi et al., 2001), but these are unlikely to be present in the workplace outside of specific research laboratories (ATSDR, 1999). Exposures to methylmercury arise from microbial methylation of inorganic mercury in aquatic sediments, bioaccumulation in aquatic food chains and subsequent human fish consumption. Occupational exposures are therefore more likely to involve inorganic mercury salts (mercurous, mercuric) or elemental mercury. Occupations with the highest potential for non-organic mercury exposure include those involving chloralkali processes, production of mercury-containing instruments (e.g., pressure gauges, fluorescent lighting), waste disposal and recycling, and dental work with amalgam fillings (ATSDR, 1999). The data concerning the potential developmental toxicity of these forms of mercury are quite limited. In

studies in which pregnant rats were exposed via inhalation to elemental mercury, it was observed to cross the placenta and accumulate in fetal tissues (Yoshida, 2002; Morgan et al., 2006). However, gross developmental effects (e.g., increased fetal loss, reduced fetal body weight) have only been observed at mercury vapor exposures which also produced maternal toxicity (maternal NOAEL = 4 mg/m³; developmental NOAEL = 8 mg/m³) (Morgan et al., 2002). A number of studies have indicated behavioral differences in the offspring of animals exposed to elemental mercury during pregnancy (Danielsson et al. 1993; Fredriksson et al. 1996; Newland et al., 1996). Studies among dental personnel, the best studied occupational group exposed to elemental mercury, have produced generally negative findings (Heggland et al., 2011; Lindbohm et al., 2007; Olfert, 2006). As regards the inorganic mercury salts, specific developmental toxicity data are lacking in both experimental animals and humans. Mercurous chloride (calomel) has been documented to produce skin inflammation, irritability, and other symptoms in children treated with this compound as a pharmaceutical (i.e., Pink disease) (Black, 1999). However, the doses involved (i.e., intentional treatment) are likely to be greater than those associated with potential para-occupational exposure. Unlike organic and elemental mercury, inorganic mercury does not readily cross the placenta (Yang et al., 1996), so developmental toxicity from *in utero* exposure is not likely. For reference, data collected by the CDC for the period of 2003–2008 indicate that the average blood mercury level in women aged 18–49 was 0.7 µg/l (Jones et al., 2010).

The evidence linking other industrial metals with DART effects is generally more limited and equivocal in nature. For example, animal studies of arsenic have indicated no developmental effects when exposures are via the inhalation route. Effects are observed in animals exposed to arsenic via injection or drinking water but these forms of exposure are not relevant to the occupational setting (DeSesso et al., 1998; DeSesso, 2001; Wang et al., 2006; Vahter, 2008). Arsenic is more poorly absorbed via inhalation exposure relative to absorption from the GI tract and thus the peak dose in drinking water and injection studies is likely to be much higher (DeSesso, 2001). Epidemiology studies of arsenic-exposed populations are equivocal and present contradictory findings (DeSesso et al., 1998). Thus the human relevance of arsenic's potential developmental toxicity is still a subject of debate, and risk assessments and exposure guidelines are driven by concerns regarding carcinogenicity. For other metals, the reader is directed to chemical-specific sections of this book.

Halogenated and Aromatic Hydrocarbon Solvents

Exposures to halogenated and/or aromatic hydrocarbon solvents are widespread and can be found in a variety of occupations, including those involving dry-cleaning, parts degreasing, painting and paint removal, printing, and

petrochemical processing (Kumar, 2004). Studies of occupationally exposed populations have suggested associations between exposure to solvents and adverse developmental outcomes but such studies are often complicated by simultaneous exposures to multiple chemicals and a limited ability to control for important nonoccupational exposures (e.g., ethanol consumption and smoking). Among this large group of chemicals, data are most extensive and suggestive for tetrachloroethylene (PCE), trichloroethylene (TCE), and toluene.

The strongest evidence of an association between PCE and developmental effects comes from occupational studies published in the late 1980s and early 1990s, which showed an association between PCE exposure and risk of spontaneous abortion (e.g., Kyyronen et al., 1989; Olsen et al., 1990; Windham et al., 1991). These studies generally lacked quantitative estimates of dose and relied on more qualitative assessments (e.g., ever exposed, low versus high exposure). Despite methodological weaknesses in these studies, and lack of supporting evidence from animal studies (Carney et al., 2006; Schwetz et al., 1975), the UK committee of independent scientists concluded that the effects observed in the occupational studies could not necessarily be discounted. In 1994, the United Kingdom's Health and Safety Executive commissioned a large ($n = 3517$), retrospective occupational cohort study of women currently or previously employed in dry-cleaning operations. This study, by Doyle et al. (1997) observed statistically significant increased spontaneous abortion risks among workers engaged in dry-cleaning operations relative to those not engaged (OR: 1.67; 95% CI: 1.17–2.36). Risks were not increased for individuals working at dry-cleaning establishments but not running dry-cleaning equipment (OR: 1.02; 95% CI: 0.65–1.60). Although results from the larger study by Doyle et al. are consistent with results from the earlier studies in showing associations between dry-cleaning work and spontaneous abortion; a biological mechanism by which PCE could cause spontaneous abortions has not been established. Exposure levels in the study population were also not quantified but were likely higher than those encountered in workplaces today (e.g., the American Conference of Governmental Industrial Hygienists (ACGIH) TLV for PCE was 100 ppm prior to 1981, 50 ppm prior to 1992 and set to 25 ppm in 1993). An animal study by Carney et al. (2006) does not provide evidence that PCE causes spontaneous abortions, but did indicate fetotoxicity at PCE concentrations that were not maternally toxic, and thus provides evidence that PCE is a developmental toxicant in rodents. Fetal effects included reduced body weights and decreased ossification of thoracic vertebrae at 600 ppm, and minor decreases in body weight at 250 ppm; there were no developmental effects at 65 ppm.

Notable evidence for TCE-associated developmental toxicity relates to cardiac effects, which have been observed in both humans and animals. A study by Bove et al. (2002) observed a significantly increased prevalence of cardiac abnormalities in children of parents residing in areas where drinking

water wells were contaminated with TCE in drinking water, compared with children of parents residing in uncontaminated areas (PR 2.58; 95% CI: 2.0–3.4). Cardiac defects were also significantly elevated in children whose parents resided in areas with high soil vapor concentrations of TCE and other VOCs (OR 1.94; 95% CI 1.21–3.12) (ATSDR, 2006). Results from some, but not all, animal studies support the epidemiological findings. For example, cardiac defects have been observed in rats exposed *in utero* to trichloroethylene, or the metabolites trichloroacetic acid (TCA) and dichloroacetic acid (DCA) in studies involving repeated exposure via the oral route (Dawson et al., 1993; Smith et al., 1989, 1992). The lowest exposure level at which effects were observed was 1.5 ppm in drinking water or approximately 0.15 mg/kg/day (Dawson et al., 1993). Cardiac effects were not observed in another study involving oral exposure (Fisher et al., 2001; TCE exposure at 500 mg/kg/day) or a study involving whole-body inhalation exposure (e.g., Carney et al., 2006). The Carney et al. study reported slight decreases in fetal and placental weight with a NOAEL of 65 ppm.

As regards the aromatic hydrocarbon solvents (benzene, ethylbenzene, toluene, and xylene) the evidence for the developmental toxicity of toluene is most clearly established. Toluene has been shown to cause congenital defects (similar to fetal alcohol syndrome) in infants born to mothers who abused toluene during pregnancy. Exposure levels in such cases would be exceptionally high (i.e., several thousand ppm; Bowen and Hannigan, 2006). Animal studies likewise have revealed malformations and reduced fetal body weight in animals exposed at concentrations in excess of 1000 ppm but no effects at concentrations in the 200–400 ppm range (Jones and Balster, 1997; Thiel and Chahoud, 1997; Jarosz et al., 2008). Thus toluene exposures at the current federal permissible exposure limit (PEL) (200 ppm, time-weighted average (TWA)) would not be expected to have developmental consequences. Data for ethylbenzene and xylene have generally been negative. For example, Saillenfait et al. (2007) reported no embryolethal or teratogenic effects in rats exposed to ethylbenzene on gestational days 6 through 20 at 250 or 1000 ppm, the higher dose producing reductions in both maternal and fetal body weights. The same research group observed a similar lack of effects for *m*- and *p*-xylene at concentrations up to 1000 ppm, a dose that produced maternal toxicity (Saillenfait et al. 2003). However, in the same study exposures to 500 ppm *o*-xylene resulted in reduced fetal body weights at concentrations below the LOAEL for maternal effects. As concerns benzene, studies of benzene-exposed pregnant animals have suggested that exposure causes retarded fetal growth, manifested mainly as decreased fetal weight and delayed ossification of the bones. These effects were observed in the presence or absence of maternal toxicity depending on the particular study (Murray et al., 1979; Mehlman et al., 1980). One group of researchers also reported that *in utero* exposure to benzene resulted in

altered hematopoietic function in neonatal animals (Keller and Snyder, 1988). The exposure levels associated with these effects are above the low exposure limits set to prevent the occurrence of benzene-induced leukemia (e.g., the current PEL is 1 ppm and the TLV is 0.5 ppm).

Glycols and Glycol Ethers

The glycols and glycol ethers are widely used industrial chemicals. Glycols (e.g., ethylene glycol, diethylene glycol, propylene glycol) may be used as chemical precursors and as heat transfer fluids ("antifreeze" in automotive usage) (NTP-CEHR, 2003a, 2003b). Propylene glycol is also used as a solvent in pharmaceutical, cosmetic and flavoring applications (NTP-CEHR, 2003b). The related glycol ethers (e.g., 2-ethoxy ethanol [EGEE], 2-methoxy ethanol [EGME], 1-methoxy-2-propanol [PGME]) and their respective acetates are primarily used as solvents for resins, lacquers, and other finishes (Nelson et al., 1984; Nagano et al., 1984). In recent years, the propyl-based ethers have displaced ethyl-based varieties due to toxicity concerns (de Ketttenis, 2005). Suitable epidemiological studies investigating the potential developmental toxicity of these compounds are lacking and thus occupational exposure guidelines are based on animal studies.

Rodent studies investigating the developmental toxicity of ethylene glycol (EG) have indicated developmental toxicity but only at exceptionally high doses, at or above 1000 mg/kg/day (Maronpot et al., 1983; Price et al., 1985; Marr et al., 1992) or 150 mg/m³ (Tyl et al., 1995). Developmental effects were not observed in rabbits dosed by gavage up to 2000 mg/kg/day (Tyl et al., 1993). In those studies where developmental effects were noted, significant maternal toxicity was also observed at or near the dose associated with developmental toxicity, suggesting that EG is slightly more toxic to the developing organism than the adult animal. Similar findings were reported in a rodent teratology study involving diethylene glycol (DEG) (Ballantyne and Snellings, 2005). Maternal and fetal rats evidenced a similar level of sensitivity (the LOAEL in each case was 1118 mg/kg/day) whereas the fetus was found to be less sensitive than the parent in mice (fetal NOAEL—2795 mg/kg/day, maternal NOAEL—559 mg/kg/day). No developmental effects were reported at DEG doses up to 1000 mg/kg/day in rabbits (Hellwig et al., 1995). A study of triethylene glycol conducted in rats reported comparable results to the DEG and EG studies (Ballantyne and Snellings, 2007). Studies evaluating the developmental toxicity of propylene glycol (Driscoll et al., 1993; Enright et al., 2010) have not observed any developmental effects at doses ranging from 1000 to 10,000 mg/kg/day.

The glycol ethers are recognized as reproductive and developmental toxicants. For example, EGME exposure in pregnant mice produced reduction in fetal body weights and skeletal malformations at 125 and 62.5 mg/kg/day, respectively, doses that did not have systemic effects in the dams

(Nagano et al. 1984; Horton et al., 1985). Fetal viability was also affected in developmental studies involving multiple species with EGME exposures as low as 50 ppm, such effects were not observed in animals treated with concentrations as high as 3000 ppm PGME (Doe, 1984a,b; Hanley et al., 1984). The results of these studies have raised questions as to whether the OSHA PEL for EGME (25 ppm, TWA) is sufficiently protective of such effects and has led to the development of physiologically-based pharmacokinetic model of EGME metabolism (Sweeney et al., 2001). Similar to EGME, studies of EGEE have demonstrated birth defects, inhibited growth and increased embryo mortality at doses of 617 ppm in rabbits and 767 ppm in rats (Andrew and Hardin, 1984). These concentrations produced adverse effects in maternal rabbits but not in maternal rats. Comparable findings have also been reported in studies of diethylene glycol dimethyl ether (Price et al., 1987; Schwetz et al., 1992) and triethylene glycol dimethyl ether (Schwetz et al., 1992). Studies of propyl and longer chain (e.g., butyl, hexyl) glycol ethers have demonstrated either much weaker or a complete lack of developmental effects (Doe et al., 1983; Nelson et al., 1984; Tyl et al., 1984, 1989; Spencer, 2005).

Due to the developmental toxicity of EG and the EG ethers, workers may also question the safety of polymers of polyethylene glycol (PEG). Polyethylene glycols occur as a mixture of different polymeric molecules of varying length with a number appended after the name (e.g., PEG 400) to indicate the average molecular weight of the polymer. In general, such polymers are too large to be absorbed in the lungs or across the skin and have negligible vapor pressures. Although some residual monomer may exist in the polymer material, the concentration is likely to be too low to be a health concern, particularly in regards to non-ingestion exposures. One study (Vannier et al., 1989) did report developmental toxicity in mice dosed orally with 0.5 ml PEG 200 (approximately 2250 mg/kg/day) but effects were not observed in rats at the same dose. A review by Fruijtier-Pölloth (2005) concluded that PEGs did not pose a risk of developmental toxicity.

Phthalates

Much recent media concern has been focused on the potential developmental toxicity of phthalates. The term phthalates describes a class of chemicals used primarily to lend flexibility to plastics and other materials. Phthalates are used in the manufacture of a vast array of equipment, including shower curtains, shoes, IV bags and tubing, bottles, cosmetics, sex toys, adhesives and glues, detergents and surfactants, packaging, paints, printing inks and coatings, pharmaceuticals, and food wrap (NAS, 2008). Because phthalates are used so extensively, it is not surprising that they are detected in human tissues in studies of the US population (CDC, 2010). A CDC study reported that geometric mean concentrations of individual phthalate

metabolites in urine varied from non-detectable to approximately 357 µg/L, depending on age, gender and ethnicity (CDC, 2010).

The potential health effects of phthalates have been studied for a fairly long time. In the 1980s a number of animal studies indicated that high doses of phthalates could lead to testicular atrophy and other reproductive problems in rodents, particularly in male rats (Oishi, 1985, 1986; Gray et al., 1982; Gray and Gangolli, 1986; Lamb et al., 1987). While the effects were unambiguous, their meaning for humans was uncertain. Other species, such as mice and hamsters, exhibited much less sensitivity, suggesting a species-specific effect in the rat (Gray et al., 1982). The doses used in these studies were also orders of magnitude above what humans might be exposed to and showed an apparent threshold well above human exposure levels. A number of phthalates have also been shown to mimic the activity of the hormone estrogen in *in vitro* systems. However, in these tests phthalates are very weak mimics of estrogen, on the order of a million times less potent than estrogen itself (Blair et al., 2000). These results did lead to studies of the effects of phthalate exposure on reproductive development in male animals. For example, Moore et al. (2001) conducted a study in which pregnant rats were exposed to diethylhexyl phthalate and male pups were evaluated after birth for effects on male reproductive system development and sexual behavior. The authors observed a significantly shorter anogenital distance (AGD) in males dosed at 750 mg/kg/day, which was more similar to the AGD observed in female rats. They also observed increased nipple retention as well as a number of other physiological effects in the high dose group. While the effects observed were notable, it was also recognized that median diethylhexyl phthalate exposures in human children were <0.008 mg/kg/day (Wittasek et al., 2007), or more than 90,000 times lower than the level at which effects were seen in the rats studied by Moore et al. (2001). These results again suggested that the endocrine disrupting effects of phthalates occurred at doses not relevant to potential human exposures.

The current controversy surrounding phthalates arises primarily from the apparent ubiquity of phthalates in human tissues and a human study conducted by Swan et al. (2005). Swan et al. measured the concentrations of phthalate metabolites in urine samples from 85 women who recently gave birth. They also evaluated genital morphology and measured AGD in the male children. Swan et al. reported that AGD (corrected for body weight) was inversely correlated with the mother's total phthalate exposure estimate. However, only some phthalates were correlated with AGD whereas others were not (including diethylhexyl phthalate, which had been found to produce such effects in the earlier rat study). The meaning of Swan et al.'s findings has been much debated. The background level of phthalate exposure experienced by the women studied was approximately 100,000 times lower than those producing effects in rats, a rather remarkable

difference in species sensitivity if true. (Marsee et al., 2006). The potential developmental effects of phthalates in humans are currently of considerable research interest and public concern.

RESOURCES FOR EVALUATING DEVELOPMENTAL HEALTH RISKS

There are a number of information resources, which can be used to evaluate potential developmental health risks. For chemicals with existing exposure limits, readers are directed to the ACGIH TLV documentation, which provides a concise summary of all of the available toxicity data (as of the date the TLV was adopted/revised), including data on reproductive and developmental toxicity. Also useful are the MAK values recommended by the Deutsche Forschungsgemeinschaft (DFG). These often contain a suffix stating whether the available toxicology data indicate the MAK value for maternal toxicity is also protective for the embryo/fetus (e.g., Group C—"no reason to fear a risk of damage to the developing embryo or fetus when MAK and BAT values are observed"). For antimicrobials (used, for example, in biological research laboratories), the U.S. Food and Drug Administration (FDA) uses a letter designation system to describe risks of exposure to the developing organism (although intake due to occupational exposure would likely be far less than that associated with medicinal use). Similar information on postnatal drug exposures can be found on the National Institutes of Health's LactMed database (<http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT>). It must be recognized, however, that many of the chemicals present in the workplace lack exposure limits or appropriate toxicology data. In such cases, it might be appropriate to consult the European chemical Substances Information System (ESIS) developed by the European Commission Joint Research Center, which contains manufacturer submitted toxicity data that may not be published in scientific journals. Interpretation of such studies should be done in consultation with a scientist familiar with toxicity testing protocols and interpretation of developmental toxicity data.

ACKNOWLEDGMENT

The author would like to express his gratitude to David Dodge and Marguerite Seeley for their assistance in the preparation of this chapter.

112

OTOTOXICITY

MATTHEW MIFSUD AND K. PAUL BOYEV

BACKGROUND

Impairment of the organs responsible for hearing and balance remains one of the most important chronic health conditions in the modern era. Given the complexity of these senses, an extensive list of underlying pathophysiologic mechanisms exists: the impact of toxic chemicals is both substantial and can be poorly understood. Ototoxicity is defined as any injury to the auditory or vestibular system caused by drugs or other chemical substances (WHO, 1994). Not surprisingly, the effects induced by these agents can be wide ranging and include tinnitus (ringing in the ear), hearing loss, dysequilibrium, or vertigo. Agents with ototoxic potential have been known to exist for over 1000 years. It was not until the nineteenth century that ototoxic substances were well described, the first two key agents being quinine and salicylate (Schacht and Hawkins, 2006). Once pure forms of these substances were synthesized and produced for evolving western medical practice, some treated with these compounds were observed to develop reversible tinnitus and hearing loss. At present the list of both known and potential ototoxins has grown expansive (see Table 112.1 for common examples). Throughout this chapter it is our hope to provide an overview of both the underlying mechanisms and context of ototoxicity.

BASIC CELLULAR BIOLOGY OF THE AUDITORY AND VESTIBULAR SYSTEM

Neural structures of both the auditory and vestibular systems are housed within the bony labyrinth of the human inner ear. It is a system of fluid-filled channels containing a series of

mechanical sensors. These transduce sound pressure and linear/angular acceleration into the electrochemical nerve impulses that are then transmitted to central hearing and balance centers in the brainstem and brain (Forge and Wright, 2002). This specialized function is dependent on an intricate cellular architecture, uniquely arrayed in each component of the inner ear (Richardson et al., 2011). The key cellular structures of the auditory system are found within an area of the cochlea known as the organ of corti. This is a tetrahedral structure that runs the length of the snail-shaped cochlea. The mechanosensory function is performed by specialized “hair cells” that are rigidly organized in four separate rows. Each cell is surrounded by numerous structural cellular elements (i.e., Deiters’ and pillar cells) and synapses with nerve bundles whose cell bodies are principally contained in a region known as the spiral ganglion. In the vestibular organs, hair cells perform the function of detecting acceleration and gravity (which is a type of acceleration). Three semicircular canals transduce angular acceleration, while the utricle and saccule transduce linear acceleration (Richardson et al., 2011).

Auditory and vestibular hair cells are distinguished by a specialized bundle of 20–300 stereocilia found along the apical surface (Phillips et al., 2008). They are organized by descending height into separate rows; on each cell surface a single long stereocilium (the kinocilium) is present. The arrangement is maintained by cellular cytoskeletal elements and linkage proteins (Forge and Wright, 2002). The stereociliary bundle can thus move in a coordinated manner in response to mechanical stimuli. Deflection of the hair cell bundle (i.e., in response to sound pressure or movements of fluid imparted by acceleration) will open mechanotransduction receptors along the apical surface, permitting influx of potassium, and calcium ions; altering the intracellular

TABLE 112.1 Agents with Commonly Reported Ototoxicity

Medicine	Antimicrobials	Aminoglycosides Macrolides Antimalarials	Gentamicin, kanamycin, amikacin, tobramycin, neomycin, polymyxin-B Erythromycin, azithromycin, clarithromycin Quinine, chloroquine
	Antineoplastic		Cisplatinum, carboplatinum, bleomycin
	Other drug classes	Salicylates Loop diuretics	Aspirin, ibuprofen, naproxen Furosemide, ethacrynic acid
	Solvents Heavy metals Asphyxiants		Toluene, styrene, ethylbenzene, xylene, trichloroethylene Mercury, lead, trimethyltin Carbon monoxide and hydrogen cyanide
Industrial			

electrical potential and generating an appropriate electrical impulse (Ciuman, 2011).

The inner ear is notable for its use of potassium as a driving force behind mechanical sensation. A relatively high potassium fluid known as endolymph fills the membranous labyrinth. Unlike most extracellular fluid, this high potassium concentration resembles that typically found within an intracellular environment, and requires significant metabolic activity to maintain. Endolymph is produced by specialized epithelial cells most prominently encountered within an area along the lateral wall of the cochlea, the stria vascularis (Forge and Wright, 2002; Raphael and Altschuler, 2003). The cell surface architecture in this region utilizes ion channels and active ion transporters (a Na-K-Cl co-transporter) to maintain this potassium concentration. This results in an electrical gradient between the apical and basal surfaces of the hair cell, which in turn creates a net positive endocochlear potential (+80 mV) that further assists passive transport of potassium into these cells and enhances the sensitivity of the ear to sound vibrations (Hibino et al., 2010).

The inner ear is especially vulnerable to dysfunction due to the presence of the unique cell types, delicate architectural framework, and high metabolic demand described above (Richardson et al., 2011). Unfortunately, the human inner ear also has essentially negligible regenerative ability, and injury is often permanent. After embryonic development, hair cells are in a postmitotic state preventing duplication. This is mediated by a group of regulatory proteins known as cyclin-dependent kinase inhibitors, which cause cell cycle arrest (Kwan et al., 2009). Interestingly, supporting cells (i.e., Deiters' cells) within non-mammalian vertebrates are able to respond to injury by trans-differentiation into auditory or vestibular hair cells. However, specialization of the mammalian inner ear has sacrificed this ability (Groove, 2010). Hair cell death in humans thus leads to irreversible changes in hearing and or balance.

OXIDATIVE STRESS AND OTOTOXICITY

It had long been presumed that clinical pathology associated with ototoxic agents was caused by direct action on target

tissue by these toxins (Schacht and Hawkins, 2006). In certain cases this is likely true; for example loop diuretics (i.e., furosemide) may cause a reversible hearing loss, by inhibition of ion channels within the stria vascularis (Rybka, 2010). Many known ototoxins do not have this direct impact on cellular targets within the inner ear. It is instead believed that cellular damage is instigated by generation of toxic intracellular oxygen and nitrogen free radicals within integral components of the hearing and balance organs (Evans and Halliwell, 1999).

Free radicals such as superoxide (O_2^-), hydroxyl (OH^-), and peroxynitrate ($ONOO^-$) are characterized by the presence of an unpaired electron. Reactive species are generally a by-product of cellular metabolism (particularly mitochondrial oxidative phosphorylation) and have multiple roles in normal cellular function, for example; (1) regulation of intracellular signal transduction, (2) maintenance of cell-to-cell signaling pathways, and (3) as a destructive force within phagocytic cells to assist in the human immune response (Valk et al., 2007). However, the inherent electrical instability of these structures is also linked to a propensity to cause damage to intracellular lipids, protein, and nucleic acids (Deaval et al., 2012).

Reactions involving reactive species can be depicted with the following formulas: (1) $X + HY = HX + Y$, or (2) $X + Y = [X - Y]$ (Evans and Halliwell, 1999). Consequently reactions involving free radicals will generate new reactive species, establishing a cascade of reactions. Under physiologic conditions, both enzymatic (i.e., superoxide dismutase) and non-enzymatic (i.e., glutathione) antioxidant mechanisms are utilized to neutralize this effect, producing an oxidative balance (Evans and Halliwell, 1999). However, when these defenses are overwhelmed by an abundance of reactive species, a chain of adverse reactions can propagate. Persistent damage to the key macromolecules will shut down normal cellular function, eventually dooming the cell to programmed death (apoptosis) or necrosis (Cheng et al., 2005).

Numerous studies over the past two decades have established that free radicals can be generated within the inner ear tissue in response to toxic substances and noise exposure (Kovacic and Somanathan, 2008). Some evidence has also

suggested that age-related changes within the inner ear are in part related to prolonged exposure to reactive species (Li and Steyger, 2009; Seidman et al., 1999). Oxidative stress is an attractive theory to explain acquired auditory and vestibular impairment given the end result on target tissue is cellular death. Recall that the inner ear is particularly vulnerable to this kind of injury due to the lack of regenerative ability.

DRUG INDUCED OTOTOXICITY

A number of currently used therapeutic agents are considered to have ototoxic potential. The vast majority of drug-induced hearing or vestibular impairment is associated with two drug classes; aminoglycoside antibiotics or platinum-based anti-neoplastic agents (Rybak, 2010). Aminoglycoside antibiotics (such as gentamycin) are bactericidal agents utilized worldwide for treatment of tuberculosis as well as for the life-threatening gram negative infections (i.e., pneumonia or endocarditis). Their notoriety for cochlear, vestibular, and renal toxicity has been a limiting factor in their use.

Ototoxicity is made possible by a tendency of these compounds to accumulate within vestibular or cochlear hair cells. Cellular entry can occur via cell surface channels found associated with stereocilia (Warchol, 2010). In animal studies, entry of aminoglycosides into hair cells is soon followed by a rapid increase in reactive oxygen species (Audo and Warchol, 2012). Free radical generation is related to their ability to chelate metal ions, including iron (Fe^{2+}). This forms highly redox-active complexes, which catalyze the generation of reactive species such as superoxide (Forge and Schact, 2000). The importance of these reactive complexes to ototoxic effects has been well described over the last two decades. Conversely, treatment of guinea pigs exposed to gentamycin with iron chelators such as deferoxamine or dihydroxybenzoate, has a protective effect on hearing as measured by auditory brainstem responses (Song and Schact, 1996).

Aminoglycoside toxicity does not demonstrate linear dose dependency, and permanent hearing loss can be observed as soon as 4 h after a single treatment (Guthrie, 2008). It has thus been difficult to prevent the ototoxicity associated with these agents, and they are used more commonly in developing nations (due to low cost) or reserved only for the most serious infections. In contrast, platinum-based chemotherapeutic agents (i.e., cisplatin) do demonstrate dose dependency. For these agents both high acute and prolonged/accumulative dosing regimens are linked to irreversible bilateral sensorineural hearing loss (Hippolito et al., 2006). Accordingly, close audiologic assessment during and after therapy is advised to limit the sequelae of hearing impairment (Al-Khatib et al., 2010).

Platinum-based agents also induce oxidative stress in target tissues, but through a separate pathway. The exact mechanism is still uncertain; however, it is likely that these agents

primarily act by depletion of antioxidant defense mechanisms. These antineoplastic drugs are DNA-intercalating agents, and in the inner ear are thought to bind key antioxidants enzymes and/or essential cofactors, preventing their function (Rybak and Ramkumar, 2007). Prolonged exposure thus alters the cellular oxidative balance, tipping the scale in favor of free radical damage. In addition, within the embryonic kidney cells, cisplatin has been shown to upregulate synthesis of a protein known as NOX3 (Banfi et al., 2004). This is an NADPH-oxidase isoform unique to inner ear tissue. Under physiologic conditions it acts to generate a low level of superoxide anion: with enhanced function under the influence of cisplatin it likely reinforces the cascade of free radical damage (Rybak and Ramkumar, 2007).

INDUSTRIAL OTOTOXICITY—THE PROBLEM OF NOISE AND SOLVENT EXPOSURE

Since the Industrial Revolution, workers have been exposed to industrial solvents, heavy metals, and other agents with potential ototoxic effects (Schacht and Hawkins, 2006). For a long time the impact of industrial work on hearing and balance was neglected, possibly due to the subtle effect of some agents and a lack of insight on disorders of the inner ear. The National Institute of Occupational Safety and Health (NIOSH) estimates that roughly 30 million American workers are exposed to hazardous conditions that can impact hearing and balance. According to a 1996 report, roughly 25% of these workers were expected to develop permanent hearing impairment due to these exposures (Franks et al., 1996). Noise standards were put into place in the 1970s to limit the burden of occupational hearing loss, but they have yet to address the role of ototoxins.

Over the past few decades, animal models have been utilized to define the ototoxic potential of many commonly used industrial agents. The most frequently described are toluene, styrene, xylene, ethyl benzene, mercury, trichloroethylene, and carbon disulfide (Prasher, 2002 and Vyskocil et al., 2012). Toluene and styrene in particular cause necrosis or apoptosis of cochlear cell types (including hair cells) in rat models (Sliwinska-Kowalska et al., 2007). In humans, investigational studies have suggested a linear dose-response relationship with high toxin exposure and hearing loss. The best example of this is toluene exposure within rotogravure printing plants. In one study of 124 printing workers in Brazil, an increasing probability of bilateral sensorineural hearing loss was demonstrated with increasing urinary concentrations of a toluene metabolite, hippuric acid (Morata et al., 1997).

Perhaps the greatest challenge posed by industrial environments is the synergistic or additive negative impact that noise and ototoxins generate. Noise causes both mechanical and metabolic stress on inner ear tissue, leading to a

decrease in cellular integrity, neuronal excitotoxicity, a decrease in blood flow (with potential for ischemia/reperfusion injury), short- or long-term alterations of the endocochlear potential, and eventually accumulation of intracellular reactive oxygen species (Henderson et al., 2006). With data derived from animal models, ototoxic agents are thought both to modify the membranous structure of inner ear tissue (increasing susceptibility to acoustic trauma) and to enhance intracellular oxidative stress, potentially leading to greater auditory and/or vestibular impairment (Fechter et al., 2002; Sliwinska-Kowalska et al., 2007).

It is theorized that in the presence of ototoxins, lower levels of noise are required to produce auditory or vestibular impairment than previously reported. This may in part contribute to occupational hearing loss remaining the most common work-related injury in the United States, despite the introduction of permissible (noise) exposure levels by the Occupational Safety and Health Administration(OSHA) (Morata, 2002).

OTOPROTECTION

Assuming a common mechanism of ototoxicity and other forms of acquired hearing loss, it is reasonable to expect that a “cure” can be identified. Most typically, it is felt that otoprotective agents can be applied, which would act to limit cellular oxidative stress or perhaps inhibit downstream cell death pathways, in order to prevent hearing loss (Poirrier et al., 2010). Numerous animal studies demonstrate the otoprotective capability of compounds such as vitamin E, amifostine, dexamethasone, allopurinol, iron chelators (i.e., deferoxamine and dihydroxybenzoate), sodium thiosulfate, D-methionine, and *N*-acetyl-L-cysteine; in humans there are unfortunately few trials (Poirrier et al., 2010). The antioxidant properties of aspirin have made it one of the more promising agents thus far, despite a well-documented reversible ototoxicity at high doses. In a randomized trial of 195 patients requiring gentamycin, the use of a 14-day course of aspirin was associated with only a 3% incidence of >15 dB hearing loss from baseline levels, in comparison to 13% in the placebo group (Chen et al., 2007). Despite the clear potential of otoprotective therapeutic agents, the studies have involved smaller numbers of subjects, and the data have yet to show a benefit, which would compel more widespread clinical use (Darrat et al., 2007).

For a significant number of individuals at risk of ototoxicity, it is practical to attempt both limiting the degree of exposure to these agents and preventing the synergistic impact of ototoxins and excess noise exposure. Given the sheer number of workers exposed to ototoxins, upwards of 10 million in Europe alone, this is perhaps most essential in an occupational setting (Prasher, 2002). Organizations devoted to occupational safety such as OSHA, the European Union, or WHO have only begun to acknowledge the probable

impact of these chemical compounds. Going forward, an ideal cooperative otoprotective strategy would likely include: (1) multidisciplinary research aimed at identifying industries and toxins most likely to cause auditory or vestibular impairment, (2) rethinking acceptable thresholds for noise exposure to take into account impact of toxin exposure, (3) increased awareness on the benefits of personal protective equipment, including hearing protection, and (4) targeting workers at highest risk for periodic audiologic screening and other relevant health surveillance (Morata, 2003; Sliwinska-Kowalska et al., 2007).

CONCLUSION

Hearing loss and vestibular impairment are important problems within the developed world, currently representing one of the most common chronic health conditions. It is estimated that greater than 30 million Americans are affected in some way, with a yearly cost of \$30 billion dollars when considering lost productivity, specialized needs, and medical treatment (Fausti et al., 2005). The inner ear is characterized by an elaborate cellular architecture required for optimal function. This causes it to be vulnerable to excess noise exposure as well as an expansive list of chemical compounds. Over the past few decades we have begun to understand that ototoxicity is an important factor behind the burden of modern day hearing and vestibular impairment. Agents encountered in medical and industrial applications are all unique, but likely share a common mechanism of toxic cellular damage via the generation of oxidative stress. In the future, attempts to limit the impact of these substances will likely require a multifaceted approach aimed at creating otoprotective therapeutics, increased public awareness, and decreasing exposures.

DERMAL AND OCULAR TOXICITY

JAYME P. COYLE, ALISON J. ABRITIS, AMORA MAYO-PEREZ, MARIE M. BOURGEOIS,
AND RAYMOND D. HARBISON

INTRODUCTION

Skin—the body's largest organ, measuring an average of around 2 m² in area—provides a substantial area for the possibility of injury and breach, and through that breach, provides a potentially large portal to internal system damage. Eyes, on the other hand, are relatively insignificant if the area dimensions are the only consideration. On face value then, it may appear counter-intuitive to combine the two organs in a discussion of the dynamics of contact damage from chemical substances. However, sensitization, irritation, and corrosive responses in both organs operate by virtually the same mechanisms.

Although the mechanisms of these three responses operate similarly within these two organs, they are distinct responses themselves. At times, they may occur simultaneously or the presence of one may mask the presence of another. However, each physiological phenomenon has its own distinct meaning.

Dermal and ocular irritation is generally accepted to be the reversible tissue damage of the organ caused by the administration of a substance. The inflammatory response from such damage is typically manifested as redness, warmth, swelling, and discomfort. Dermal or ocular corrosion is generally accepted to be the irreversible damage to tissues of the exposed organ. The inflammatory response is magnified, with loss of tissue integrity. Sensitization is a two-phase immunological response that may manifest as irritation or even corrosion in severe cases, but the tissue damage is actually a result of the body's own response to the exposure.

For the skin and eyes, risks of an exposure actually eliciting a dose response are very different. The epidermis or the skin is made up of several layers, the outer layer of which (the stratum corneum) provides a protective shield

against most of the large complex molecules. In the absence of a breach, substances of exposure must be of smaller molecular structure, or be of such an irritative or corrosive nature that they can breach the layer themselves. Providing additional protection by way of garments, gloves, footwear, and headgear can generally be achieved without great difficulty, except against the more corrosive of substances.

The eyes, however, provide an optimal milieu for penetration by multiple sizes and forms of substances. The mucosal membranes allow easy absorption of soluble substances, while the fragility of the highly vascular tissues provides easy breaching by irritative substances. Of the 61% of facial injuries and injuries involving workday loss, roughly 70% involved eye injury from chemical exposure or from contact with foreign matter (Harris, 2011). Protective eye-wear is generally easily obtainable but maintaining full scope of vision without distortion or sight field restriction can often be problematic, depending upon the degree of protection needed.

Methods of testing substances to determine their capacity for tissue damage have only recently evolved into quantitative methods. Curiously, the origins of ocular and dermal testing arose not from the occupational injuries, but from consumer complaints and injuries from cosmetics, such as coal-tar-based mascara (Wilhelmus, 2001). One of the most known tests for both ocular and skin irritation/corrosion is the Draize test which exposed rabbits to irritative substances on a specific schedule of concentrations and different time spans (Draize et al., 1944). The test soon came under scrutiny as public concerns for the treatment of test animals and the conditions in which they were subjected to testing became a topic of discussion. While the Draize test is still considered "an effective, practical method of evaluating skin irritation

and contact sensitization reactions" (Farage et al., 2011), other testing protocols have been developed to substantially reduce the need for *in vivo* testing and to reduce the use of animals in tests for which there is no substitute for *in vivo*. Most regulatory agencies in the United States, as well as many other countries, show preferences for testing methods other than the Draize (OECD, 1992, 2010a, 2010b, 2010c).

The importance of consumer protection notwithstanding, an understanding of the nature of eye and skin responses to substance exposure and the testing protocols in use are an important facet in industrial toxicology. Exposures can come directly through industrial processes or indirectly by secondary contact. Sole reliance on a substance's material safety data sheet (MSDS) may not provide adequate protection. There is a potential for insufficient information concerning dermal and ocular damage through contact with the substance (Cashman et al, 2012). A lack of overt skin reaction upon accidental exposure may not mean that no tissue injury will happen. Certain tests may show the existence of adverse dermatological response, but not the relationship of dose to response. The most efficient way to reduce risk from a potentially harmful substance is to consider the testing protocols, workers exposure, and industrial processes.

DERMAL SENSITIZATION

OVERVIEW

Skin sensitization, also referred to as allergic dermatitis or allergic contact dermatitis, is defined as an immunological response to a substance exposure which occurs in the cutaneous tissue, manifesting itself most often as pruritus (itching), erythema (redness), edema (swelling), papules (pimples or small bumps), vesicles (fluid-filled bumps), bullae (large blisters), or some combination thereof (U.S. EPA, 2005). Skin irritation and sensitization have often been considered somewhat synonymously as an inflammatory response to an exposure with testing methods, such as patch testing, doing little to differentiate between the two (Farage et al., 2011). However, the foundations for each response are decidedly different.

The degree of skin irritation by a substance is directly related to the ability of the substance or its soluble components to damage the epidermis and/or other skin layers; is generally confined to the area of exposure; and is usually measured in seconds or minutes considering physiological response time. Skin sensitization is mediated by the degree of bodily response to the substance exposure, irrespective of the degree of substance's ability to cause direct physiological damage to the body tissue. The effects of skin sensitization, by activating a cascade of immunological responses, may display well beyond the borders of the exposure, may affect

physiological systems, and may not manifest itself until minutes to several hours after exposure.

MECHANISM OF SENSITIZATION

As with immunological reactions, skin sensitization is a two-phase process. The first phase, induction, involves the passage of the substance through the stratum corneum of the epidermis and the subsequent formation of hapten–protein complexes. This complex can be formed with either the original substance or its bioactivated metabolite. The complex is then taken up by the Langerhans cells, which migrate through the lymphatic system to the draining lymph nodes where memory T-cells are created (OECD, 2012; Robinson et al., 2000).

The second phase, elicitation, is initiated upon recontact with the substance or its reactive metabolite. Memory T-cells are then triggered, inducing the formation of cytotoxic T-cells, as well as other inflammatory response cells.

The complexity of a sensitization reaction also allows for some constraints on its formation. The substance must be able to permeate the outer epidermal layer so as to make contact with the dendritic cells necessary for its transport. If the metabolite is the sensitizer, then the substance permeation must be in the physiological range for its bioactivation. Industrial organic compounds are thought to form covalent bonds with the thiols or primary amines in skin proteins (OECD, 2012) thus substrate structure and the accessibility of these residues may also play a role in the degree of induction responses.

METHODS OF SENSITIVITY TESTING

As mentioned, skin irritation and sensitization have historically been used almost interchangeably. Patch tests, sleeve tests, and other protocols of topical or intradermal administration have used visual and colorimetric measurements to define the degrees of response (Farage et al., 2011). Unfortunately, visual measures can be insufficient to determine the actual underlying mechanism of injury. In Figure 113.1, the erythema, edema, papule, and bullae formation appear quite similar even though the left image is a sensitization reaction and right image is an irritative reaction. While the general opinion is that the greater percentage of occupational dermatitis may arise from irritative properties, some studies of occupational dermatitis indicated that allergic dermatitis may be more likely to occur than irritative dermatitis depending upon the industry and worker demographics (Belsito, 2005; Cashman et al., 2012).

Many of the techniques for *in silico/in vitro/in vivo* methods are used interchangeably with studies for skin and ocular irritation/corrosion and are well-described in the following sections. Currently, there are three accepted methods for skin sensitization *in vivo* under the Federal

FIGURE 113.1 Visual similarities in skin reactions by different mechanisms. The left image shows skin sensitization reaction to neoprene keyboard wrist rest while the right side shows severe irritation/corrosion due to contact with alkalis (CDC, 2001).

Insecticide, Fungicide, and Rodenticide Act of 1947 (FIFRA) and the Toxic Substances Control Act of 1976 (TSCA) which are the murine local lymph node assay (LLNA), the guinea-pig maximization test (GPMT) and the Buehler Test (EPA, 2003). The LLNA protocol allows for lesser test animal distress than the GPMT and the Buehler Test, while providing greater accuracy in calculations of dose per unit area (EPA, 2003; Robinson et al., 2000). In the global community, the LLNA has been modified to compensate for testing locations with limited access to radioisotopes of thymidine or iodine or difficulties with the disposal thereof (OECD, 2010a, 2010b). Of the three, the LLNA is the preferential method for sensitization testing and thus will be discussed within this section.

Murine Local Lymph Node Assay (LLNA)

The LLNA is a sensitization test that gauges the induction phase through the measurement of lymphocytic proliferation in lymph nodes proximal to the area of substance administration. The substance is applied to the dorsum of the test mouse. Measurement of the lymphocytic proliferation is performed by β -scintillation counting of radioisotopes ^3H -methyl thymidine or ^{125}I -iododeoxyuridine, one of which having been injected in solution via tail vein prior to sacrifice of the animal (OECD, 2010c). Visual assessments of erythema are noted on a numerical scale of severity and post-mortem ear-punch skin samples are measured for changes in ear thickness.

The advantages of the LLNA include a lesser degree of distress to the testing animal, lower costs associated with animal acquisition and housing, and a more precise ability to calculate dose per unit area (OECD, 2010c; Robinson et al., 2000). Disadvantages, as stated, are that access to and/or disposal of the radioisotopes may be restricted in some world regions. In such cases the use of modified LLNA protocols, the LLNA-DA and the local lymph node assay-5-bromo-2-deoxyuridine-enzyme-linked immunosorbent assay (LLNA-BrdU-ELISA), are also permitted under the guidelines of the

Organisation for Economic Co-operation and Development (OECD), of which the United States is a member. Local lymph node assay-DA exchanges the use of radioisotopes with the measurement via bioluminescence to quantify the adenosine triphosphate (ATP) content of the lymphocytes (OECD, 2010a). Local lymph node assay-BrdU-ELISA similarly replaces the radioisotopes with BrdU, the uptake of which is measured by ELISA (OECD, 2010b). All three protocols are meant to assess the induction phase of skin sensitization and provide a quantitative determination of the dose-response relationship.

OCCUPATIONAL CONSIDERATIONS

The two-phase process generally requires some passage of time between phases for the complete development of the induction phase. Rarely, a dermal sensitivity response may appear to be almost immediate when the substance is readily absorbed into the skin of a highly immunoreactive individual. More commonly, the first contact with a substance elicits only the induction phase and no overt dermal response is noted. Therefore, the lack of a dermal response from workers in the occupational setting is not an indication of a lack of sensitization in the same.

Some substances are more likely than others to elicit a sensitization reaction. According to some patch test studies, nickel sulfate may be twice as likely to cause a skin sensitization as another substance such as formaldehyde (Cashman et al., 2012).

DERMAL IRRITATION

OVERVIEW

Several compounds are known to be either dermal irritants or corrosive. Occupationally, the reported rates of new cases of

skin diseases have been estimated to be between 0.5 and 1.0 case per 1000 workers in Europe, and responsible for about 33% of the suspected work-associated diseases in 2010. From 90 to 95% of the total reported skin diseases were accredited to contact dermatitis (Diepgen, 2012). In the United States, estimates from the 2010 National Health Interview Survey conducted by the National Institute for Occupational Safety and Health (NIOSH) reported a prevalence of dermatitis at 9.8% among those currently working, though the rates of allergic versus irritant were not reported (Luckhaupt et al., 2013). Both reports, however, recognize that these figures may be subjected to underreporting, possibly on the order of 50-fold or higher. Hanifin et al. (2007) reported that 10.7% of survey participants of the general population demonstrated at least one eczematous symptom consistent with contact dermatitis, though not all cases were confirmed by physician diagnosis. However, the rates of dermatitis in the general population are unknown, thus undermining the fraction credited to occupational dermatitis, especially with suspected high rates of underreporting in both the general and working populations. Therefore, objective methods for delineating agents suspected to cause dermal irritation, sensitization, and corrosion remain paramount in the regulatory as well as in the workplace setting.

Recently, a paradigmatic shift in regulatory dermal toxicity testing has been underway, moving from *in vivo* models to *in vitro* models due to animal safety and general reductions in laboratory animal use, development of sensitive *in vitro* models, and difficulty in bridging animal data with human toxicological relevance. Table 113.1 shows tests on current common use. Therefore, regulatory testing relies on *in vivo* testing typically when the weight of evidence from existing human and animal data cannot rule out the necessity of testing, especially for agents known or suspected to cause harm. Often, suspected agents, which are expected to produce substantial dermal and systemic injury resulting in pain and suffering, are tested using a standardized sequential tiered approach in order to reduce the number of test animal required to exhibit dermal irritation or corrosion.

DERMAL IRRITATION ASSAYS

In the regulatory framework, irritants are described as agents which have the potential to produce reversible dermal erythema (dermal redness), eschar (focal dermal necrosis) or edema (subcutaneous fluid accumulation). In some instances, generalized inflammatory response may be exhibited, but these responses lack humoral involvement typical of sensitization. Therefore, for an agent to be an irritant, even first-time contact can produce symptoms described above, though symptoms presented may be similar to allergic reactions.

Historically, irritants have been determined and graded based on severity, using an *in vivo* approach using albino

TABLE 113.1 Common Dermal Tests

Test Name	Dermal Endpoint Assessed	In Vivo/In Vitro/Ex Vivo
Guinea pig maximization test	Sensitization	<i>In vivo</i>
Buehler test	Sensitization	<i>In vivo</i>
Local lymph node assay	Sensitization	<i>In vivo</i>
Human repeat insult patch test	Sensitization	<i>In vivo</i>
<i>In vitro</i> assays (various)	Sensitization	<i>In vitro</i>
Draize skin irritation test	Contact irritant corrosion	<i>In vivo</i>
Reconstructed human epidermis systems	Contact irritant corrosion	<i>In vitro</i>
Membrane barrier test (Corrositex®)	Corrosion	<i>In vitro</i>
Transcutaneous electrical resistance test	Corrosion	<i>Ex vivo</i>

rabbits called the Draize skin irritation test. Often, the Draize test combines screening for both irritant and corrosive agents, the latter which shall be discussed later. However, interest in increasing predictive power of dermal irritant detection has prompted a shift from the Draize test to several commercially available *in vitro* models individually validated by the European Centre for the Validation of Alternative Methods (ECVAM). Assessment of novel *in vitro* models depends on their comparative sensitivity and specificity against the Draize test. Paradoxically, neither the Draize test nor the *in vitro* models have been compared to direct human testing, thus confirmation of irritant class to humans is lacking for both models, but is generally supported with existing human and animal data (Basketter et al., 2012).

Dermal irritant classes have been promulgated by the United Nations (UN) Globally Harmonized System of Classification and Labelling of Chemicals (GHS), and span Category 1 (corrosive), which shall be later discussed, Category 2 (irritant), and Category 3 (mild irritant); the latter is subject to optional labeling depending upon the agency. Criteria for irritant classes are listed in Table 113.2. Any compound with a pH ≤2, pH ≥11.5, or test positive in any valid *in vitro* dermal test is immediately classified as corrosive (Category 1) (United Nations, 2013).

In Vivo Tests

Draize Skin Irritation Test The Draize skin irritation test, referred to as the Draize test, is a standardized mammalian model developed by Draize et al. (1944) to screen for dermal irritants and corrosives. The principle of this test relies on the ability of the investigated agent to produce local dermal irritation after a single acute exposure lasting no more than 4 h. The maximum observation period is 14 days to include any latent dermal irritation. Three to six albino rabbits are of

TABLE 113.2 UN GHS Dermal Irritant Classification Criteria (Excludes Corrosion)

Category	Pretesting Considerations Warranting Classification	Draize Testing Criteria (Mean Scores)
2	- Existing data warrants classification - Positive result of valid <i>in vitro</i> test - QSAR-based classification	- Score ≥2.3 and <4.0 for erythema/eschar or edema in 2 of 3 animals - Persistent inflammation at the end of the 14-day observation period in 2 of 3 animals
3	- Existing data warrants classification	- Score ≥1.5 and <2.3 for erythema/eschar in 2 of 3 animals

standard sample sizes; generating preliminary results with one test animal is highly recommended, followed by confirmation with two additional animals only in instances of dubious results. The test procedure is described in the OECD Testing Guidelines 404 (2002), and has been validated for solid and liquid substances, but not other physical states. Any resulting dermal lesions are assessed for lesion type (e.g., erythema, eschar, edema, and otherwise noted) as well as reversibility and are tabulated based on a predetermined severity scale measured subjectively. Draize test scoring is provided in Table 113.3.

In Vitro Assays

Reconstructed Human Epidermis Interest in replacement of the Draize skin irritation test has precipitated the

TABLE 113.3 Draize Skin Irritation Test Grading

	Score
<i>Erythema and Eschar Formation</i>	
No erythema	0
Very slight erythema (barely perceptible)	1
Well-defined erythema	2
Moderate to severe erythema	3
Severe erythema (beef redness) to eschar formation preventing grading of erythema	4
<i>Edema Formation</i>	
No edema	0
Very slight edema (barely perceptible)	1
Slight edema (edges of area well defined by definite raising)	2
Moderate edema (raised approximately 1 mm)	3
Severe edema (raised more than 1 mm and extending beyond area of exposure)	4

introduction of complex, physiologically relevant *in vitro* reconstructed human epidermis (RHE) tests that not only models the keratinaceous barrier of the skin, the *stratum corneum*, but also the underlying stratified layers of the human epidermis, including the strata *basale*, *spinosum*, and *granulosum*. Test compounds applied to the *in vitro* RHE are assessed by histological staining morphology and cellular viability via 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide [MTT] reduction; the latter assay is responsible for categorizing the agent according to skin irritant class. Reductions in treatment cell viability of $\leq 50\%$ compared to controls warrant classification to dermal irritant Category 2 (causes skin irritation), while cytoviability counts above 50% warrant categorization into Category 3 (causes mild irritation) or simply as a nonirritant. Currently, these systems cannot distinguish between mild irritants and non-irritants, thus requiring further confirmatory testing; however, Category 2 irritants need not undergo *in vivo* confirmation. Additionally, these systems are not validated for gas or aerosolized exposures and are limited to only solid or liquid media. As the system contains an underlying nutrient medium, characterization of cytokines resultant of exposure can be performed to include inflammatory markers.

Therefore, regulatory utilization of RHE offers tangible modeling to assess dermal irritation using four validated commercially available systems (EpiSkin™ (SM); EpiDerm™ SIT (EPI-200); SkinEthic™ RHE; LabCyte EPI-MODEL24 SIT) accepted by the OECD and the United Nations Globally Harmonized system (UN GHS). Validation of the LabCyte EPI-MODEL24 SIT, for example, has determined the sensitivity and specificity of the model as 82.3% and 72.6%, respectively (OECD, 2011).

DERMAL CORROSION ASSAYS

In Vivo Assay

Draize Skin Corrosion Test The Draize skin irritation test simultaneously assesses for corrosion; therefore, the particular aspects of this test as it pertains to the regulatory framework are discussed above. However, the delineating factor between corrosion and irritation is the irreversible tissue damage (necrosis) resultant of acute exposure, e.g., between 3 min and 4 h. Subcategorization within skin irritation Category 1 (labeled superficially as corrosive) depends on the time point observed for the onset of irreversible tissue damage (Table 113.4). Given the severe nature of necrotic tissue damage, the emphasis of using one animal for preliminary assessment is strongly recommended for agents suspected to have corrosive potential based on the weight of evidence from both structural and activity relationships to known corrosives and from existing data (OECD, 2002). This test remains the gold standard for dermal corrosion categorization, but remains subject to partial replacement by *in vitro* methods.

TABLE 113.4 UN GHS Skin Irritation Category 1 (Corrosive)

Category 1 Subcategory	Exposure Time to Endpoint	Observation Period
1A	≤ 3 min	≤ 1 h
1B	>3 min but ≤ 1 h	≤ 14 days
1C	>1 h but ≤ 4 h	≤ 14 days

In Vitro Assays

Two *in vitro* assays have been validated by the UN GHS for determining dermal corrosion agents from non-corrosives. The first of which uses three RHE models used for skin irritation, but utilize the same endpoints (histology and MTT reduction) for analysis and subcategorization. The EpiSkin™ (SM) model provides the highest resolution to distinguish 1A versus 1B/1C versus non-corrosive. The test cannot distinguish between 1B and 1C corrosives, thus any non-1A corrosive agents are categorized as 1B and 1C. The test system, however, provides high sensitivity (100%) and specificity (80%) in delineating corrosive from non-corrosive. The EpiDerm™ SIT (EPI-200) and SkinEthic™ RHE models are also utilized for this purpose, but both tend to overpredict the severity score to produce a significant rate of false 1A results. Cytoviability thresholds for subcategorization varies depending on the system used, but are dependent upon the time point to produce the criteria for cytoviability (OECD, 2013).

Another validated method available is the membrane barrier test method, commercially known as the Corrositex® assay, and aims to delineate skin corrosives using a proteinaceous matrix supported by a dermal-like basal layer. A positive result is demonstrated by a change in the underlying solution containing an indicator dye. The sensitivity and specificity of this method to categorize known corrosive agents are 89% and 75%, respectively, based on 40 tested chemicals (OECD, 2006).

DERMAL SENSITIZATION ASSAYS

In Vivo Assays

Guinea Pig Tests The guinea pig remained the gold standard in determining sensitization agents within the regulatory framework as *in vitro* and QSAR methods are not sensitive enough to replace the GPMT or the Buehler test; however, the murine LLNA is now the current gold standard, except in few situations. Nevertheless, the GPMT and Buehler test are methodologically comparable, except that the GPMT uses a sensitization potentiator (Freund's complete adjuvant) to maximize sensitization, thus aiming to limit false negative results. These sensitization assays determine whether agents

produce a humoral memory T-cell-mediated immune response upon topical challenge, a process which necessitates exceedance of the induction dose threshold and a 10–14 day refractory exposure period. Responses are scored according to the Magnusson and Kligman scale, while histological examination and skin fold thickness may also provide important clinical endpoints. The use of an adjuvant, irritating or inappropriate solvent vehicle, and relevant concentrations may limit translation to human sensitization potential or may over-categorize sensitizing agents (OECD, 1992).

Murine Local Lymph Node Assay The murine LLNA, created by Kimber et al. (1989), focuses resources on detecting a sensitive proxy of the humoral induction phase, rather than the elicitation phase required of the guinea pig tests. Therefore, the LLNA continues to appreciate refinement in anticipation for its continued replacement of most applications of the guinea pig sensitization model. The LLNA measures the relative lymphocyte proliferation within the auricle lymph nodes after bilateral ear exposure of the tested sensitizing agent. The test originally required lymphocyte uptake of tritiated methyl thymidine or a mixture of 125I-iododeoxyuridine and fluorodeoxyuridine as proxies of lymphocyte proliferation; however, non-radioisotope reporters, such as BrdU uptake and ATP measurement are available (OECD, 2010a, 2010b, 2010c). The index measured is referred to as the stimulation index (SI) with a positivity threshold of 3, meaning the uptake, translated to lymphocyte proliferation, is threefold above that of control animals. The LLNA demonstrates limitations as the LLNA is insensitive to some metals and high molecular weight sensitizers; has a tendency of high false positives, e.g., for surfactants and natural organic acids; requires 3 consecutive daily exposures; cannot distinguish contact dermatitis from hypersensitivity; and remains subject to variability based on the chosen vehicle (Anderson et al., 2011). Nevertheless, the LLNA does not require adjuvant application, decreases time, costs, and welfare concerns, and is a quantitative assay; all of which confer advantages in testing (OECD, 2012).

Nonvalidated Methods

Several nonvalidated and fringe methods exist for assessing sensitizing agents. The method with the highest extrapolation potential, but least favored ethically, remains the human repeat insult patch test (HRIFT). Therefore, the HRIFT is employed only when the benefits far outweigh the risks of the individual participants, especially since result variability is generally high (Baskettter, 2009). In addition, several *in vitro* models have been proposed, such as the Genomic Allergen Rapid Detection Test, VITOSENS Test, Myeloid U-937 Skin Sensitization Test [MUSST], Human Cell Line Activation Test [h-CLAT], and the THP-1 cell line, but none have gained general acceptance compared to the LLNA and

guinea pig tests, despite comparable sensitivity and specificity compared to the LLNA. *In vitro* tests generally do not capture the complex nature of inter-tissue interactions, especially with regards to inflammatory responses; thus competition against the robust *in vivo* assays has not currently taken precedence. Unifying the *in vitro* studies, however, is the concept that novel biomarkers associated along the adverse outcome pathway of allergic dermatitis have been identified and may augment evidence in support of the validated methods (Aeby et al., 2010; Ashikaga et al., 2010; Lambrechts et al., 2010; OECD, 2012).

OCULAR IRRITATIVE INJURIES

OVERVIEW

There are two major physiological effects that may result from test chemicals exposure on the eye—corrosion and

irritation. Eye corrosion is defined as the production of irreversible tissue damage following application of a test substance to the anterior surface of the eye. Eye irritation is defined by reversible changes following the application of a test substance to the anterior surface of the eye (EPA, 1998). Strongly acidic ($\text{pH} < 2$) or alkaline substances ($\text{pH} > 11.5$) can be presumed to be an eye corrosive.

MECHANISMS OF EYE IRRITATION

For simplicity, chemicals have been classed by one of four general modes of action; cell membrane lysis, coagulation, saponification, and actions on macromolecules. Assignment to these categories is far from absolute as chemicals may possess properties from more than one. Cell membrane lysis, the breakdown of the cellular membrane, involves substances such as surfactants, organic solvents, ketones, alcohols, volatile liquids, ethers, polyethers, esters, or aromatic amines. Coagulation, the denaturation of macromolecules, involves the following chemical classes: acids, cationic surfactants, or organic solvents. Saponification, a breakdown of lipids, involves alkalis. Finally, actions on macromolecules where chemicals react with the organelles of the cell involve the chemical classes of peroxides, mustard agents, alkyl halides, epoxides, or oxidizers (Scott et al., 2010).

The U.S. Environmental Protection Agency (US EPA) and the UN GHS have determined that when a test chemical evaluated during the Tier 1 phase of the testing strategy is judged as potentially causing severe ocular damage, a single animal testing method is then considered appropriate. If anticipated or unanticipated ocular damage is actually observed then no further animal testing is required. However, additional testing may be warranted if no damage is observed in order to establish a threshold for onset of irritation. A more detailed description of this process will be discussed later.

TESTING

Current Standard: Draize Eye Test

The Draize eye test is the current ocular testing standard to evaluate eye irritation potential of test chemicals; all other tests to replace Draize are still in the validation stages. The United States and the European Union are incorporating various testing models into a tier-staging model (Adriaens et al., 2014; Barile, 2010). Draize testing was developed to identify reversible and irreversible (corrosive) effects of substances *in vivo*. Draize, a pharmacologist at the Food and Drug Administration, was tasked with developing an evaluative test when the government passed the Federal Food, Drug, and Cosmetic Act of 1938 in response to reports of ocular damage in women using eyelash dye (Wilhelms, 2001).

Common chemicals with the potential for eye contact are evaluated using the Draize eye test. The basic protocol uses a single-dose application (0.1 ml or >100 mg) to one eye of several albino rabbits with a treatment time of 24 h before rinsing out the test substance. The treatment effects are evaluated by observation for at least 72 h and up to 21 days (Draize, 1944; EPA, 1998). The test grades ocular lesions in the cornea as well as the typical oculotoxic endpoints of corneal opacity, inflammation, and cytotoxicity (Barile, 2010; Draize, 1944; OECD, 2012b; Wilhelmus, 2001). The Draize eye test method has several limitations, including a lack of reproducibility; subjective assessment; variable interpretation; high test dosage requirements; and over-prediction of the human response to the chemical (Barile, 2010).

Alternative Testing Methods to Draize

Eye irritation testing is used for the evaluation of ocular sensitivity and corrosion test chemicals. As previously stated, no single *in vitro* method or combination of methods have been validated to fully replace Draize eye testing (Adriaens et al., 2014; Scott et al., 2010). The primary difficulty in developing an alternative testing method is the inability to predict the range of irritation across different classes of chemicals currently provided by Draize (OECD, 2013b). Put simply, most new methods fall short. The criteria for the validation of alternative testing methods include: the evaluation of toxic tissue effects; the irreversibility (corrosiveness) of eye damage; within test variability; and assessment of target values of sensitivity, specificity, and accuracy as compared to the Draize eye test values (Adriaens et al., 2014; Katoh et al., 2013).

Generally, the main reasons for method validation failure are high within test variability and low posttest sensitivity, specificity, and accuracy. All the alternative test methods discussed later demonstrated highly variable results, could not distinguish eye irritants from non-irritants or misclassified chemicals (Barile, 2010). These setbacks have made it difficult for agencies to fully replace *in vivo* testing. Using these methods as a part of a multi-tiered or “stacked” strategy has been approved by the United States and other international agencies to reduce the overall burden of *in vivo* testing and perceived animal cruelty. Many cosmetic and pharmaceutical companies have instituted these methods in-house in order to completely eliminate animal testing. Others opt to shift their product evaluations to third party laboratories to eliminate on-site animal testing.

Tier-Testing Strategy

As previously written, none of the alternative methods to Draize eye test are considered valid as a stand-alone replacement for *in vivo* rabbit eye testing. The United

States and the international community have adopted a tier-testing strategy to systematically evaluate test chemicals limiting the use of *in vivo* testing until later stages (Barile, 2010; OECD, 2013a; Scott et al., 2010). A substance considered as a potential hazard at Tier 1 would advance to Tier 2 for further testing and so on. Tier 1 uses the structure activity relationship and physiochemical properties to assess the molecule under review. Tier 2 uses short-term bacterial or mammalian assays to assess the test chemicals cytotoxicity and potential inflammatory properties based on cellular release of inflammatory cytokines and other mediators. Tier 3 makes a risk assessment of human and animal eye irritation. This strategy is based on the principle of weight of evidence approach which considers all available information to evaluate eye irritation (Barile, 2010). A relatively simple decision tree permits evaluation of the test chemical given commonly available data; *in vitro* assessments of severe eye irritancy; and finally *in vitro* testing of mild to moderate irritancy (Barile, 2010).

Bottom-Up and Top-Down Approach

This approach is named for the strategy to use presumptive non-irritants in the bottom-up approach and presumptive severe eye irritants in the top-down approach. This approach is applicable in four domains of testing: categorization a test chemical's irritation severity; the test chemical's mode of action; identification of the chemical class; and the physiochemical compatibility (Barile, 2010). Scoring of test chemicals is based both on the specific tissue lesion size and persistence of lesions over time.

Several modes of action have been identified: cell membrane lysis, saponification, coagulation, and actions on macromolecules (Scott et al., 2010). Cell membrane lysis is a breakdown of membrane integrity; coagulation is the precipitation/denaturation of macromolecules such as proteins; saponification is the breakdown of lipids by alkaline action which is progressive with time; actions of macromolecules are chemicals that react with cellular constituents/organelles such as alkylation or oxidative attack on macromolecules (Scott et al., 2010). One major advantage in the bottom-up/ top-down approach is that methods that include a stromal layer, as is available in isolated organ methods like isolated chicken and isolated rabbit eye testing, possess the greatest potential to identify severe eye irritants (Scott et al., 2010). The principle is based on the ability of the test chemical to create a lesion that penetrates the epithelium down to the stromal layer (Scott et al., 2010).

Cell Function and Cytotoxicity-Based Assays

Cell function and cytotoxicity-based assays rely on membrane lysis to determine the functionality of the cell based on membrane integrity (Scott et al., 2010).

Fluorescein Leakage Test Fluorescein leakage (FL) test, developed by Tchao (1988) is an in vitro test method that can classify chemicals as irritants or corrosives. It uses the principle based on the integrity of trans-epithelial permeability which is a functional characteristic of the cornea and conjunctiva of the eye (OECD, 2012a). There is a correlation between the increasing permeability of corneal epithelium and the level of inflammation and surface damage observed in the eye with the introduction of an irritant. (OECD, 2012a) The toxic effects of short-term exposure can be measured on a monolayer of Madin-Darby canine kidney cells (MDCK) by the increase of permeability of sodium fluorescein through the monolayer (OECD, 2012a). It is indicated for testing the irritancy of surfactants and surfactant-based materials. It has limited use at this time because it can only accurately classify irritation/corrosion eye risk for a limited number of chemicals. It also requires high chemical concentrations due to its short-term exposure period (OECD, 2012a). This method is currently expected to be best utilized in the top-down approach in a tier testing strategy where the FL test is used when high eye irritancy potential is suspected (OECD, 2012a; Scott et al., 2010).

Isolated Organ Method or Organotypic

Isolated Chicken Eye (ICE) or Isolated Rabbit Eye (IRE) This model was discussed in Prinsen and Koëter (1993) which uses isolated corneas from animals used for consumption. Standard application amounts are 0.3 ml or 0.3 g to the surface (OECD, 2013b). The model measures test chemical effects up to 4 h posttreatment. ICE/IRE measures increases in corneal thickness as a proxy for corneal swelling; corneal opacity to assess corneal damage; morphological changes in cornea epithelium (pitting and loosening); and permeability through corneal cell layers using fluorescein retention (Barile, 2010; OECD, 2013a). This model is limited because it only evaluates corneal effects but does not identify slow acting irritants (Barile, 2010). This model has been found to have high false positive rates for alcohols and high false negative rates of solids and surfactants, although the false negative tests are not considered as critical because of testing by other in vitro methods as part of the tier-testing strategy (OECD, 2013b).

Bovine Corneal Opacity and Permeability (BCOP) This model assumes that corneal damage is a reliable indicator of visual impairment. Using isolated eyes from slaughtered cattle as first described by Gautheron et al. (1992), the degree of a substance's irritative properties are measured by light transmission through the cornea (opacity), sodium fluorescein dye passage through the full thickness of epithelial cell layers (permeability), corneal swelling and histological evaluations of morphological alterations. (Barile, 2010; OECD, 2013a). The bovine corneal opacity and permeability

(BCOP) standard application amount for surfactants is 10% w/v in 0.9% sodium chloride solution, distilled water, or any other solvents with no adverse effect on the experiment, while liquid test chemicals remain undiluted. Non-surfactant solids are applied at 20% w/v concentration in 0.9% sodium chloride solution, distilled water, or any other solvents with no adverse effect on the experiment (OECD, 2013a). Opacity is quantitatively measured using an opacimeter, while permeability is measured by an evaluation of optical density using a UV/VIS spectrophotometer set at 490 nm (Barile, 2010). Low density, water-insoluble substances are not adequately tested using this model, as the substances may not be sufficient for the corneal contact during testing. Additionally, irritants and non-irritants are poorly differentiated by BCOP; thus it is only approved in tier-testing strategies (Barile, 2010; OECD, 2013a).

The BCOP was evaluated by the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) and the ECVAM. The BCOP was recommended to be used in the bottom-up approach for the classification of chemicals that do not pose a risk of irritation or eye damage. In top-down testing strategies, BCOP is recommended as the initial step in to identify chemicals inducing serious eye damage, preventing further animal testing. (OECD, 2013a).

Porcine corneal opacity (PCOP) follows similar protocols and evaluations which can be used to evaluate eye irritation, thus will not be discussed here.

Organotypic Models

Hen's Egg Test—Chorioallantoic Membrane (HET-CAM) The Hen's egg test—chorioallantoic membrane (HET-CAM) model tests a substance's irritative effects on the conjunctiva based on the observation that the CAM of the embryonated hen's egg is similar to the vascularized mucosal tissues of human or rabbit eye (Barile, 2010; Luepke and Kemper, 1986; Parish, 1985). A maximum of 300 µl of test substance is applied to the surface of the CAM for 20 s, after which hyperemia, hemorrhage, coagulation, and changes in blood vessels such as vessel lysis, vasoconstriction, or vasodilation are evaluated as irritation endpoints (Barile, 2010). This model has been validated to predict ocular corrosives and severe irreversible effects and is best used in a multi-tiered testing strategy to assess severe eye damage (Barile, 2010). Chorioallantoic membrane—trypan blue staining (CAM-TBS) is another chorioallantoic membrane method similar to HET-CAM. Unlike HET-CAM, CAM-TBS evaluates histological and pathological changes in the CAM with dye staining (trypan) to determine the absorbance of dye into the cell membrane, which is an indicator of cell death (ECVAM DB-ALM, 1995; Yang et al., 2010).

Cytosensor Microphysiometer (CM) Cytosensor microphysiometer is based on the observation that the measurement

of small changes in cellular metabolism reflected by extracellular release of acidic byproducts of energy metabolism (Hartung et al., 2010). The process is automated to measure metabolism in living cells based on the change in the release rate of proton into the culture medium, thus it can detect small changes in pH (Hartung et al., 2010). Cytosensor microphysiometer uses seeded mouse fibroblasts (L929 cells) exposed to a 20 min dosing cycle to determine the changes in cell metabolism (IIVS, 2014). The endpoint analysis is the MRD50 which is the dose of the test material that induces a 50% decrease in metabolic rate relative to a negative control (IIVS, 2014). This testing method tends to be associated with a misclassification error in the middle range of irritancy (Curren et al., 2006).

Reconstituted Human Tissue Models

EpiOcularTM (MatTek Corp.) The EpiOcular model is an *in vitro* human corneal model in which cultured epithelium is used as a proxy for corneal epithelium. Human-derived epidermal keratinocytes are coaxed into a membrane several layers thick, creating a cultured membrane compositionally similar to corneal tissue (Barile, 2010; MatTek, 2014). The MTT colorimetric assay is used to measure cell viability. Since the matrixed cells remain mitotically and metabolically active, growth patterns and the release of cytokines continue akin to *in vivo* conditions (Barile, 2010; MatTek, 2014). This model can be used to evaluate hydrophilic and hydrophobic test chemicals in either their liquid or solid state with the additional benefit of staging irritants as mild, moderate, or severe (Barile, 2010). EpiOcularTM is in the validation stage for replacement of Draize eye testing by ECVAM.

Human Corneal Epithelial (HCETM) (SkinEthic Lab) The human corneal epithelial (HCETM) model consists of immortalized human corneal epithelial cells cultured in a fashion similar to the EpiOcularTM model. Both models use an air–liquid interface and thus lack a stratum corneum, resembling the corneal mucosa. As in the EpiOcularTM model, the MTT colorimetric assay is used to evaluate cell viability. *In vitro* indicators are also used with this model, such as LDH release, histology, cytokine release, and gene expression (Barile, 2010). Human corneal epithelial appears useful as an *in vitro* model for detecting corneal repair and recovery, and as a “prescreen” method to evaluate test substance ingredients (Barile, 2010). According to its developer, HCETM can be used to evaluate corneal permeability and metabolism as well as a corneal differential display, i.e., mucin production (SkinEthic, 2014). Validation testing for ocular irritative testing by EVCAM is ongoing.

Other Alternative Methods

There are some *in vitro* tests that have not been discussed because they are not used extensively in eye irritation testing;

however, they can be used for dermal, mucosal, and eye irritation studies. slug mucosal irritation assays (SMI) use the *Arion lusitanicus* as a test subject because the mucosal body surface of slugs can mimic the mucosal surfaces of humans in the ear, nose, throat, and eye. The mucosal surface of the slug contains mucus secreting cells covering a sub-epithelial connective tissue. When slugs are placed on an irritant substance they will produce mucus, and, in severe cases, tissue damage. The release of proteins and enzymes can be measured to determine the toxicity of the test chemical (Adriaens, 2006). red blood cell assay (RBC) is an *in vitro* test that evaluates hemolysis by measuring hemoglobin release in the plasma following the exposure to a test chemical to rat RBCs (ECVAM DB-ALM, 1994b). Neutral release red or neutral red uptake (NRR) is an *in vitro* assay using seeded BALB/c 3T3 cells treated with a test chemical and incubated with neutral red dye to determine the cell membrane permeability based on dye absorption in the cells (ECVAM DB-ALM, 1994a). Irritation[®] uses a protein matrix that mimics the biochemical components of cornea proteins. This assay measures the denaturation and degradation of matrix proteins by optical density (In Vitro International, 2007).

SUMMARY

Many *in vitro* testing methods have been developed as an alternative to *in vivo* (live animal testing) methods. The alternatives described herein have been used to study eye irritation but may also apply to dermal and mucosal irritation of the ear, nose, throat, and skin. These methods have undergone numerous independent validation studies. Although none of these alternative methods may currently be used as a stand-alone replacement for the *in vivo* Draize eye test, their use as part of a multi-tiered testing strategy can reduce the number of animals used for chemical testing. Development of these methods began in earnest over 25 years ago. Despite its documented drawbacks and even with the chemical misclassifications, no alternative to *in vivo* testing has been found to match the predictive reliability of the Draize eye test. The *in vitro* testing methods are best used for extremes on the spectrum of eye irritation. Some are best for testing severe eye irritants while others are accurate at testing non-irritants. The ICC-VAM and ECVAM validate proposed models using three major criteria: chemical classification accuracy, within test variability or interlaboratory reproducibility, specificity of eye damage and its correlation to the human eye. Unfortunately, all alternative *in vitro* methods have failed to meet the standards in one or more of these areas. Currently, all eye irritation ratings continue to use the Draize eye test outcomes when applicable to determine the eye irritant classification of a chemical.

REACTIVE AIRWAYS DYSFUNCTION SYNDROME (RADS)

DAVID J. HEWITT

BACKGROUND

Reactive Airways Dysfunction Syndrome (RADS), also termed acute irritant-induced asthma, is an asthma-like illness that develops after a single high-level exposure to a pulmonary irritant. First described by Brooks and colleagues, the criteria and clinical features with minor variations have included the following (Brooks et al., 1985; Brooks, 1992, 1998):

1. No history of asthma-like respiratory disease.
2. Onset follows a single exposure incident or accident.
3. The exposure was to an irritant gas, smoke, fume, vapor, or dust in very high concentrations.
4. The onset of symptoms was abrupt, developing within minutes or hours but always within 24 h after the exposure and persisted for at least three months.
5. Requires immediate medical assistance.
6. Symptoms are similar to asthma with cough, wheezing, and dyspnea.
7. Pulmonary function tests (PFTs) may show airflow obstruction.
8. Methacholine challenge testing was positive in the range characteristic of asthma (i.e., 8 mg/ml).
9. Other types of pulmonary diseases were ruled out.

RADS cases originally described by Brooks and subsequent reports in the medical literature have been characterized by intense high-level exposures to a pulmonary irritant, which resulted in acute respiratory symptoms of a severity generally requiring immediate medical attention and hospitalization. The exposure typically occurred in a

confined space, an environment with limited ventilation, or in circumstances where the individual was not able to immediately escape the exposure. Subsequently reported symptoms include cough and bronchospasm in response to a wide variety of non-specific irritants such as cigarette smoke, cold air, traffic fumes, household cleaners, or perfumes. The diagnosis is often made in the setting of an accidental occupational exposure with resulting medicolegal ramifications.

The validity of the diagnosis of RADS has been an area of controversy. Diagnosis may be difficult due to the absence of pre-exposure baseline respiratory function data and the inability to fully exclude other potential causes of respiratory symptoms such as smoking, allergies, infections, other exposures, or other health conditions. In a review of published RADS cases, Shakeri et al. (2008) noted that the case report descriptions were remarkably inconsistent and often did not allow a diagnosis of RADS based on the information provided. The development of RADS after an irritant exposure is considered relatively rare. In a prospective study of individuals evaluated at a poison control center for accidental irritant inhalation exposures, Blanc et al. (1991) reported that 6% had symptoms for more than 2 weeks and only 2% had symptoms for more than 30 days after the exposure. Of interest was their finding that residual morbidity did not seem to be related to the degree of irritant exposure. It has been noted that most individuals diagnosed with the condition recover completely over a period of weeks to months without significant clinical or physiologic sequelae (Bardana, 1999). Further complicating the assessment of potential RADS cases is the suggestion of “not-so-sudden” irritant-induced asthma syndromes in individuals who had exposure to lower levels of irritants for an extended period (Brooks et al., 1998).

EXPOSURES WHICH HAVE BEEN ASSOCIATED WITH RADS

An initial case series reported by Brooks et al. (1985) included 10 individuals and illustrates characteristics of the condition. The exposures were variable and included uranium hexafluoride, floor sealant, spray paint, hydrazine, heated acid, fumigating fog, metal coat remover, and fire/smoke. It was noted that all the substances were pulmonary irritants, which was either gas or aerosol. The authors noted that in several cases, the exposure was to a mixture and the exact agent could not be determined. There was no information regarding the air concentrations of the substance. The duration of exposure ranged from a few minutes to 2–3 h. Symptoms were reported to occur within minutes to twelve hours after the exposure. Reported symptoms included cough, dyspnea, wheezing, chest pain, and chest tightness. In seven of the cases, symptoms were present for a year or more. The cases were evaluated anywhere from 4 to 140 months after the exposure for the persistent respiratory symptoms. A methacholine challenge was obtained for each of the cases and confirmed airway hyperreactivity.

Since the initial case series, there have been numerous additional case reports of RADS. Virtually any type of pulmonary irritant can be implicated as a potential cause of RADS. Incriminated substances have included various acids, ammonia, bleach, cleaning agents, dust, hydrogen sulfide, oxides of nitrogen or sulfur, paints, pesticides, smoke, and many others (Shakeri et al., 2008).

DOSE-RESPONSE RELATIONSHIPS

By definition, most RADS cases are identified retrospectively when respiratory symptoms do not seem to improve after the reported exposure. As such, there is typically no information regarding the exact concentrations of substances to which an individual may have been exposed and as noted by Brooks et al., the exact composition of the substance may not even be known. In short, there is no reliable information as to the magnitude or duration of exposure, which is necessary to produce the RADS condition.

SOURCES OF EXPOSURE

RADS cases have been reported from both non-occupational and occupational exposures. Reported cases are typically secondary to an accidental release and may involve scenarios such as residents living near an industry, road, or railway in which there was an unexpected chemical release or occupational situations in which a worker was unexpectedly exposed to high levels of an irritant chemical due to an unforeseen release, failure of personal protective equipment, or inability to immediately escape exposure.

INDUSTRIAL HYGIENE

Because RADS cases typically involve an unexpected chemical release, there are rarely any air monitoring data available to document the extent of exposure. Simulation of the reported exposure with air monitoring and/or modeling may be obtained in special situations but are rarely available. Even if such air monitoring data was immediately available, this could not reliably predict whether an individual would develop a persistent respiratory condition such as RADS. However, when assessing a situation with the potential for a RADS case, it is important to document that the individual also experienced other symptoms that would be consistent with exposure to high levels of a respiratory or mucous membrane irritant. Based on known irritant thresholds for some chemicals, this may provide some estimate of the exposures, which may have occurred. The presence of irritant symptoms and their severity in other nearby individuals may provide additional information in estimating potential exposures, which may have occurred.

MEDICAL MANAGEMENT

For a high level irritant exposure such as those associated with the development of RADS, the initial medical management is supportive, including maintenance of the airway and adequate oxygenation. Severe pulmonary irritant exposures may be associated with bronchospasm, pulmonary edema, pulmonary hemorrhage, and hypoxia. In general, there is no specific antidote or treatment, which has been identified that can decrease the risk of a subsequent persistent respiratory condition such as RADS. It is impossible to predict those who may develop a RADS condition.

There is not a specific diagnostic test, which confirms RADS. The diagnosis is one of exclusion and is based on the exposure history and the persistence of characteristic respiratory symptoms more than three months after the initial exposure. Diagnostic methods which may be used to support a diagnosis of RADS include a PFT usually showing an obstructive process and a methacholine challenge test which demonstrates increased airway reactivity. Both tests are non-specific with multiple potential causes for abnormalities.

In particular, a positive methacholine challenge may be cited as proof of RADS. Methacholine challenge testing is not commonly obtained by primary health care providers and the significance of test results is not always understood. Methacholine is a cholinergic agonist, which causes bronchoconstriction when inhaled at sufficient concentrations. Individuals with asthma or reactive airways react to lower concentrations of methacholine. The test is performed by having an individual inhale an aerosolized mist containing methacholine at increasing concentrations through a nebulizer. The response to methacholine is measured by performing a PFT after each

dose. The primary measure of interest is the forced expiratory volume in 1 second (FEV1). If the respiratory airways are narrowed, such as in an asthma attack, the FEV1 will be reduced and may be interpreted as obstruction. A positive test is usually defined as a 20% decrease in the FEV1 at a methacholine dose <16 mg/ml. Levels of 4–16 mg/ml are considered borderline (Crapo et al., 2000). A negative methacholine challenge test virtually excludes the diagnosis of asthma or RADS. However, specificity of the test is poor as there are many relatively common conditions, which may be associated with a positive test result. These include cigarette smoking, allergies, recent respiratory infection, gastroesophageal reflux, and others (Hewitt, 2008).

Caution is emphasized when making a diagnosis of RADS. Review of litigated cases has shown that some health care providers have made a diagnosis of RADS without a clear understanding of the chemical involved, the extent of exposure, and/or the known association, if any, between the chemical in question and RADS. This may result in a cascade of events including empiric respiratory treatments with significant side-effects, misinterpreted diagnostic studies, or incomplete consideration of alternative explanations for the reported symptoms. One or more of these factors may lead to an erroneous diagnosis of a chronic respiratory condition with attendant disability. The potential for respiratory medications used in the initial treatment of an irritant exposure to cause continued symptoms have been noted (Hewitt, 2011). Prior to diagnosing RADS and instituting treatment, the treating health care provider should ensure they understand the reported exposure and whether its association with RADS is plausible. This may require consultation with an occupational medicine physician, toxicologist, and/or industrial hygienist to fully assess the reported exposure.

Treatment of RADS is non-specific and is similar to any case of asthma. Medications may include bronchodilators, nebulizers, or inhaled steroids. The optimal duration of treatment has not been established. RADS cases may spontaneously resolve over time or in some cases, have symptoms,

which reportedly persist for years. Because an individual with RADS is not sensitized to the causative substance, the individual can return to work in areas in which the substance is present but at levels below those, which cause aggravation of respiratory symptoms.

PULMONARY SENSITIZATION

DAVID J. HEWITT

BACKGROUND

Sensitization refers to the development over time of an allergic reaction to a chemical or substance. Initial exposure to the substance does not result in adverse health effects. However, repeated exposure may cause sensitization reactions, which can become more severe with repeated exposure and may also occur at lower levels of exposure. Sensitization is generally permanent once it occurs. hypersensitivity pneumonitis (HP) and occupational asthma (OA) are the two most common conditions related to pulmonary sensitization in the occupational or industrial environment and are described in the following section.

HYPERSensitivity PNEUMONITIS

Hypersensitivity pneumonitis, also called extrinsic allergic alveolitis, is a respiratory condition caused by the inhalation of a substance to which the individual has developed an immunologic sensitivity. There are numerous substances that have been identified as a cause of HP. The most common causes include bacteria, fungi, or animal proteins, although some chemicals have also been associated with the condition. Specific substances include thermophilic bacteria such as *Thermoactinomyces vulgaris* found in contaminated hay; fungi such as *Aspergillus*, *Penicillium*, *Alternaria*, or *Cladosporium* species; avian proteins related to bird droppings or feathers; and chemicals such as diisocyanates and trimellitic anhydride. HP may also be identified by a particular occupational syndrome or presentation such as farmer's lung, mushroom worker's lung, humidifier lung, or bird-fancier's lung (Rose, 1996). Occasional outbreaks of HP with multiple

cases secondary to a common exposure may occur (Bracker et al., 2003; Robertson et al., 2007).

Prevalence of HP in the occupational environment has not been defined. Bourke et al. (2001) estimated that only 5–15% of individuals exposed to a sensitizing agent will develop the condition. Primary risk factors include the duration and magnitude of exposure. Cigarette smoking appears to have a protective effect for unknown reasons. Once a susceptible individual becomes sensitized, an acute exposure classically results in symptoms of fever, chest tightness, dyspnea, and general malaise or flu-like symptoms, which usually occur within a few hours after the exposure and resolves in 24–48 h. Alternatively, some individuals will present with progressive dyspnea from chronic exposures with no obvious temporal variations in symptoms.

In the acute form, symptoms recur with each exposure and sensitivity may increase. Repeated exposure may be associated with progressive respiratory effects, including increasing dyspnea in the absence of exposure, pulmonary function test (PFT) abnormalities (usually restrictive), and chest imaging abnormalities with patchy alveolar infiltrates, which are classically described as "ground glass" in appearance. Late stage effects may include honeycombing fibrotic patterns with irreversible respiratory effects. Lung diffusion capacity is the most severely affected physiological measurement.

OCCUPATIONAL ASTHMA

Asthma may be defined as a reversible airway obstruction in which the airways in the respiratory tract constrict and narrow in response to various stimuli. Occupational asthma can be defined as asthma that occurs secondary to

a work-related exposure to a pulmonary sensitizing agent. This differs from preexisting asthma that may be aggravated by exposure to respiratory irritants in the workplace that do not cause sensitization. Reactive Airways Dysfunction Syndrome (RADS), is sometimes identified as a type of OA that occurs secondary to a high level irritant exposure, does not involve an immunologic sensitization reaction, and has no latency between the exposure and the onset of the asthmatic condition. Approximately 10–15% of adult onset asthma is considered to be related to occupational exposures (Balmes et al., 2003; Blanc and Toren, 1999).

As with HP, the number of substances that have been associated with classic OA is lengthy and continues to grow. Specific substances include bacteria and molds, animal proteins, wood dusts such as Western red cedar, metals such as chromium or nickel, and chemicals such as isocyanates. Some substances have been associated with both HP and OA. It is difficult to predict who may develop OA. Potential risk factors include a history of atopy, preexisting asthma, increased duration of exposure, and exposure to increased air concentrations of the substance (Dykewicz, 2001; Mapp et al., 2005).

The condition is characterized by the onset of asthma symptoms such as dyspnea, cough, and wheezing, which occurs after repeated exposure to a pulmonary sensitizing agent. Symptoms may occur shortly after exposure, or several hours later depending on the specific substance and sensitivity. With repeated exposure, the individual may become more sensitized and react to lower airborne concentrations of the substance. Symptoms characteristically improve with removal from the exposure. However, continued exposure can result in progressively increased asthmatic symptoms, which may not fully resolve after elimination of exposure.

SOURCES OF EXPOSURE

Work environments that may be associated with pulmonary sensitization reactions are highly variable. Those that seem to be more at risk include those involving paints, plastic manufacture, electronics, welding, metal dusts, metal fluids, agriculture, hair salons, healthcare, and laboratory environments (Dykewicz, 2001).

DOSE-RESPONSE RELATIONSHIPS

The specific level of exposure necessary to result in pulmonary sensitization for HP or OA is unknown. Risks of sensitization in susceptible individuals may increase with increasing exposure; however, a threshold has not been defined for most substances.

INDUSTRIAL HYGIENE

Industrial hygiene can play an important role in identifying the potential for pulmonary sensitization conditions. This can include review of job duties and identifying potential substances in the workplace, which could cause a condition of HP or OA. In the event such exposures are identified, steps can be taken to decrease or eliminate exposures. This may include identification of alternative substances that are not associated with pulmonary sensitization, improved ventilation to decrease exposures, and identification of appropriate respiratory protection. Air testing may be considered to document that a pulmonary sensitizing agent is present and thereby assist in confirming a medical diagnosis. Repeated testing of the workplace can be performed to determine the effectiveness of control measures for decreasing exposures.

MEDICAL MANAGEMENT

Criteria for confirming suspected cases of pulmonary sensitization include identification of an agent within the workspace that has been associated with sensitization; a history that is consistent with characteristic respiratory symptoms temporally related to work (i.e., occur during or after work with the suspected substance and improve when away from work on weekends or vacations); and characteristic clinical findings. Laboratory testing may be able to support a diagnosis using immunologic tests for specific substances. Because pulmonary sensitization can have significant effects regarding employment, it is important to reliably confirm the diagnosis.

Pulmonary function testing in the form of baseline testing, serial testing, and peak flow monitoring is a primary component in attempting to verify an occupationally related condition. Ideally, a baseline PFT obtained prior to the individual starting work can be used to compare with subsequent tests obtained during or after work. Alternatively, serial PFT's can be obtained at several times during the workweek to determine if there is a change. Such testing can be performed at the beginning and end of the workweek or during several different times during a workday. Peak flow testing involves the use of a small peak flow meter that an affected individual can carry with him/her during the workday and quickly measure respiratory function throughout the workday and away from work. Individuals are generally asked to record peak flow measurements in a log or graph several times a day, which can show whether there is a consistent pattern of change with work exposures. Interpretation of peak flow measurements is confounded by reliance on self-reported data and the individual performing the test correctly with maximum effort each time (Townsend, 2000). Of these methods, serial PFT's are likely to provide the most reliable

information as the test is performed according to strict criteria by a trained individual. Results can be assessed for reproducibility, validity, and effort. However, provision of on-site PFTs may be impractical.

Skin prick testing or serological testing (i.e., specific IgE) may be useful in some cases to identify evidence of sensitization and suggest a causal association (Grammer et al., 1989). However, such tests may not be readily available for the exposure of concern and may have limited sensitivity. Blood tests appear to be less sensitive than skin testing (Tan and Spector, 1999). A positive test does not automatically confirm the diagnosis and should be evaluated in the context of other information (Anonymous, 1992).

Additional diagnostic criteria specific to HP include a history of exposure to an agent known to cause HP, characteristic chest X-ray or CT findings, and precipitating antibodies to causative antigens (Rose, 1996). Significant predictors of HP have included exposure to a known offending antigen; positive precipitating antibodies to the antigen, recurrent episodes of symptoms; inspiratory crackles on exam, symptoms occurring 4–8 h after exposure; and weight loss (Lacasse et al., 2003).

For OA, a methacholine challenge test can be used to confirm increased airway reactivity in cases in which the diagnosis is unclear. A negative test virtually excludes the diagnosis of asthma. A positive test does not necessarily confirm asthma as there are numerous causes of increased airway reactivity, which may need to be considered (Hewitt, 2008). Immunological testing, if available, is generally most useful for high molecular weight substances where a negative result essentially rules out the agent as a cause of OA (Cruz and Munoz, 2012). In most cases, reliable documentation of exposure to a sensitizing agent with associated work-related decreases in pulmonary function is the most common method of verifying the diagnosis.

The definitive test for diagnosis of pulmonary sensitization is to have the individual undergo a specific challenge in which the individual is placed in a controlled environment and exposed to the substance of concern (Tan and Spector, 1999). Reproduction of symptoms or PFT decrements confirms the diagnosis. Such testing may be employed in cases in which there is uncertainty regarding the diagnosis or medicolegal issues regarding causation. However, specific airway challenge testing is rarely available to the general practitioner.

The first treatment goal for individuals with a condition related to pulmonary sensitization is to remove them from the exposure. If identified early, the chances of persistent respiratory health effects are substantially decreased. Continued exposure may result in increasing respiratory morbidity that can be permanent. Acute episodes of HP are treated symptomatically and typically resolved within 1–2 days after an exposure. Occupational asthma is treated the same as non-OA and involves medications such as bronchodilators,

nebulizers, or inhaled steroids. With cessation of exposure and time, the need for respiratory medications may decrease or be eliminated. The duration of required respiratory treatment in an OA case is difficult to predict and may be affected by factors such as the chronicity of exposure prior to diagnosis.

Because an individual with HP or OA is sensitized to the causative substance, they should have a permanent restriction from working with the responsible substance. Alternative work duties or positions may need to be implemented to insure the individual does not have continued exposure.

“STREET” AND PRESCRIPTION DRUG ABUSE

SHARON S. KELLEY, JAMES GODIN, AND JOHN CHRISTIE

INTRODUCTION

Drug abuse in the workplace has been a concern for occupational and environmental healthcare professionals for many reasons, including but not limited to:

- Detrimental short-/long-term health effects experienced by the employee and their families
- Diminished quality of job performance
- Safety of the employee, fellow employees, clients, and the general public
- Liability of the employer for medical and/or legal costs incurred by drug abuse

During the last century, illicit drug abuse was the focal point of scrutiny in the workplace but in the past decade, the abuse of prescription drugs and steroids has risen dramatically.

The contents of this chapter have been provided to equip occupational healthcare professionals in their understanding of the physical and psychological presentations associated with each of the listed drugs. This information, coupled with other identifying tools such as “street” names, laboratory analysis caveats, and management recommendations, specific to the drug, will hopefully serve to increase the practitioner’s ability to recognize drug abuse and thereby reduce morbidity and mortality as well as corporate loss and liability.

AMPHETAMINES AND METHAMPHETAMINE

BACKGROUND AND USES

Due to concerns in the 1920s regarding the availability of naturally occurring ephedrine, specifically that sufficient supplies would not be available to meet the demands of asthmatic patients, laboratories were encouraged to design synthetic means of producing this β -adrenergic drug.

The name “amphetamine” is an acronym for α -methylphenylethylamine which belongs to the phenylethylamine family. As substitutions are made on the phenylethylamine base structure, numerous analogs are created with varying effects and potencies. The commonality among analogs is their stimulant action and high potential for abuse which has led to these drugs to be classified as Schedule II drugs per the Controlled Drugs and Substances Act (Goldfrank et al. 2007).

Medical uses include treatment for attention deficit hyperactivity disorder (ADHD), narcolepsy, depression, and weight control.

Methamphetamine originated when Japanese chemist Ogata, in his attempts to produce ephedrine, synthesized *d*-phenyl-isopropylmethylamine, which came to be known as methamphetamine. MethedrineTM and BenzedrineTM, two forms of methamphetamine, were sold by US pharmaceutical houses as agents which would provide relief from nasal congestion with additional benefits of reduced fatigue

and increased alertness. Growing abuse, with drug-related deaths, resulted in the removal of methamphetamine from the market during the 1950s/1960s. A reformulated product, Desoxyn™ is a currently prescribed for ADHD and weight control (Karch 2009) (National Institute on Drug Abuse 2014).

Brand names for amphetamine include: Adderall®, Adderall XR®

Street names include: crank, uppers, kid speed, whiz

Brand names for methamphetamine include: Desoxyn® and Methampex®

Street names include: meth, crank, crystal, ice and poor man's coke

PHYSICAL AND CHEMICAL PROPERTIES

Physical Properties

While amphetamine is typically ingested in tablet form, associated analogs such as methamphetamine may appear in a variety of physical forms:

White or pink crystalline small chunk-like forms (shards)
which may be utilized for smoking

White, off white, tan powder (appropriate for snorting)

Tablets

Clear liquid

Chemical Properties

Amphetamine

Chemical Name: 1-phenylpropan-2-amine

Metabolized via P450 enzymes CYP2D and CYP3A

Methamphetamine

Chemical name(s): N- α -dimethylbenzenethanamine, *d*-N- α -dimethylphen ethylamine, *d*-deoxyephedrine

Metabolized via P450 enzymes CYP2D and CYP3A

TOXICOLOGY

Acute Effects

CNS: Increased alertness, enhanced libido, anorexia, hyperactivity, mydriasis, diaphoresis, anxiety, bruxism, blurred vision, headache, hyperthermia, seizures, insomnia, dizziness, twitching, stroke, hallucinations in the presence of more psychoactive analogs such as MDMA

Gastrointestinal (GI): Diarrhea, constipation

Cardiovascular: Tachycardia, hypertension, myocardial ischemia

Chronic Effects

CNS: Psychosis, neurotoxicity due to prolonged dopamine upregulation, anxiety, post-acute withdrawal syndrome

Oropharyngeal: Dental caries ("meth mouth") (Donaldson 2006)

Cardiovascular: Hypertrophy possibly attributed to calmodulin activation, left ventricular dysfunction due to stress-induced cardiomyopathy, interstitial fibrosis from myocyte disruption, microvascular disease, multivessel coronary artery disease

Dermatological: Dermatillomania (persistent skin scratching)

Mechanism of Action

Amphetamines stimulate the central nervous system(CNS) through the neurotransmitters dopamine, serotonin, and norepinephrine specifically the facilitation of their release into the synaptic cleft, inhibition of their reuptake, and increased stimulation of postsynaptic receptors. Due to the lipophilic nature, the drugs cross the blood brain barrier more rapidly than similar stimulants. Amphetamines are metabolized by means of monoamine oxidase (MAO) degradation hence warnings are provided to patients to avoid amphetamines, and their analogs, should be taking MAO inhibitors (Horton et al. 2013).

As chronic use of methamphetamine results in damage to dopaminergic receptors, long-term neurological sequelae may be present. In addition, to loss of normal dopamine functions, serotonin, tyrosine, and tryptophan hydroxylase activity is also diminished. Methamphetamine may also exert its detrimental effects through binding to a G protein-coupled receptor TAAR₁. Trace amine-associated receptors are activated by amphetamine type molecules. (Hong & Amara 2013)

MODES OF ADMINISTRATION

Oral

Intravenous

Inhaled (smoked)

Insufflated (snorted)

DRUG SCREENING

Detection time in urine is $20.7 \text{ h} \pm 7.3 \text{ h}$ (amphetamine), $23.6 \pm 6.6 \text{ h}$ (methamphetamine)

Screening assays include the Marquis and Simon tests. If methamphetamine is present, the Marquis test will yield an orange/brown color while the Simon test will produce a blue color which distinguishes methamphetamine from amphetamine which manifests a red coloration.

"SAHMSA 5" drug screens include amphetamines as one of the paneled drug classifications. Tests would need to be evaluated for whether dextroamphetamine and methamphetamine would also be detected.

Care must be given during drug testing as similar stimulants may cross react and result in a "false positive" when reviewing the screen. An example would be the patient/employee using nasal inhalers. As there are two amphetamine enantiomers, the *l*- and *d*-forms, a "false positive" may occur when the active agent in the inhalers produces a "positive" result. However, inhalers possess the *l*-enantiomer which contains none of the psychoactive properties. Other drugs include commercially available cold remedies, weight reduction aids, and psychotropic medications. False positives may also occur by the metabolism of certain drugs such as selegiline as amphetamine and methamphetamine are chief metabolites (Moeller et al. 2008) (McPherson et al. 2007).

Other lab abnormalities associated with the amphetamine/analog use that may be noted are hyperglycemia, elevated CPK, elevations in liver function tests, myoglobinuria, and leukocytosis.

Mass spectroscopy (MS): Major ions are found at m/z = 42, 56, 57, 58, 59, 65, 91, and 134.

Gas chromatography (GC): Testing can be improved by N-derivatization. If using a urine sample, the limit of detection (LOD) = <10 µg/l.

MEDICAL MANAGEMENT

Supportive care is emphasized in the management of methamphetamine ingestion. Several caveats in this treatment would include safety to staff as methamphetamine can induce severe agitation and psychosis as well as the awareness of poisoning by accompanying adulterants such as heavy metals.

As in all cases of medical management, monitoring and support of airway, breathing and circulation are tantamount to successful patient outcomes. In addition, industrial healthcare specialists should also consider the following:

Specific treatments for heavy metal toxicity caused by contaminants in some methamphetamine preparations may be needed (Burton 1991).

Hyperthermia should be addressed with cooling measures, including but not limited to, the use of intravenous fluids (Santos 2005).

Electrolyte abnormalities should be considered due to anorexia and diaphoresis.

Seizure activity may benefit from the administration of benzodiazepines or related drugs (Derlet 1990).

Severe psychotic episodes may warrant the use of sedatives and appropriate antipsychotic drugs (Zorick 2008).

Antiarrhythmic medications should be utilized when indicated; however, the use of β-blocking agents should be avoided due to the risk of hypertensive crisis induced by

diminishing α-adrenergic opposition (Cone et al. 2011) (Steadman & Birnbach 2003).

Rhabdomyolysis, due to long periods of immobility from taking CNS depressants to counteract the stimulatory effect of amphetamines/analogs, should be considered and CK levels utilized as part of the diagnostic process. Treatment would include IV crystalloids, sodium bicarbonate to raise pH and prevent myoglobin precipitation in the renal tubules while avoiding urinary acidity (Richards 1999).

ANABOLIC STEROIDS

BACKGROUND AND USES

The use of drugs to enhance performance and increase strength dates back to as early as 776 BC when Greek Olympians were alleged to have used dried figs, mushrooms, and strychnine to enhance performance (Grivetti & Applegate 1997). Medical use of testicular extract began in the late 1800s and anabolic steroids can be traced to the 1930s when scientists synthesized a form of testosterone in order to treat men unable to produce a sufficient amount for typical development and sexual function.

In the 1940s, supraphysiological doses of anabolic androgenic steroids (AAS) were administered in eugonadal patients for anabolic benefit and in World War II artificial testosterone aided malnourished soldiers in weight gain and performance. High dose AAS have been used as therapy to promote muscle deposition post-burns, surgery, radiation therapy, and aging-related sarcopenia.

Brand names include: Androderm®, Androgel®, and Andropatch®

Street names include: Roids, gym candy, Arnolds, stackers, and juice

PHYSICAL AND CHEMICAL PROPERTIES

Physical Properties

Liquid

Gel

Chemical Properties

Chemical name of testosterone is 17-betahydroxyamndrost-4-en-3-one.

Steroids are a special class of lipids with a common feature being that of four-fused hydrocarbon rings, which offers the opportunity for a large variety of molecules.

Cholesterol, a key steroid, has within its structure a hydroxyl group that is responsible for the amphipathic character of the molecule. This is of importance as cholesterol can be incorporated into biological membranes as a lipid component.

Naturally-occurring anabolic steroids are synthesized in the testis, ovaries, and adrenal glands from cholesterol via pregnenolone.

Synthetic anabolic steroids are created through modification of testosterone in one of three ways:

- Alkylation of the 17-carbon
- Esterification of the 17-OH group
- Modification of the steroid nucleus

TOXICOLOGY

Acute Effects

Cardiovascular: Acute myocardial infarction, arrhythmias

Cerebrovascular: Stroke

Pulmonary: Embolism

Chronic Effects

Cardiovascular: Hypertension, left ventricular hypertrophy, cardiomyopathy, peliosis hepatitis (Stergiopoulos et al. 2008)

Dermatologic: Acne, male pattern baldness (Hoffman & Ratamess 2006)

Psychological: Manic symptoms associated with aggressive behavior and violence, depression

Hematologic: Polycythemia

GU: Decreased sperm count, testicular atrophy, gynecomastia, impotence (Korkia & Stimson 2007)

Musculoskeletal: Premature epiphyseal plate closure, intramuscular abscesses, possible increase in tendon tears (Casavant et al. 2007)

Apoptosis in neuronal cells (Estrada et al. 2006)

Mechanism of Action

Anabolic androgenic steroid increases lean body mass through elevated amounts of actin and myosin in skeletal muscle cells, which arises from increased protein synthesis (Patil et al. 2007). This originates from testosterone through a series of steps, which activates mRNA to increase transcription (Karch 2009). Secondary anabolic effects are achieved by an increased creatine kinase activity, upregulation of insulin-like growth factor-1 receptors in conjunction with an increase of insulin-like growth factor-1 as well as reducing the catabolic effect that glucocorticoid activity has on muscle tissue.

MODES OF ADMINISTRATION

Intramuscular injection

Oral

Sublingual

Transdermal

DRUG SCREENING

Radioimmunoassay measures urinary ratios of testosterone to epitestosterone and luteinizing hormone.

Urinary T/LH ratio is a more sensitive and specific than urinary T/E ratio (Perry et al. 1997).

MEDICAL MANAGEMENT

Treatment for myocardial ischemia with oxygen therapy and nitrates dependent upon hemodynamic stability (Wysoczanski et al. 2008)

Potential phlebotomy for polycythemia

Antihypertensive agents as required

Antiarrhythmic agents as required. Note: Avoid β-blockers in the event of concomitant use of cocaine or other β-adrenergic agents (see cocaine)

Evaluation for neurological intervention in the event of cerebrovascular accident (García-Esperón et al. 2013)

Evaluation for fibrinolytic therapy in the event of pulmonary embolism (Fengler & Brady 2009)

BENZODIAZEPINES

BACKGROUND AND USES

Benzodiazepines were first discovered in the 1930s by Leo Sternback, an employee of Hoffman-LaRoche but were not medically used until 1957 when Librium[®] was prescribed as an anxiolytic. Benzodiazepines grew to be one of the most highly prescribed drugs in the United States and reports of abuse in the 1980s led to these drugs being classified in Schedule IV as per the Controlled Substance Act (Rosenbaum et al. 2005).

Benzodiazepines are used as anxiolytics, amnestic, hypnotics, anticonvulsants, sedatives, and muscle relaxants.

Brand names include: Xanax[®] (alprazolam), Ativan[®] (lorazepam), Valium[®] (diazepam), and Versed[®] (midazolam)

Street names include: Bennies, bars, tranks, benzos, xanies, xanabars

PHYSICAL AND CHEMICAL PROPERTIES

Physical Properties

Tablet, capsule

Liquid

Chemical Properties

Benzodiazepines are composed of a benzene ring, which is joined to a seven member diazepine ring.

Unique compounds are created based upon substituents on side chains and modification of the rings.

TOXICOLOGY

Acute Effects

CNS: Bradypnea, apnea, somnolence, coma, impaired motor coordination, confusion, altered vision, dizziness/vertigo, impaired cognitive function

Cardiovascular: Bradycardia

GI: Vomiting

Psychological: Mood swings, erratic behavior, agitation, euphoria in the presence of other drugs

Neurological: Seizures, myoclonus

Chronic Effects

CNS: Memory and cognitive impairment, confusion, disorientation, slurred speech, diminished coordination

Tolerance typically for usage >6 months

Cross-tolerance with other CNS depressants, including alcohol

Mechanism of Action

Depresses CNS by enhancing GABA_A's inhibitory effects
Active receptors sites are found in the periphery with the highest concentration being found in steroid-producing cells specifically the adrenal and anterior pituitary glands as well as the reproductive organs. (Goldfrank et al. 2007)

In cocaine cardiotoxicity, benzodiazepine usage may be justified due to the presence of cardiac benzodiazepine receptors

Increases the frequency and duration of opening chloride channels mediated by GABA

MODES OF ADMINISTRATION

Oral

Insufflation

DRUG SCREENING

Not part of the standard "SAMHSA-5" (UNODC 2012)

Can be detected 48–72 h after ingestion

Presumptive screens—Zimmerman test

Chromatography (e.g., TLC, GC, or HPLC)

Spectroscopy (e.g., IR, UV, MS)

MEDICAL MANAGEMENT

Respiratory support is emphasized due to CNS depression especially when other CNS depressants are present as well. Endotracheal intubation may be necessary based upon adequacy of respiratory effort.

Flumazenil can be used to reverse benzodiazepine intoxication at a starting dose of 0.2 mg intravenously over 30 min. Flumazenil cannot be given via the endotracheal tube as compared to the opioid reversal agent naloxone.

Abrupt discontinuance of benzodiazepines therapy can induce seizures, anxiety, irritability, hallucinations, and diarrhea (Tetrault & O'Connor 2008).

Withdrawal syndromes may be manifested within 2–10 days after removal of the drug.

Flumazenil can induce withdrawal

Benzodiazepines are not associated with any specific organ toxicity

Benzodiazepine overdoses are rarely lethal unless accompanied by other CNS depressants. (Goldfrank et al. 2007)

COCAINE

BACKGROUND AND USES

Cocaine is derived from the leaves of the *Erythroxylum coca* plant which is indigenous to South America, Indonesia, and the West Indies (Levine 2010). Early uses included roles in religious rites but workers in the mountainous ranges discovered benefits from cocaine's activity on the CNS that specifically increased energy, stamina, and appetite suppression. This benefit was especially helpful during long working days at high altitudes.

Cocaine was first utilized as a local anesthetic in Europe during the 1800s and the drug was legally used as a recreational drug in the United States until 1914. The vasoconstrictive properties, in addition to its anesthetic activity, made cocaine a valuable agent in both nasal and eye surgeries but its use has diminished with newer, and safer, local anesthetic agents (Karch 2009).

Cocaine is second only to marijuana, as a commonly abused illicit drug in the United States. For the occupational

health practitioner, it is important to recognize “street” terms for the drug as they might be commonly heard during patient histories and reports of potential abuse from co-workers (Albertson 2014).

Brand names for cocaine include: Pharmaceutical cocaine
Street terms for cocaine include: Coke, crack, blow, snow, and nose candy

PHYSICAL AND CHEMICAL PROPERTIES

Physical Properties

Cocaine hydrochloride—the most common of the potential salts made by combining the alkaline cocaine with various acidic compounds. Typically cocaine hydrochloride will present as a white, crystalline powder but tinting with other colors may be noted due to adulterants and manufacturing methods. Polar and easily dissolved, this form is utilized primarily for insufflation and intravenous administration.

“Crack” cocaine: Appears as an irregularly shaped, amorphous “rock” or may also appear as a thin wafer depending upon the method of “cooking.” Typically, “crack” or “rock” cocaine will appear as white, off-white, yellow, or potentially light brown. The methods of manufacture to convert the base and adulterants are responsible for varying tints. Easily vaporized.

Freebase cocaine: Prepared by utilizing ammonia and cocaine to produce a “base” form of the cocaine. It is typically a white powder of higher potency than the “rock” form which utilizes baking soda as a conversion agent.

Infusion: Prepared by utilizing dried coca leaves and filtering them to form a “tea.” It is more common in South American countries; and used as an herbal, medicinal agent.

Chemical Properties

Chemical name: Methylbenzoylecgonine

An ester of methylecgonine and benzoic acid (Yang et al. 2001)

The ecgonine component includes four chiral carbons which can exist as four racemic forms and eight optical isomers

Subsequent to hydrolysis of the ester alkaloids from the coca plant, cocaine can be synthesized by combining the (-) ecgonine with methanol and benzoic acid (Fandiño et al. 2002)

TOXICOLOGY

Acute Effects

Cardiovascular: Myocardial ischemia, myocardial infarction, hypertension, aortic dissection, stroke, arrhythmias

(i.e., sinus tachycardia, supraventricular tachycardia, ventricular tachycardia, ventricular fibrillation) (Derlet et al. 1994) (Wenzel et al. 2004)

Pulmonary: Hypoxia, pulmonary edema, pneumothorax, pneumomediastinum, pneumopericardium, tachypnea, “crack lung”¹

ENT: Mydriasis, acute glaucoma, malarosis, oropharyngeal burns

GI: Ulcer perforation, ischemic colitis

Musculoskeletal: Rhabdomyolysis

Psychological: Restlessness, agitation, psychosis, paranoia, “Superman syndrome”

CNS: Seizures, hyperthermia, coma, focal neurologic abnormalities, cerebral hemorrhage (Larossa 2013)

Obstetrics and gynecology (OB/Gyn): abruptio placentae

Chronic Effects

Cardiac: Cardiomyopathy, myocardial spasm, ischemia, infarction

Pulmonary: Dyspnea, hemoptysis, bronchospasm, alveolar infiltrates without effusions, chest pain, lung trauma, pruritis, sore throat, asthma, hoarseness, eosinophilia

Neurological: Hemorrhagic and ischemic stroke

GI: Nausea, vomiting, abdominal pain

Dental: Gingivitis, enamel breakdown due to bruxism

ENT: Nasal septal erosion and perforation (Businco et al. 2008)

Autoimmune: Lupus, vasculitis, Goodpasture’s disease (Chan et al. 2011)

Renal: Glomerulonephritis (Chan et al. 2011)

Dermatological: Burn to lips, callouses to extremities, “crack thumb” due to burns from holding the “crack” pipes

Mechanism of Action

Cocaine is a sympathomimetic that potentiates the effects of biogenic amines such as dopamine, norepinephrine, epinephrine, and serotonin by increasing release and blocking reuptake of these neurotransmitters back into the presynaptic neurons.

When dopamine accumulates in the synaptic cleft, prolonged postsynaptic effects occur at the receiving neuron, specifically psychomotor agitation. Habitual use leads to the downregulation of dopamine receptors, which can lead to depression and addictive behavior. Serotonin (5-hydroxytryptamine, 5-HT) effects include the depression and addiction listed above as serotonin is a modulator of dopamine. The 5-HT2 receptor is associated with cocaine-related hyperactivity (Baigent 2003).

Adrenally derived epinephrine is responsible for tachycardia while hypertension arises from neuronally produced norepinephrine.

Cocaine's action as a local anesthetic arises from sodium channel blockade thus interfering with action potentials. Additionally, cocaine may bind to the Kappa-opioid receptor.

Chemical Pathology

Vasospasm, increased coagulatory activity and hemorrhage from increased vascular sheering forces are all attributed with end-organ toxicity in multiple organ systems.

MODES OF ADMINISTRATION

Insufflation (snorting)

Inhalation (smoking)

Transmucosal application (e.g., nasal, gingival, vaginal, rectal)

Transdermal

Intravenous

Gastrointestinal (swallowing, "body packing")

DIAGNOSTIC METHODOLOGIES

The half-life is shortest when cocaine is smoked as "free based" or "crack" and longer when sniffed or snorted for 15 and 45 min, respectively. Urine and blood samples are the most commonly used for acute exposures while saliva, hair, and meconium may also be considered. Although the elimination half-life is 40–80 min, metabolites may be detected in urine screens for a period of 48–72 h after acute use and potentially several weeks in those chronically abusing the drug.

Commercial immunoassay testing kits may only detect the chief metabolite, benzoylecgonine (BZE), but other metabolites such as ecgonine methyl ester (EME), and ecgonine are also significant. Cobalt thiocyanate is the most common screening test for cocaine and yields a blue color with reactivity.

MS: The major ions found are m/z = 82, 182, 83, 105, 303, 77, 94, and 96

GC: In blood, the LOD in blood is 20 µg/l

Of particular interest is the metabolite methylecgonidine that would only be found in abusers who have smoked the drug. The pyrolysis induces this particular metabolite that eliminates other modes of administration (Scheidweiler et al. 2003).

Cardiac testing should include 12 lead electrocardiography (ECG), which is suggested for potential observance of acute changes, and cardiac enzymes would be considered as a substantial adjunct for the determination of cardiac injury.

Chest radiography could be helpful in determining the etiology of chest pain or related pulmonary injury.

MEDICAL MANAGEMENT

As cocaine demonstrates combined cardiac inotropic and vasoconstrictive effects, β-blockers should be avoided in the treatment of cocaine-induced tachycardia as this may result in a lack of opposition to the adrenergic, or "alpha," effects of cocaine and can exacerbate coronary vasoconstriction and systemic hypertension leading to hypertensive crisis. Preferred treatments would include nitrates, calcium channel blockers such as diltiazem, benzodiazepines, and hydralazine (Goldfrank et al. 2007) (McCord et al. 2008).

Consideration should be given to the potential adverse effects of adding epinephrine to local anesthetics as this could possibly exacerbate vasoconstriction and thereby attenuate cardiac ischemia and associated arrhythmias (Cone 2011).

As cocaine is primarily metabolized through the liver, via hepatic and plasma cholinesterase; ester-based local agents should also be avoided.

GAMMA HYDROXYBUTYRATE (GHB)

BACKGROUND AND USES

The first report of γ -hydroxybutyric acid (GHB) synthesis was in 1960 as a structural analog of the neurotransmitter gamma aminobutyric acid (GABA). This enabled research, which led to the discovery that GHB is a naturally occurring neurochemical in the human brain.

γ -hydroxybutyric acid was originally used as an anesthetic agent due to its CNS depressant effect but newer drugs with higher safety profiles have resulted in decreased use of this agent. Presently, the only medical use for GHB is in the treatment of narcolepsy under the trade name of Xyrem[®] (Johnson & Griffiths 2013).

Additional, nonmedical, uses include:

Weight reduction

Athletes seeking performance enhancement through increased muscle mass

Drug facilitated sexual assault: “date rape”

Brand names include: Xyrem[®]

Street names include: Blue thunder, blue nitro, women’s Viagra, liquid ecstasy, easy lay, scoop, jib, liquid X, G

PHYSICAL AND CHEMICAL PROPERTIES

Physical Properties

Colorless, odorless liquid

Slightly salty taste

When shaken, bubbles persist on surface of fluid
Prior to dilution, the salt is found as a white/off-white powder

Chemical Properties

γ -hydroxybutyric acid is synthesized from γ -butyrolactone (GBL) by the addition of sodium hydroxide (lye) in either ETOH or H₂O (Schepp et al. 2012).

γ -hydroxybutyric acid converts to GBL dependent upon the matrix, temperature, and pH. A pH lower than 4.72, will cause GBL to predominate.

TOXICOLOGY

Acute Effects

CNS: Bradypnea, apnea, somnolence, coma, miosis (Aromatario 2012)

Cardiovascular: Bradycardia AV heart blocks

GI: Vomiting

Psychological: Hallucinations, euphoria, extreme agitation upon arousal, empathogenesis

Neurological: Seizures, myoclonus

Salivation

Amnesia

Loss of sexual inhibition

Chronic Effects

Psychosis (van Noorden et al. 2009)

Depression

Increased muscle mass

Weight reduction

Mechanism of Action

Exogenous GHB increases dopamine in the presynaptic terminal and a release of endogenous opioids. The anesthetic properties exhibited by GHB are similar to those of a structural analog, GABA (Kelley & Larison 2009).

γ -hydroxybutyric acid increases stages 3–4 and REM sleep, which is when the muscle growth hormone is predominantly released resulting in the increased muscle mass desired by athletes using the drug for performance enhancement.

MODES OF ADMINISTRATION

Oral

Transmucosal (rectal/vaginal)

DRUG SCREENING

Detectable in blood/urine up to 6 h post ingestion
 Requires a special laboratory analysis typically not performed in the hospital setting (McCusker 1999)
 MS: Major ions are found at: m/z 147, 233, 117, 158, 148, 149, 143, 133, 204, 234, and 235.

MEDICAL MANAGEMENT

Respiratory support due to CNS depression (Goldfrank et al. 2007)
 Potential warming of hypothermia
 Consideration of α/β -adrenergic agents for hypotension, and bradycardia
 Naloxone (Narcan) may be helpful even though GHB doesn't bind specifically with the opioid receptor.
 There is a potential need for physical/chemical restraints due to extreme agitation (Dyer 2001).

Rectal/vaginal examination for tampons
 Consider sexual assault examination (Levine 2010)
 Sedation, volume replacement, and cooling measures may be necessary for management of withdrawal. Note: Benzodiazepines primarily affect the GABA_A whereas GHB activity is mediated by the GABA_B receptor therefore may be administered.

- MARIJUANA AND SYNTHETIC CANNABINOIDS**
- BACKGROUND AND USES**
- The earliest records of marijuana usage date back to the 3000 BC and, according to the United Nations, it is the most widely abused drug in the world. Marijuana is the most commonly abused illicit drug in the United States and is derived from the hemp plant *Cannabis sativa* (Rudgley 1998) (UNODC 2006). There are many psychoactive agents found in marijuana but the primary agent is a lipid-soluble compound referred to as delta-9-tetrahydrocannabinoid (THC) (Levine 2010). In the United States, marijuana is used for recreational purposes and, in some states, is legal for medical purposes in the treatment of glaucoma, breakthrough nausea and vomiting subsequent to chemotherapy/surgery and anorexia experienced by HIV patients. Commercially, marijuana may also be used for the production of hemp.
- In 1995, a Clemson University professor conducting research on the cerebral effects from the use of cannabinoids (CB) used a synthetic compound, which was later described as part of a published research paper. Readers began reproducing the method of developing this compound, in order to get marijuana-like "high." From this one compound there are now five identified compounds (WH-018, JWH-073, JWH-200, CP-47, 497, cannabicyclohexanol—three of which list the initials of the Clemson professor) that are being sprayed on herbal blends and smoked. The effects of this "synthetic marijuana," though similar to that of THC, produce distinctive and psychoactive behavior aberrant from THC alone. And, due to these deleterious manifestations, in March 2011, the U.S. Drug Enforcement Administration (DEA) temporarily placed these five compounds into Schedule I of the Controlled Substances Act (CSA) (Macher 2012).
- The main chemical observed is JWH-018 and, just like THC, it attaches to the CB receptors but with a much higher affinity and level of potency than THC (Albertson 2014).

Brand names for marijuana: Marinol®

Street names for marijuana include: pot, reefer, mary, mary j, weed, grass

Street names for “synthetic marijuana” include: K2, spice, Mr. Nice Guy

PHYSICAL AND CHEMICAL PROPERTIES

Physical Properties

Marijuana is a collective term for various parts of the *Cannabis sativa L.* plant, including the seeds, resin, and derived compounds but excluding mature stalks, fiber, and oil extractions.

Tetrahydrocannabinol is an oil, which is highly soluble in lipids but insoluble in water.

Chemical Properties

The component of marijuana that is cited as having the greatest psychological effect on users is delta-9 THC. By weight, the leaves may contain from 1 to 10% THC by weight with a higher percentage, up to 15%, may be detected in hash oil/resin made from the flowering tops of the plant.

Approximately 95% of the THC exists as monocarboxylic acids, which will rapidly decarboxylate when heated. This coincides with the manner in which the drug is administered specifically through smoking and/or baking in foods.

Cannabis contains a large number of chemical compounds, including cannabinoids such as cannabidiol, which is only 10% as active a psychoactive agent as THC.

TOXICOLOGY

Acute Effects

Marijuana:

CNS: Sedative effect with intense relaxation, euphoria, altered mentation, hyporeflexia, anxiety, difficulty with thinking and problem solving (El-Alfy 2010). *Note: The inclusion of adjunctive drugs such as phencyclidine or formaldehyde, known as “smoking wet,” can produce hallucinations, violent behavior*

Cardiovascular: Tachycardia, bradycardia, myocardial depression, hypotension (Cone et al. 2011)

Ophthalmologic: Conjunctival congestion

Pulmonary: Reactive airway exacerbation, bullae formation, laryngospasm

“Synthetic Marijuana”

CNS: Muscle twitching, hyperactivity, hallucinations, loss of consciousness, convulsions (Schneir & Baumbacher 2011)

Cardiovascular: Tachycardia, hypertension (Miretal. 2011)

Pulmonary: Difficulty in breathing

Psychological: Paranoia, psychosis, panic, anxiety (Oluwabusi et al. 2012)

Chronic Effects

Marijuana:

Pulmonary: Increased risk of lung cancer, which is heightened with concurrent use of tobacco

Immunologic: Increased risk of infection secondary to modulation of the immune response specifically T and B lymphocytes, macrophages and immune cytokines

CNS: Increased restlessness, insomnia, irritability, sleep disturbances

OB/Gyn: Decreased fertility rates

“Synthetic” Marijuana

CNS: Increased restlessness, insomnia, irritability, sleep disturbances (Papanti et al. 2013)

Psychological: Paranoia, psychosis, panic, anxiety

Mechanism of Action

Tetrahydrocannabinoid readily crosses the blood brain barrier and binds to CB1 and CB2 receptors both of which are G-protein coupled receptors. Cannabinoid receptor type 1 is found in both the brain and periphery and acts as the presynaptic neural cannabinoid receptor. When THC binds to CB1, it is released as GABA in the cerebral cortex, hippocampus, and amygdala (Goldfrank et al. 2007).

Due to their high lipid solubility, cannabinoids may be detected in the body for long periods of time in comparison to other drugs. A single usage may be detected up to 4 weeks post ingestion. The potential accumulation in the lipid membranes of neurons has been a topic of interest with regard to manifestations by chronic users.

MODES OF ADMINISTRATION

Inhalation

Oral

DRUG SCREENING

The leaves of *Cannabis sativa* and its resin may be identified utilizing microscopy with detection of the glandular trichomes and cystolithic hairs being deemed as confirmatory (McPherson et al. 2007).

The Duquenois test is utilized for screening cannabinoids and produces a blue violet color when reacting with *p*-dimethylbenzaldehyde.

MS: Major ions are m/z = 41, 43, 55, 231, 271, 295, 299, and 314.

Tetrahydrocannabinoid is stored in adipose tissue and has a half-life of approximately 56 h in occasional users and 28 h in chronic users.

Due to high lipid solubility, it may take as much as thirty (30) days to completely eliminate a single use of marijuana metabolites.

Approximately 30% of THC is excreted in the urine and detection using standard urine drug screens, may occur for 1–4 weeks post ingestion.

A metabolite of THC, THC-COOH, is predominantly found in the urine. Hair and fluids such as oral samples and sweat will reflect THC predominantly. Blood samples will reflect both (Karch 2009).

The most commonly used screening test for THC is the Duquenois-Levine; however, this is a screening test and numerous examples are cited of false positives due to cross-reactivity with other agents.

MEDICAL MANAGEMENT

No specific management strategies are cited with regard to THC and there is no known withdrawal syndromes associated with cessation of drug use.

Due to the extreme agitation manifested with patients having ingested "synthetic marijuana," practitioners should be prepared to provide physical/chemical restraints in order to protect the patient, and other patients, from harm.

Practitioners should be alerted to physical manifestations associated with other drugs used in correlation with THC specifically adulterants such as "crack" cocaine or PCP and formaldehyde. The latter two agents are combined with marijuana in a "street" practice known as "smoking wet." This practice involves soaking the ends of the marijuana cigarette in these agents, which creates an increase in hallucinogenic effect but may also induce CNS stimulation, cardiovascular and pulmonary complications (EMCDDA 2012).

Obvious injuries, incurred due to altered mental status, should be prevented or treated with appropriate methodologies.

OPIATES AND OPIOIDS

BACKGROUND AND USES

Opiates are alkaloids derived from the opium poppy *Papaver somniferum*, which was first cultivated in Mesopotamia as early as 3400 BC. The term "opiate" is often misused as it describes only those drugs made from the actual plant whereas the term "opioid" describes a much broader class of drugs, still producing an opium-like response, but also binding to the mu (μ), kappa (κ), and delta (δ) receptors. Examples of opiates include codeine and morphine where examples of semisynthetic "opioids" would include heroin, hydrocodone, hydromorphone, oxycodone, and oxymorphone. Semisynthetics are drugs derived from altering an opiate molecule as compared to synthetic opioids which are not derived from an opiate. Examples of synthetic opioids include fentanyl, meperidine, and methadone.

Whereas many opioids have established medical uses, heroin is an opioid which is illicit in its use. Heroin was first synthesized in 1874 when an English chemist added two acetyl groups to the morphine molecule thus the name diacetylmorphine. In 1895, Bayer marketed diacetylmorphine, under the trade name of "Heroin," as an over-the-counter drug which would serve as a substitute for morphine cough suppressants with their associated risk of addiction. Due to its lipophilic nature and water solubility, the effects of heroin are rapidly experienced by the user making it a very popular drug for potential addiction.

Today, opiates and opioids have a broad range of medical uses, including analgesia, anxiolysis, sedation, decreasing gastric motility, and serving as antitussives. However, prescription opioid abuse has presently risen to "epidemic" levels in the United States with a continual rise since 1999. In November 2011 the director for the Centers for Disease Control and Prevention (CDC), Dr. Thomas Frieden, was quoted as saying that "Overdoses involving prescription painkillers are at epidemic levels and now kill more Americans than heroin and cocaine combined." (CDCP 2011)

Brand names include: Oxycodone, hydrocodone, fentanyl, oxymorphone, hydromorphone

Street names for opioids/opiates include: Heroin ("H", junk, horse, tar, skag) and prescription analgesics (oxy's, roxy's, percs, vikes, blues for prescription opioids.

PHYSICAL AND CHEMICAL PROPERTIES

Physical Properties

Heroin salt (diacetylmorphine hydrochloride)—crystalline powder, typically white in color but color could vary dependent upon adulterants. This is the illicit form of the morphine and would be utilized for snorting or intravenous use due to its high boiling point.

Freebase heroin: Crystalline powder but typically a duller shade of white. This too is an illicit form of the drug and, due to its lower boiling point, is acceptable to smoke.

"Black tar" heroin: Solid, putty-like substance, which may be black or brown and is manufactured with a more rapid method utilizing morphine derivatives other than heroin.

Prescription analgesics may be found in tablet, liquid, and gel preparations.

Chemical Properties

Chemical name of diacetylmorphine (heroin) is ($5\alpha, 6\alpha$)-7,8-Didehydro-4,5-epoxy-17-methylmorphinan-3,6-diol diacetate (ester) (Karch 2009)

Pharmacodynamic effects of a specific opioid are determined by its steriospecificity when binding to certain

receptors as well as the molecular structure of the drug (Levine 2010) (Katchman et al. 2002).

TOXICOLOGY

Acute Effects

CNS: Bradypnea, diminished level of consciousness, coma, miosis, hypothermia, seizures (Kleinschmidt et al. 2001) (Offiah & Hall 2008)

Pulmonary: Hypoxia, apnea, hypercarbia, decreased tidal volume, pulmonary edema, chest wall rigidity

Cardiac: Bradycardias, myocardial ischemia, hypotension, QT prolongation leading to of potentially life-threatening ventricular arrhythmias (e.g., torsades de pointes)

GI: Decreased gastric motility, ileus

Renal: Rhabdomyolysis may occur due to long periods of unconsciousness, or intra-arterial administration, resulting in potential acute renal failure

Metabolic: Hypo/hyperglycemia in diabetics secondary to vomiting

Immunological: Immunoregulatory effects of endogenous opioids may be affected by presence of exogenous opiates (Saurer et al. 2009) (Ye et al. 2001).

Chronic Effects

GI: Constipation

Metabolic: Hyponatremia secondary to increased vasopressin release

CNS: abscesses secondary intravenous-related infections

Mechanism of Action

The analgesic and euphoric effects experienced subsequent to administration of opioids is a result of agonism of the mu receptors even though other receptors have also been identified such as the kappa- and delta-opioid receptors. Hypercarbia and hypoxia risks are increased when mu agonism occurs due to decreased chemoreceptor sensitivity of these two conditions. Tidal volume is decreased and bradypnea may occur resulting in decreased oxygen saturation and increased carbon dioxide retention.

The route of administration distinguishes the metabolism of heroin. If taken intravenously, the first pass metabolism, normally occurring with an oral ingestion, will be missed. Due to the acetyl groups and subsequently the increased fat solubility compared to the morphine molecule, it will cross the blood brain barrier very quickly. As in an oral ingestion, the drug is deacetylated into the active metabolite 6-monoacetylmorphine, the inactive metabolite 3-monacetylmorphine and

morphine which will bind to the μ -opioid receptors. The binding to those receptors is responsible for the analgesic and anxiolytic manifestations of the drug. An adverse effect, however, occurring in both intravenous heroin and morphine users, is pruritus which occurs subsequent to a drug-induced histamine release (Rook et al. 2006).

Repetitive use of heroin results in physiological changes, such as upregulation—an increase in μ -opioid receptors. These changes which are associated with the dependence and addiction are also responsible for withdrawal symptoms after cessation of drug use.

MODES OF ADMINISTRATION

- Intravenous
- Oral
- Insufflation
- Inhalation

DRUG SCREENING

"SAHMSA 5" tests for opiates will screen for morphine and codeine but not for opioids such as oxycontin, methadone, and fentanyl (Quest Diagnostics n.d.)

Samples may come from blood or plasma, urine, saliva, and hair

Fluorescence, microparticle and enzyme immunoassays are recommended for urine samples

ELISAs (enzyme-linked immunosorbent assays) are utilized for non-urine samples

Confirmation analysis includes MS, gas chromatography–mass spectrometry (GC–MS), gas chromatography–tandem mass spectrometry (GC–MS/MS), liquid chromatography (LC), liquid chromatography–mass spectrometry (LC–MS), and liquid chromatography–tandem mass spectrometry (LC–MS/MS)

Not all drugs detectable using saliva and hair

The half-lives of opioids depend on a number of factors, including patient tolerance, bioavailability, administration route, and chemical breakdown

Opioids taken orally or administered intravenously are typically well absorbed and peak effects are observed in 60–90 min

MEDICAL MANAGEMENT

Consideration naloxone administration –0.4–2.0 mg in adults in patients with significant respiratory compromise. Higher doses, up to 10 mg, may be necessary if the ingestion involved a synthetic opioid.

Naloxone may be given by intravenous, intramuscular, endotracheal, or subcutaneous routes. If administering by the endotracheal route the dose should be multiplied by 2–2.5 times that of the dose for intravenous administration. Though rare, a small percentage of patients may experience withdrawal symptoms, including seizures, pulmonary edema, and cardiac arrhythmias such as asystole.

Respiratory support, including endotracheal intubation in the presence of inadequate respiratory effort (Sather & Tantawy 2006)

Circulatory support with α -adrenergic agents

Observe for "track" marks especially in areas hidden from common view (e.g., between fingers, in tattoos)

Treatment of hypoglycemia

Consider associated trauma, infection, and metabolic etiologies

Utilize EKG monitoring, including 12-lead EKG's to observe for QT prolongation associated with opioids such as levoacetylmethadol and methadone. If QT prolongation occurs, the sodium channel blockade in the myocardium may be treated with lidocaine and sodium bicarbonate through competitive displacement.

In the presence of hypotension, diphenhydramine should be considered as a means of counteracting histamine release.

In clonidine withdrawal, patients may experience hypertensive crisis. Administration of vasodilators such as sodium nitroprusside, esmolol, labetalol, or nicardipine should be considered.

MYCOTOXINS

CLARA Y. CHAN AND BRUCE J. KELMAN

Mycotoxins are secondary metabolic products produced by fungi under certain environmental conditions. The presence of fungal growth cannot be used as an indicator of mycotoxins as the production of mycotoxins by fungi depends on myriad environmental conditions, including nutrient availability, growth substrate, moisture, temperature, maturity of the fungal colony, and competition with other microorganisms (Goldblatt, 1969). A species of fungi may also produce more than one mycotoxin, and a specific mycotoxin may be produced by many different species of fungi (D'Mello, 1997). Potentially toxicogenic fungi are commonly found in the outdoor environment (Sudakin and Fallah, 2008).

Potential worker exposure to mycotoxins exists through inhalation and dermal contact associated with the handling and storing of contaminated commodities. While mycotoxins are not volatile and do not evaporate from the mold spore or substrata, they may be present in agricultural environments where airborne concentrations of dusts and mold spores may be high. As of this writing, it appears that aflatoxins and ochratoxins are the primary mycotoxins for which there is potential occupational concern. There is an abundance of literature supporting exposure by the general population to mycotoxins through ingestion but only a limited number of studies on inhalation exposure in the work environment.

Considerable research has been done on the issue of inhaled mycotoxins in spores present in indoor environments. As of this writing, the weight of the scientific evidence shows no causal relationship between exposure to mycotoxins in damp indoor environments and a constellation of health effects of concern (American College of Occupational and Environmental Medicine, 2011; Hardin et al., 2009; Institute of Medicine. Committee on Damp Indoor Spaces and Health, 2004; Kelman et al., 2004).

AFLATOXINS

More than a dozen different aflatoxins are produced by several fungal species in the genus *Aspergillus*. The four major types of aflatoxin (B₁, B₂, G₁, and G₂) are regularly produced by *Aspergillus parasiticus* and *Aspergillus flavus*, and have on occasion been shown to be produced by other species of *Aspergillus* and by species of *Penicillium* and *Rhizopus* (Goldblatt, 1969). *A. flavus* growing on peanuts can produce aflatoxins at temperatures between approximately 13 °C and 41 °C at a 98% relative humidity (Goldblatt, 1969). Other types of aflatoxins (such as M₁, P₁, Q₁, B_{2a}, and G_{2a}) are not food contaminates but are mammalian metabolic products of aflatoxins B₁, B₂, G₁, or G₂ (Eaton and Groopman, 1994).

Aflatoxins exist as colorless to pale-yellow crystals and have a water solubility value of 3150 mg/l at 25 °C (Pohland et al., 1982; U.S.National Library of Medicine, 2013). Aflatoxins have melting point temperatures ranging from 237 to 320 °C and are not destroyed under normal cooking or food processing conditions (Betina, 1989).

INDUSTRIAL HYGIENE

Aflatoxins may occur in commodities such as oil seeds, grains, and nuts. Exposure to aflatoxins by the general population primarily occurs through consumption of contaminated food. *A. flavus* has been found to produce aflatoxins on numerous foods, including peanuts, corn, wheat, rice, and soybeans (Goldblatt, 1969). Consumption of milk and milk products from animals fed on aflatoxin-contaminated feed is a source of potential exposure to aflatoxin M₁. Since

mycotoxins are present in foods as natural contaminants and cannot be completely prevented, mycotoxins are regulated in many countries to limit the exposure by the general population (Table 117.1) (Food and Agriculture Organization, 2004).

Aflatoxin contamination is promoted by stress or damage to the crop due to drought before harvest, insect activity, poor timing of harvest, heavy rains at and after harvest, and inadequate drying of the crop before storage (Strohsnider et al., 2006). Aflatoxins may be present in agricultural dusts and workers in the animal feed industry involved with grain handling and processing may experience occupational exposure to aflatoxin.

Inhalation exposure to aflatoxins occurs by exposure to airborne particles containing aflatoxins such as dust or mold fragments. Airborne aflatoxins levels in occupational

environments can range between 0.002 and 3390 ng/m³ (Table 117.2). Currently there are no standards, guidelines, or regulations for workplace exposure to aflatoxins in the United States.

Analytical methods for measuring aflatoxin concentrations in agricultural commodities and food products include the use of multifunctional columns (MC), immunoaffinity columns (IC), high performance liquid chromatography (HPLC), enzyme-linked immunosorbent assay (ELISA), and thin layer chromatography (TLC). These methods are validated by the Association of Official Analytical Chemists International (AOAC) and the European Committee for Standardization (Gilbert and Anklam, 2002; Lerda, 2011; Trucksess, 2000). A complete list of approved test kits for use at field testing locations can be found through the website of USDA Federal Grain Inspection Service (USDA, 2014).

TABLE 117.2 Measured Concentrations of Aflatoxins in Air in Industrial Settings

Ghosh et al. (1997)	Total AF	0.19 and 0.26	Work and storage area (respectively) of rice and maize processing plants in India
Nuntharatanapong et al. (2001)	Total AF	0.99, 1.55, and 6.25	Handling of animal feed in Thailand

Chromatographic techniques are commonly used to determine airborne and dust aflatoxin concentrations in occupational environments (Burg et al., 1981; Burg and Shotwell, 1984; Selim et al., 1998; Shotwell et al., 1981). Currently, there are no standardized analytical methods for mycotoxins, including aflatoxins, in environmental samples in non-agricultural environments.

Measurement of mold spores in nonagricultural environments, such as residences, schools and offices are commonly done by either culture or nonculture methods (Macher et al., 1999). These methods do not test for the presence of mycotoxins and cannot be used to assess mycotoxin exposure. Because mycotoxins production depends strongly on the environmental conditions present, the presence of toxigenic mold species measured in the indoor samples cannot be extrapolated as evidence of the presence of mycotoxins (Burge, 2001).

Measures to reduce the level of aflatoxins in specific commodities include ensuring proper post-harvest storage conditions, monitoring aflatoxin levels in susceptible commodities, and encouraging proper food preparation (Strosnider et al., 2006).

The removal of aflatoxin from contaminated foodstuffs can be achieved by several methods. Degradation of aflatoxin occurs with exposure to irradiation, autoclaving, or treatment with strong acids or bases, oxidizing agents, or bisulfate. Adsorbants, such as bentonite and activated charcoal, can physically remove aflatoxin from liquid foods. Chemical treatment with ammonia gas at high temperature and pressure can decrease aflatoxin levels in contaminated seed meals (Betina, 1989; Eaton and Groopman, 1994; Goldblatt, 1969).

ACUTE EFFECTS

Aflatoxin B₁ is acutely toxic in all species studied (Klaassen, 2013). Acute aflatoxin exposures have been associated with epidemics of human aflatoxicosis in regions of India, Southeast Asia, and Africa as a result of ingesting aflatoxin-containing foodstuffs (Krishnamachari et al., 1975a; Lewis et al., 2005; Lye et al., 1995; Ngindu et al., 1982). Clinical manifestations of aflatoxicosis include vomiting, diarrhea, abdominal pain, jaundice, low grade fever, pulmonary edema, and fatty infiltration and necrosis of the liver (Kensler et al., 2011; Krishnamachari et al., 1975b; Lye et al., 1995).

Aflatoxins are possible teratogens. A number of studies reported the presence of aflatoxin in maternal and cord blood and growth impairment in young children; however, there were confounding factors (such as poor nutritional quality) and inconsistency in the reports (Gong et al., 2004; Gong et al., 2002; Gong et al., 2003; Turner et al., 2007). Aflatoxins may also have immunomodulatory effects on humans, but this association has not been conclusively demonstrated

(Allen et al., 1992; Jiang et al., 2005; Jiang et al., 2008; Turner et al., 2000; Turner et al., 2003).

CHRONIC EFFECTS

Aflatoxins are classified as carcinogenic to humans because they are mutagenic and hepatocarcinogenic (International Agency for Research on Cancer, 2012). The liver is the principal target organ for aflatoxin B₁-induced toxicity and epidemiologic studies have shown a positive correlation between high consumption of aflatoxins and the incidence of liver cancer (National Toxicology Program, 2011). Multiple studies have found that individuals exposed to aflatoxins, as measured by urinary aflatoxin metabolites, show increased risk for hepatocellular carcinoma (Qian et al., 1994; Ross et al., 1992; Wang et al., 1996; Yu et al., 1997). Persons with hepatitis B infection have a much greater risk for hepatocellular cancer upon aflatoxin exposure compared to those without infection (Azziz-Baumgartner et al., 2005).

Although aflatoxin B₁ may play a role in the induction of human lung cancer, more research is needed to confirm this effect. Laboratory studies suggest a possible role for aflatoxin B₁ in the induction of lung tumorigenesis, but the limited number of epidemiology studies prevent conclusions about the level of risk (Baxter et al., 1981; Dickens et al., 1966; Dvorackova, 1976; Dvorackova and Pichova, 1986; Dvorackova and Polster, 1984; Dvorackova et al., 1981; Hayes et al., 1984; Massey et al., 2000; Olsen et al., 1988; Van Nieuwenhuize et al., 1973; Wieder et al., 1968).

METABOLISM

Few studies have quantified the relationship between dietary intakes of aflatoxins and the levels of aflatoxin metabolites in human body fluids following absorption and distribution. Toxicokinetic animal studies showed complete absorption after oral, intraperitoneal, and intravenous administration of aflatoxins (Eaton and Groopman, 1994). The dermal permeability rate (K_p) of aflatoxin B₁ was determined to be 2.11×10^{-4} cm/h by an *in vitro* Franz diffusion cell (FDC) infinite dose model using dermatomed split-thickness human skin (Boonen et al., 2012). Concentrations of aflatoxin M₁ in urine and human milk have been correlated to dietary aflatoxin intake. No consistent correlations have been demonstrated regarding aflatoxin concentrations in food and aflatoxin-protein or aflatoxin-DNA adducts in urine and serum (International Agency for Research on Cancer, 2002).

Aflatoxin B₁ is metabolized by cytochrome P450 CYP1A2 and CYP3A4 to aflatoxin-8,9-epoxide, which is short-lived but highly reactive. The epoxides of aflatoxin B₁ are detoxified by glutathione S-transferase (GST)-mediated conjugation to reduced glutathione (GSH) to form aflatoxin

B_1 epoxide-GSH conjugates. The epoxides can also undergo a non-enzymatic hydrolysis to form 8,9-dihydrodiol. Other metabolites formed from aflatoxin B_1 include aflatoxin Q_1 and M_1 , which are produced by CYP1A2 and CYP3A4, respectively (International Agency for Research on Cancer, 2002; Wild and Turner, 2002). Aflatoxin Q_1 and M_1 are present in the urine of individuals exposed to aflatoxins (International Agency for Research on Cancer, 2002). A pilot study in three human volunteers showed rapid absorption of aflatoxin B_1 equivalents into systemic circulation with peak plasma aflatoxin concentrations reached within an hour of oral dosing (^{14}C -aflatoxin B_1 , 30 ng, 5 nCi, by capsule), following a first-order process in a two-compartment model of absorption. The study reported an elimination with a rapid distribution phase followed by a slower elimination phase with >95% of the total urine aflatoxin B_1 equivalents produced within the first 24 h after exposure (Jubert et al., 2009). Rats exposed to a single dose of aflatoxins by intratracheal exposure had a slightly faster initial absorption of aflatoxin B_1 than those exposed to aflatoxin B_1 by ingestion. For both routes of exposure, excretion of aflatoxins was primarily in the feces and excreted at a similar elimination rate (Coulombe and Sharma, 1985).

Excretion of aflatoxin B_1 and its metabolites occurs primarily through the biliary pathway. A considerable amount of aflatoxin M_1 is excreted in the milk in lactating animals (Betina, 1989).

MECHANISM OF ACTION

Aflatoxin is a known genotoxin that causes genetic damage such as formation of DNA and albumin adducts, gene mutations, micronucleus formation, sister chromatid exchange, and mitotic recombination (National Toxicology Program, 2011). The hepatocarcinogenicity of aflatoxin B_1 is associated with its biotransformation by cytochrome P450 to aflatoxin-8,9-epoxide, a reactive electrophilic epoxide which forms covalent adducts with DNA, RNA, and protein. The epoxide forms adducts with the DNA-N⁷ position of guanine, promoting depurination and subsequently apurinic site formation. Metabolically activated aflatoxin B_1 has been shown to induce G to T transversion mutations in bacteria and G to T transversions in codon 249 of the p53 tumor-suppressor gene in human liver tumors from geographic areas with high risk of aflatoxin exposure and in experimental animals (International Agency for Research on Cancer, 2012).

BIOMONITORING

Aflatoxins and their metabolites in human tissues and body fluids may be analyzed by LC-MS/MS and ELISA, immunoaffinity purification, immunoassay, HPLC with

fluorescence or ultraviolet detection, and synchronous fluorescence spectroscopy. Biomarkers that may be used to assess aflatoxin exposure include urinary metabolites such as aflatoxin-DNA adduct, aflatoxin M_1 , and aflatoxin B_1 -mercapturic acid, and the aflatoxin-albumin adduct in blood serum (Groopman et al., 1993; Shephard, 2009; Wild and Turner, 2002). The levels of urinary metabolites and adducts reflect intake on the previous day while the levels of aflatoxin-albumin adducts are assumed to reflect exposure to aflatoxin over the previous 2–3 months based on the half-lives of albumin (Eaton and Groopman, 1994; International Agency for Research on Cancer, 2002).

RISK ASSESSMENT

There are limited studies of occupational exposure to aflatoxins and resulting health effects. Aflatoxin exposure levels are not quantified in the available studies as of this writing. Epidemiologic studies have shown a positive correlation between high consumption of aflatoxins and the incidence of liver cancer (National Toxicology Program, 2011).

There are marked species differences in sensitivity to aflatoxin carcinogenesis, with the rat being extremely sensitive and the mouse and hamster being resistant. These variations in carcinogenicity are paralleled by differences in DNA and protein adduct formation for a given aflatoxin dose. A considerable part of the interspecies variation is a reflection of differences in expression of detoxification enzymes. Rodents express a hepatic α -class of GST that efficiently conjugates with the aflatoxin-8,9-epoxide while humans have relatively low aflatoxin-8,9-epoxide conjugation (Wild and Turner, 2002).

Differences in species susceptibility to aflatoxin make it extremely challenging to extrapolate animal toxicity data to humans.

OCHRATOXINS

The ochratoxins A (OTA) and ochratoxin B (OTB) are produced primarily by *Aspergillus ochraceus* and *Penicillium viride* fungi. The minimum temperature and water activity of the substrate for ochratoxin A production by *A. ochraceus* is 12 °C and 0.83–0.87, respectively (Betina, 1989). With *P. viride*, a temperature of 24 °C and a water activity of 0.95 are optimal for ochratoxin A production (Betina, 1989). Ochratoxin A is colorless and has melting points ranging from 94 to 221 °C (Betina, 1989; Pohland et al., 1982). Ochratoxin A is not destroyed by common food preparation procedures. Temperatures above 250 °C are required for several minutes to reduce ochratoxin A concentration (Boudra et al., 1995).

TABLE 117.3 Maximum Tolerated Levels ($\mu\text{g}/\text{kg}$) of Ochratoxins in Foodstuffs

Source: Food and Agriculture Organization (2004).

INDUSTRIAL HYGIENE

Ochratoxins are commonly found in barley, oats, rye, wheat, coffee beans, and soy products (Council for Agricultural Science and Technology, 2003; Halsall et al., 2007). It is also found in wine made from grapes contaminated with ochratoxin A during the berry ripening phase (Codex Alimentarius Commission, 2007). There are no U.S. regulations for ochratoxin A in food commodities, but it is regulated by other countries such as those in the European Union (Table 117.3).

Occupational inhalation exposure to ochratoxins may occur by exposure to airborne particles containing ochratoxins, such as grain dust (Table 117.4). Currently there are no standards, guidelines, or regulations for workplace exposure to ochratoxins in the United States.

Analytical methods for the analysis of ochratoxins in food commodities include liquid chromatography with fluorescence detection, HPLC and TLC (Food and Drug Administration and Office of Regulatory Affairs, 2013; Lerda, 2011;

Monaci and Palmisano, 2004; Truckless, 2000; World Health Organization, 2002).

Methods to reduce the level of ochratoxins in food commodities include adequate treatment of field crops and post-harvest storage conditions to prevent growth of ochratoxin-producing fungi. Ochratoxins may also be removed from contaminated agriculture foodstuffs by physical methods such as cleaning, mechanical sorting and separation, treatment with high temperatures, and irradiation. The use of adsorbent materials, degradation by microbes, and chemical approaches such as ammoniation can also be effective in removing ochratoxins (Amezqueta et al., 2013; Varga et al., 2010).

ACUTE EFFECTS

Most studies on ochratoxins have focused on ochratoxin A since ochratoxin B is less toxic (Betina, 1989). The kidney is the primary target of ochratoxin A toxicity. It exerts its

TABLE 117.4 Measured Concentrations of Ochratoxin A in Air in Industrial Settings

primary effect on the proximal convoluted tubules and is a possible causal factor in regional endemic nephropathies, including Balkan endemic nephropathy (BEN) and chronic interstitial nephropathy (CIN), seen in Southeastern European and North Africa countries (Krogh et al., 1977; Maaroufi et al., 1995; Pavlovic et al., 1979; Smith and Moss, 1985; Zaied et al., 2011). Balkan endemic nephropathy is characterized by tubular dysfunction and atrophy, interstitial fibrosis and edema, and tubular degeneration (Plestina, 1992; Vukelic et al., 1992). Patients with BEN have a high incidence of end-stage renal failure and have a high risk of developing tumors of the urinary tract (Fuchs et al., 1991; Grossi et al., 2003; Pfohl-Leszkowicz et al., 2002). Although a direct link between BEN or CIN and ochratoxin A exposure remains to be established, epidemiology studies correlate an increase in serum and urine ochratoxin A levels with a higher incidence of nephropathy and urothelial tumors in humans (Castegnaro et al., 2006; Fuchs et al., 1991; Petkova-Bocharova and Castegnaro, 1991).

A case of acute renal failure was reported in a farmer's wife who worked 8 h sieving wheat that was stored for more than 2 years in a granary, which was closed for several months. Both the farmer and his wife reported epigastric tension, a retrosternal burning sensation, respiratory difficulty and asthenia. The farmer's condition resolved within 24 h, but his wife's condition worsened and she was admitted for hospitalization. Inhalation of ochratoxin A was postulated as the possible cause of her acute renal failure based on the isolation of ochratoxin A in the contaminated wheat. No biological samples were obtained (Di Paolo et al., 1993, 1994).

In animals, ochratoxin A is hepatotoxic, teratogenic, and immunosuppressive (Al-Anati and Petzinger, 2006; Alvarez et al., 2004; Gilani et al., 1978; Harvey et al., 1992; Mayura et al., 1983; O'Brien and Dietrich, 2005; Patil et al., 2006; Wei and Sulik, 1993; Xue et al., 2010).

CHRONIC EFFECTS

Based on sufficient evidence of carcinogenicity in animal studies, ochratoxin A is classified as "possible carcinogenic to humans" (Group 2B) by the International Agency for Research on Cancer (IARC) classification (International Agency for Research on Cancer, 1993) and as "reasonably anticipated to be a human carcinogen" in the U.S. National Toxicology Program (NTP) classification (National Toxicology Program, 2011). Ochratoxin A is thought to be the cause of urinary tract tumors in humans (National Toxicology Program, 2011; Petkova-Bocharova et al., 1991; Wafa et al., 1998). Liver and mammary-gland tumors were observed in experimental animals after oral exposure to ochratoxin A (Bendele et al., 1985; Huff, 1991). Based on a correlational study of incidence rates for testicular cancer and consumption per capita of foods commonly

contaminated with OTA and a study in which rats were given ochratoxin A by gavage, it is postulated that ochratoxin A exposure may be associated with testicular cancer (Jennings-Gee et al., 2010; Mantle, 2010; Schwartz, 2002).

METABOLISM

Studies on rodents show that ochratoxin A is readily absorbed from the upper gastrointestinal tract, in particular from the small intestine (Galtier, 1991; Li et al., 1997; Suzuki et al., 1977). Ochratoxin A was absorbed from the lungs following intratracheal administration in rats, with a bioavailability of 98% (Breitholtz-Emanuelsson et al., 1995). The dermal permeability rate (K_p) of ochratoxin A was determined to be 8.20×10^{-4} cm/h by an *in vitro* FDC infinite dose model, using dermatomed split-thickness human skin (Boonen et al., 2012).

After absorption from the gastrointestinal tract, ochratoxin A binds to serum proteins (mainly albumin) and can accumulate in body tissues and fluids. It is metabolized into 4R- and 4S-hydroxyochratoxin A (4R-OH-OTA and 4S-OH-OTA), OP-ochratoxin A, OTA-quinines, 10-hydroxy-OTA, and ochratoxin- α (Malir, 2013; Ringot et al., 2006).

Ochratoxin A is reabsorbed from the intestine, recirculated into the enterohepatic circulation, and reabsorbed in the kidney proximal and distal tubules. It is then slowly eliminated from the body by excretion into bile, feces, and urine (Galtier, 1991; Li et al., 1997; Petzinger and Ziegler, 2000; Ringot et al., 2006; Stander et al., 2001; Studer-Rohr et al., 2000; Suzuki et al., 1977; Zingerle et al., 1997). The main excretion route of ochratoxin A in rodents is the biliary route while humans excrete ochratoxin A mainly via the kidney (Pfohl-Leszkowicz and Manderville, 2007). The serum half-life of ochratoxin A in humans is about 35 days (Studer-Rohr et al., 2000).

MECHANISM OF ACTION

The carcinogenic mode of action of ochratoxin A is unclear. Based on *in vivo* and *in vitro* studies, mechanisms of ochratoxin A toxicity include oxidative stress, apoptosis, interference with the cytoskeleton, lipid peroxidation, and inhibition of mitochondrial respiration. Ochratoxin A is a competitor of phenylalanine-tRNA ligase, thereby inhibiting protein synthesis. Other enzymes are also affected by exposure to ochratoxin A (O'Brien and Dietrich, 2005).

A significantly higher kidney tumor incidence following ochratoxin A exposure has been observed in males versus females in both rats and mice. Proposed mechanisms for the gender difference in susceptibility have included differences in ochratoxin A transporters in the kidney, differences in expression of cytochrome P450 enzymes involved in the

metabolism of ochratoxin A, and the presence of α -2u-globulin in the adult male rat. It is proposed that the binding of ochratoxin A to the male rat specific protein, α -2u-globulin, may result in rapid delivery of ochratoxin A to the kidney proximal tubule epithelial, concentration of ochratoxin A at the target site, and consequently nephrotoxicity (Haighton et al., 2012).

Evidence of formation of OTA-DNA adducts is inconclusive. DNA adducts from patients in the Balkans provide evidence for the involvement of ochratoxin A in ochratoxin A-induced neurotoxicity while advanced chemical analytical procedures failed to demonstrate the existence of specific OTA-DNA adducts (Mally and Dekant, 2005).

BIOMONITORING

Human exposure to ochratoxin A can be determined by plasma/serum and urine analyses for the presence of the mycotoxin or one of its subunits by HPLC (Castegnaro et al., 2006; Duarte et al., 2010; Gilbert et al., 2001). The parent compound ochratoxin A was the major compound found in blood, whereas ochratoxin α is the major compound detected in urine (Muñoz et al., 2000). The long biological half-life of ochratoxin A in human blood facilitates biomonitoring studies. There are no validated methods for the analysis of ochratoxin A in human blood (World Health Organization, 2002). There has been indication of a higher correlation between urinary OTA levels and OTA consumption than between plasma levels and ochratoxin A consumption (Ministry of Agriculture, Fisheries, and Food, 1999).

Detection of the toxicological effects of ochratoxin A, such as increased urinary β 2-microglobulinuria (β 2M), has been suggested as one method to determine human exposure to ochratoxin A (Hassen et al., 2004). β 2-microglobulin is typically filtered by the glomerulus and reabsorbed and catabolized by the proximal tubular cells. Increased urinary excretion of β 2-microglobulin has been regarded as an indicator of tubular injury; however, the specificity of the detection of β 2-microglobulinuria as a biomarker for ochratoxin A exposure is limited because it requires unhealthy levels of ochratoxin A contamination to be triggered and is highly non-specific since most subjects suffering from renal tubular dysfunction, regardless of cause, tend to show increased β 2-microglobulin levels (Wibell, 1978). The usefulness of OTA-DNA adducts as a biomarker of ochratoxin A exposure is uncertain due to the conflicting results reported for formation of OTA-DNA adducts.

RISK ASSESSMENT

There are species differences in the toxicokinetic and toxicodynamic outcomes upon ochratoxin A exposure. The

ochratoxin A elimination is slower in humans than in other species tested. The considerable variations in serum half-lives across species are apparently dependent on the affinity and extent of protein binding (Dietrich et al., 2005; Galtier, 1991).

The available epidemiology studies indicate that BEN may be associated with the consumption of ochratoxin A-contaminated foodstuffs and urinary tract tumors were observed in those with BEN; however, a direct causal role of ochratoxin A in the etiology of nephropathy and urinary tract tumors in humans has not been shown. There are limited studies of occupational exposure to ochratoxins and health effects and those that do report relevant exposure have not quantified exposure.

PHOSPHINE

MICHAEL W. PERKINS, BENJAMIN WONG, DORIAN OLIVERA, AND ALFRED SCIUTO

First aid: Eye: Immediately wash (irrigate) the eyes with large amounts of water for at least 15 min, occasionally lifting the lower and upper lids. Get medical attention immediately. If frostbite occurs and eyes are frozen because of exposure seek immediate medical attention.

Skin: Immediately flush the contaminated skin with soap and water. Remove contaminated clothing and flush the skin with water. If frostbite occurs do not remove clothing or touch the affected area. Get medical attention promptly if irritation persists.

Inhalation: Quickly move the exposed individual to fresh air, calm and at rest in half-up right position. Monitor and maintain airway and blood pressure. If breathing has become difficult administer oxygen; if stopped, perform artificial respiration. Get medical attention as soon as possible.

Ingestion: Get medical attention as soon as possible.

Target organ(s): Lungs, heart, central nervous system (CNS), and respiratory and gastrointestinal tracts

Occupational exposure limit

OSHA PEL: 0.3 ppm (0.4 mg/m³) TWA, 1 ppm (1 mg/m³) STEL

NIOSH REL: 0.3 ppm (0.4 mg/m³) TWA, 1 ppm (1 mg/m³) STEL

ACGIH TVL: 0.3 ppm (0.42 mg/m³) TWA, 1 ppm (1.4 mg/m³) STEL

Risk/safety phrases:

R12: Extremely flammable

R17: Spontaneously flammable in air

R26: Very toxic by inhalation

R34: Causes burns

R50: Very toxic to aquatic organisms

S1/2: Keep locked up and out of the reach of children

S28: After contact with skin, wash immediately with plenty of . . . (to be specified by the manufacturer)

S36/37: Wear suitable protective clothing and gloves

S45: In case of accident or if you feel unwell, seek medical advice immediately (show the label where possible).

S61: Avoid release to the environment. Refer to special instructions/safety data sheets.

S63: In case of accident by inhalation, remove casualty to fresh air and keep at rest. S46: If swallowed, seek medical advice immediately and show this container or label.

BACKGROUND AND USES

Phosphine is a colorless, flammable, toxic gas and is the hydrolysis byproduct of aluminum (AlP), magnesium (MgP), and zinc phosphides (ZnP) (World Health Organization, 1988; Anand et al., 2011). When AlP, MgP, or ZnP comes into contact with water, phosphine gas is formed via the following reaction: $\text{AlP} + 3 \text{H}_2\text{O} \rightarrow \text{PH}_3 + \text{Al(OH)}_3$. Phosphine is used to fumigate a wide variety of raw agricultural commodities, including stored grain, processed foods, and non-food agricultural products (Wilson et al., 1980; United States Environmental Protection Agency, 1998). Several fatal occupational and intentional exposures to phosphine gas originate from its use as a pesticide and rodenticide have been reported (Jones et al., 1964; Wilson et al., 1980).

Incidents of phosphine poisonings reported in Europe consisted of 28% by intentional ingestion and 65% by accidental inhalation (Lauterbach et al., 2005). However, the last two decades have seen a dramatic rise in the number of documented cases of phosphine use for the purpose of suicide (Chugh et al., 1991; Gupta and Ahlawat, 1995; Anand et al., 2011). National concern over phosphine's potential as a terrorist threat agent against targeted populations has increased because of the ease with which toxic phosphine fumes are produced from rodenticides in addition to its low cost, widespread use, and retail access.

The primary uses of phosphine are as a fumigant for stored food products and a reactive intermediate in the chemical industry. As a chemical intermediate, phosphine is used in the synthesis of organophosphines for oil additives and pharmaceutical applications (World Health Organization, 1988), in the preparation of organic phosphonium derivatives for the manufacture of flame retardants (Toy and Walsh, 1987), in the manufacture of solar or photovoltaic cells (Bretherick, 1990), as a dopant for silicon semiconductors, as a polymerization initiator, and as a condensation catalyst (Lewis, 2007). As a fumigant in pest control, phosphine is produced on-site by the hydrolysis of aluminum or magnesium phosphides, which are used in powder form. Phosphine is also generated as a byproduct in many other industrial processes, including the production of phosphorus (Al'zhanov et al., 1983) and ferrosilicon alloys (Anon, 1956; Lutzmann et al., 1963), machining of spheroidal graphite iron (Bowker, 1958; Mathew, 1961), steel pickling (Vdovenko et al., 1984), and other metallurgical operations (Habashi and Ismail, 1975). It is difficult to quantify the production of phosphine, since much of it is manufactured and used in relation to other processes.

PHYSICAL AND CHEMICAL PROPERTIES

Phosphine, also referred to as hydrogen phosphide, trihydrogen phosphide, phosphorus hydride, and phosphorated hydrogen, is a colorless, odorless, flammable, irritant toxic gas. It can ignite spontaneously on contact with air and is highly reactive with oxidizers, acids, halogenated hydrocarbons, and aqueous solutions. The physical and chemical properties of phosphine are listed in Table 118.1 (Thienes and Haley, 1972; Daubert and Danner, 1989; O'Neil, 2001; National Institute for Occupational Safety and Health, 2005; Lewis, 2007).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Phosphine is of limited environmental contamination concern as it is extremely volatile, and quickly evaporates into

TABLE 118.1 Physical Properties of Phosphine

CAS number:	7803-51-2
Structural formula:	PH ₃
Formula weight:	34.00
Boiling point:	-87.7 °C
Gas density, 20 °C:	1.17
Specific gravity, gas, 20 °C:	1.185
Vapor pressure:	2.93 × 10 ⁴ mmHg at 25 °C
Solubility:	Slightly soluble in water. Soluble in alcohol, ether, and cuprous chloride solution
Color:	Colorless
Odor:	Fish- or garlic-like odor due to impurities (pure compound is odorless)
Odor threshold:	0.03 parts per million (ppm) (200 ppm for pure)
Conversion factors:	1 ppm = 1.41 mg/m ³ 1 mg/m ³ = 0.71 ppm (20 °C, 760 mmHg)

the atmosphere. Natural occurrences of phosphine are extremely rare and are mostly limited to transient formation in marsh gas and other sites of decay of phosphorus-containing organic matter or waste (Ciba Foundation, 1978; O'Neil, 2001). Phosphine does occur naturally in the form of metal phosphides, but is extremely rare and only found in iron meteorites as the mineral schreibersite (Fe,Ni)₃P (Van Wazer, 1961). Apart from natural sources, atmospheric phosphine results from emissions and effluents from industrial processes, such as phosphide hydrolysis and the storage of ferrous alloys (Stellman and International Labour Office, 1998), and the use of phosphides as rodenticides and fumigants (Dumas, 1980; World Health Organization, 1988). Volatilization from metal phosphides is expected to be the most important fate process, with phosphine expected to volatize rapidly from both moist and dry soil (O'Neil, 2001). However, studies have shown that sub-surface phosphine may bind with the organic matter in the soil, where it rapidly degrades (Spanggord et al., 1985). In the atmosphere, phosphine is degraded by reaction with photochemically produced hydroxyl radicals (O'Neil, 2001) and has a reported atmospheric half-life of <1 day (Spicer et al., 1993).

ECOTOXICOLOGY

Only minute amounts of phosphine and phosphides are naturally occurring, and those that have an impact on the environment are not persistent. Phosphine and phosphides are introduced into the environment for pest control, a role for which they are well suited because of their efficacy, lack of persistence, and harmless decomposition products. Careful bait positioning and low toxicity of carcasses for scavengers of poisoned animal targets minimize the toxicity on non-targeted species. Phosphine and phosphides are oxidized

in the environment, and the final product, phosphate, is ubiquitous in the natural environment. However, it has been suggested that zinc phosphide may persist in aquatic sediments despite a general lack of aquatic toxicological data. A major accidental release of stored phosphine would not be expected to result in chronic environmental consequences (World Health Organization, 1988).

MAMMALIAN TOXICOLOGY

Acute Effects

Inhalation is the most common route of acute phosphine poisoning and affects the cardiovascular, respiratory, gastrointestinal, and CNS. Initially, symptoms consist of an irritated throat, tightness in the chest, dyspnea, abdominal pain, nausea, and vomiting followed by a persistent cough. These symptoms can persist for 15 min to 3 h and gradually progress to pulmonary edema and respiratory distress. However, the onset of symptoms may be delayed for days. Death primarily occurs within the first 12–24 h post-exposure because of cardiovascular failure, but can also occur after 24 h as a result of liver or kidney failure (ATSDR, 2007). Congestion of the lungs and severe pulmonary edema were the most common findings in 26 deaths following acute phosphine poisoning (Harger and Spolyar, 1958). Exposure to high concentrations of phosphine can also result in severe seizures and coma.

Phosphine poisoning can occur following accidental or intentional ingestion of metal phosphide pellets or tablets, which interact with the gastric secretions of the stomach. Acute poisoning by ingestion may induce severe gastrointestinal irritation and hemorrhage, as well as cardiovascular, respiratory, and renal failure within minutes, and hepatic damage. In one study, post-mortem findings in 10 patients who died from zinc phosphide ingestion included blood in body cavities, pulmonary congestion and edema, hemorrhage of the intestinal epithelium, and necrosis of the liver and kidneys (Stephenson, 1967).

Chronic Effects

Chronic effects of exposure to phosphine include anemia, bronchitis, and gastrointestinal, visual, speech, and motor disturbances. Consequences of long-term exposure include liver damage, jaundice, and renal failure, the onset of which may occur from 48 to 72 h after exposure. Reports of long-term occupational exposure to zinc phosphide tablets include minor symptoms such as cough, dyspnea, headache, lethargy, anorexia, and epigastric pain (Misra et al., 1988). Chronic effects of phosphine toxicity can last for several months or years and may cause weight loss, toothache, swelling of the jaw or necrosis of the jaw bone, and spontaneous fractures of bones (World Health Organization, 1988).

Furthermore, phosphine exposure may exacerbate the symptoms of any preexisting respiratory conditions, especially in patients suffering from obstructive airway diseases.

Chemical Pathology

Phosphine toxicity originates from multiple factors, but its primary symptoms are seen in the cardiovascular and respiratory systems. Following exposure to phosphine and/or metal phosphides, aerobic metabolism is inhibited, resulting in oxidative damage to tissues and cells affecting the metabolic mechanisms. Mortality is primarily the result of pulmonary edema, myocardial injury, and cardiac arrest. Post-mortem examination of brains from eight acute phosphine poisoning cases indicated multifocal small hemorrhages and marked congestion with areas of exudation (Misra et al., 1988). This study observed various histopathological changes, including pulmonary edema, desquamation of the lining epithelium of the bronchioles, vacuolar degeneration of hepatocytes, dilatation of sinusoids and hepatic veins, and nuclear fragmentation. Chromosomal abnormalities have been recorded in the blood samples of workers, who apply fumigant (Garry et al., 1996). Tests examining cardiac enzyme, liver, and kidney function, by measuring levels of blood urea, electrolytes, creatinine, bilirubin, alkaline phosphates, lactic dehydrogenases, plasma cortisol, and rennin levels, are strongly recommended following phosphine and/or metal phosphates poisoning (World Health Organization, 1988; Chugh et al., 1990). Ingestion of metal phosphides can lead to severe gastrointestinal hemorrhage and respiratory and renal failure. Although an unlikely route of exposure, direct contact with liquid or compressed phosphine can cause frostbite.

Mode of Action(s)

Phosphine is a broad-spectrum toxicant that affects a host of target organs. Cellular poisoning and oxidative stress as a result of phosphine exposure causes a variety of systemic effects, including metabolic disturbances, circulatory failure, hepatic damage, electrolyte imbalance, and cardiovascular, pulmonary, gastrointestinal, and neurological toxicity (Anand et al., 2011). The primary mode of toxicity is the reduction in the aerobic respiration by the inhibition of mitochondrial cytochrome C oxidase (Chefurka et al., 1976; Nakakita, 1987). Disruption of the mitochondrial function interferes with various cellular activities, including aerobic metabolic rates, energy utilization, and protein and enzyme synthesis. Inhibition of the endogenous antioxidants and oxidative damage caused by the formation of highly reactive hydroxyl radicals also occurs following phosphine poisoning (Chaudhry, 1997; Quistad et al., 2000). Additionally, phosphine inhibits the enzyme acetylcholinesterase (AChE), resulting in the accumulation of the neurotransmitter

acetylcholine, which induces cholinergic effects such as hypersecretions, bronchoconstriction, respiratory distress, seizures, and death.

SOURCES OF EXPOSURE

Occupational

Occupational exposure to phosphine may occur in workers producing phosphine and phosphides or those in operations that can release phosphine, such as fumigators and pest-control operatives and transport workers (World Health Organization, 1988). Concentrations necessitating the use of personal respiratory protection have been reported in metal phosphide production areas (Jackson and Elias, 1984). Exposure to phosphine has been described in the operation of acetylene generators (Harger and Spolyar, 1958), in the production of phosphorus (Beloskurskaya et al., 1978), in steel pickling (Vdovenko et al., 1984), in the manufacture of magnesium powder (Cole and Bensett, 1950), and in the machining of spheroidal graphite iron (Bowker, 1958; Mathew, 1961). Although phosphine is used extensively in semi-conductor manufacture, there are no published data of occupational exposures. Since in this context, phosphine is used under precise and strictly controlled conditions, and frequently diluted with inert gases in semi-conductor manufacture, exposure of workers is unlikely (NIOSH, 1977). In the United States an estimated one million workers are at risk of inadvertent exposure; 10,000 of these workers are engaged in the grain freight trades where accidental exposure is a considerable hazard (NIOSH, 1977).

Environmental

The high volatility, limited natural sources, and negligible concentration in ambient air all ensure that any environmental exposures to phosphine are as a result of the accidental release from failed industrial processes or improper commercial usage. In most countries, strict controls exist for fumigation to prevent public exposure to phosphine, and guidelines for safe fumigation are available. These factors combine to effectively prevent nearly all environmental exposure to phosphine (World Health Organization, 1988).

INDUSTRIAL HYGIENE

Recommended personal protective equipment (PPE) for liquid phosphine includes impervious clothing, self-containing breathing apparatus, splash-proof safety goggles, rubber gloves and bands around legs, arms, and waist (United States Environmental Protection Agency, 1998). Table 118.2 shows exposure limits (NIOSH, 1977).

TABLE 118.2 Phosphine Exposure Limits

Immediately Dangerous to Life or Health (IDLH)	50 ppm
National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit (REL)	Time-weighted average (TWA) 0.3 ppm (0.4 mg/m ³)
Occupational Safety and Health Administration (OSHA) permissible exposure limits (PEL)	TWA 0.3 ppm (0.4 mg/m ³)

RISK ASSESSMENTS

Phosphine is an extremely volatile, flammable gas that reacts violently with air, water, and other aqueous products. It is used extensively as a fumigant and rodenticide, and within the last decade has been increasingly used in industry for the synthesis of various chemicals (Berners-Price and Sadler, 1988; Chaudhry, 1997). The primary route of exposure to phosphine gas is via inhalation, either occupationally or accidentally, in which it is rapidly absorbed in the pulmonary system and systemically distributed. Incidents of ingestion of metal phosphides, predominantly aluminum and zinc, have also increased, as a result of homicides and suicide attempts (Goel and Aggarwal, 2007). Phosphine is a severe pulmonary irritant that has various adverse effects on the cardiovascular, respiratory, gastrointestinal, and CNS. The health effects of phosphine are primarily acute, with early indications of exposure consisting of respiratory and gastrointestinal effects that generally occur within hours, but can be delayed for days. Other adverse effects may consist of damage to the kidneys and liver, and also convulsions and pulmonary edema. The chronic effects of phosphine inhalation exposure are less defined, but can include pulmonary effects, especially in individuals with predisposing conditions. Phosphine is not classified as a carcinogenic, reproductive, or developmental toxicant because of limited and inadequate human data (U.S. Environmental Protection Agency, 2005).

DIESEL EXHAUST

J. MICHAEL BERG, PHILLIP T. GOAD, AND THOMAS W. HESTERBERG

First aid: Remove individual from source

Target organ(s): Eyes and respiratory system

Occupational exposure limits: OSHA PEL: Does not exist; NIOSH REL: Does not exist; ACGIH TLV: Does not exist; US MSHA PEL: $160_{TC} \mu\text{g}/\text{m}^3$

Reference values: USEPA RfC: $5 \mu\text{g}/\text{m}^3$ DPM

Risk/safety phrases: Not available

BACKGROUND

The diesel engine, in contrast to conventional spark ignition combustion, operates by injecting atomized fuel into compressed air under high temperature and pressure. Under these conditions, diesel fuel auto-ignites, generating power with increased efficiency and durability over conventional combustion engines (USEPA, 2002). In theory, the complete combustion of a hydrocarbon fuel in a diesel engine would yield gaseous carbon dioxide (CO_2) and water (H_2O); however, in practice, many chemical factors (e.g., fuel composition and additives) and physical processes (e.g., engine technology, type, age, and operating conditions) may influence the resultant combustion products, termed “diesel exhaust” (Hesterberg et al., 2005; Hesterberg et al., 2009).

Due to the ever evolving—and therefore more stringent—diesel exhaust regulatory environment, a review on diesel engine emissions would not be complete without a brief overview of past and present regulatory standards. During the early 1950s, experimental studies using organic extracts of diesel exhaust particulates (DEP) raised the possibility that emissions from internal combustion engines, including

diesel, may elicit a tumorigenic response in laboratory mice (Kotin et al., 1954a, 1954b, 1955).

These ever-increasing concerns over human exposure to diesel exhaust prompted the enactment of the first regulatory “smoke standard”¹ on heavy-duty diesel engines in the late 1960s (33 FR 8304, 1968). Shortly thereafter (1974), the United States Environmental Protection Agency (USEPA) introduced the first regulatory limits on gaseous phase emissions, including carbon monoxide (CO), hydrocarbons (HC), and oxides of nitrogen (NO_x). During this same time, however, the particulate-component of diesel exhaust remained unregulated. The identification of solvent-extractable mutagenic compounds from DEP in 1977 prompted the EPA to issue a precautionary notice of diesel exhaust carcinogenicity, and introduce the first DEP on-road standards for light-duty and heavy-duty diesel engines in 1982 and 1988, respectively (Huisingsh et al., 1978; NY Times, 1977). However, the relevancy of such organic solvent extractable mutagens is currently under debate, as a growing fraction of scientific literature suggests that these compounds have limited bioavailability in the aqueous environment of the lung (Hesterberg et al., 2012a). Since 1988, increasingly stringent emission regulations, combined with advancement in diesel engine and fuel technology, have resulted in heavy-duty diesel on-road engines, made in 2007 and later, which have 80% reductions in NO_x emissions and 98% reductions in particulate matter (PM) emissions compared to pre-1988 levels (USEPA, 2002).

As a result of significant innovations in diesel engine technology (e.g., fuel injection), modifications to fuel composition (e.g., ultralow sulfur (SO_x) diesel), and engine after-treatments; diesel exhaust emitted from 2007 and later

¹ Smoke emissions measured as the percent opacity of light.

heavy-duty on-road engines is both quantitatively and qualitatively very different from that of traditional (pre-1988) diesel exhaust (TDE). This distinct type of exhaust has been termed “New Technology Diesel Exhaust,” or NTDE (Hesterberg et al., 2005). The NTDE is defined as the diesel exhaust from newly integrated systems intended to meet the stringent 2007 USEPA standards for PM and NO_x. Thus, as the majority of toxicological investigations draw conclusions based on diesel exhaust generated by the use of pre-1988 diesel engines, the applicability of such research to current and future exposures to NTDE is currently in question.

PHYSICAL AND CHEMICAL PROPERTIES

Emissions from diesel engines or diesel-engine powered vehicles are a highly variable and complex mixture of PM and gaseous-phase compounds derived from the incomplete combustion of hydrocarbon fuels, fuel additives, and lubricating components. At the rudimentary level, diesel exhaust is comprised of a few basic elements: a respirable carbon-based diesel exhaust particulate with a layer of adsorbed sulfates and solvent-extractible organics and a mixture of vapor- and gaseous-phase compounds (including, but not limited to, 1,3-butadiene, formaldehyde, acrolein, dioxins, and polycyclic aromatic hydrocarbons (PAHs)), and trace metals (Cheng et al., 1984; Kittelson, 1998; USEPA, 2002). However, the application of a strict compositional definition to the term “diesel exhaust” is not inherently possible, as a variety of chemical and physical factors, including the engine age and operating conditions, as well as the type of fuel, fuel additives, and exhaust filters, may impact the resultant emissions (Hesterberg et al., 2005; Hesterberg et al., 2009).

From a toxicological perspective, the physicochemical properties of DEP are known to largely influence the biological response (Park et al., 2011). DEP are comprised of a solid carbonaceous core with adsorbed organic compounds, sulfates, metals, and other trace elements (USEPA 2002; Wichmann, 2007). Together, these DEP components form aerosolized particulates in the fine (<2.5 µm) and ultrafine (<100 nm) size range. From a regulatory perspective, fine-sized particles dominate the particulate mass; however, by number, up to 90% of the particles are within the nanometer size range (Cheng et al., 1984; Kittelson, 1998; USEPA, 2002). The large fraction of ultrafine particulates within traditional diesel exhaust is currently attracting significant scientific attention, as particulates within this size range combine increased available surface area for organic material binding with increased potential for alveolar deposition (Geiser and Kreyling, 2010; Hesterberg et al., 2010).

TDE is comprised of a mixture of hundreds of organic and inorganic compounds (HEI, 1995; USEPA, 2002). In

addition to CO₂ and CO, the organic component of the particulate phase of diesel exhaust may include, but is not inclusive of, alkane and alkene hydrocarbons, aldehydes, as well as mono- and poly-cyclic aromatic compounds and their nitro-substituted derivatives. Inorganic components, including oxides of NO and oxides of SO, are formed during the high temperature oxidation of NO and SO present in the air and fuel, respectively.

As noted in the previous section, the compositional make-up of diesel exhaust from present-day (2007 and later) diesel engines is both qualitatively and quantitatively different than that of the past TDE. These engines, able to meet the stringent 2007 USEPA NO_x and DEP emissions standards, have been documented to achieve substantial reductions in the formation and emission of both regulated (PM, NO_x, NMHC) and nonregulated species (aldehydes and aromatics) (Hesterberg et al., 2008). The representative contribution and composition of particulate matter in TDE and NTDE is provided in Figure 119.1. A more thorough review of differences between TDE and NTDE exhaust may be found elsewhere (Hesterberg et al., 2011).

ENVIRONMENTAL FATE

Diesel exhaust is released into the atmosphere where its individual constituents are subjected to physical (e.g., agglomeration and dry and wet deposition) and chemical modification (e.g., photolysis, reaction with atmospheric compounds). Chemical modification processes lead to calculated atmospheric lifetime ranging from minutes (NO₂; solar radiation) to years (aldehydes; ozone). As discussed in the Health Effects Institute Special Report on diesel exhaust (1995), these processes have the potential to define human exposure to diesel exhaust by “(1) influencing the ambient concentrations of each specific emission products, and their reaction products, at different locations, and (2) by potentially altering the toxic, mutagenic, or carcinogenic properties of the original emission constituents as well as creating new toxic, mutagenic, or carcinogenic transformation products.”

The topics of atmospheric fate and transport of compounds present in diesel exhaust have been thoroughly discussed in previous reviews. In this regards, the reader is referred to a 1995 Health Effects Institute publication entitled “Diesel Exhaust: Critical Analysis of Emissions, Exposure, and Health Effects” (Winer and Busby, 1995).

ECOTOXICOLOGY

There exists limited information on the ecotoxicological effects of diesel exhaust as a whole. In this respect, individual

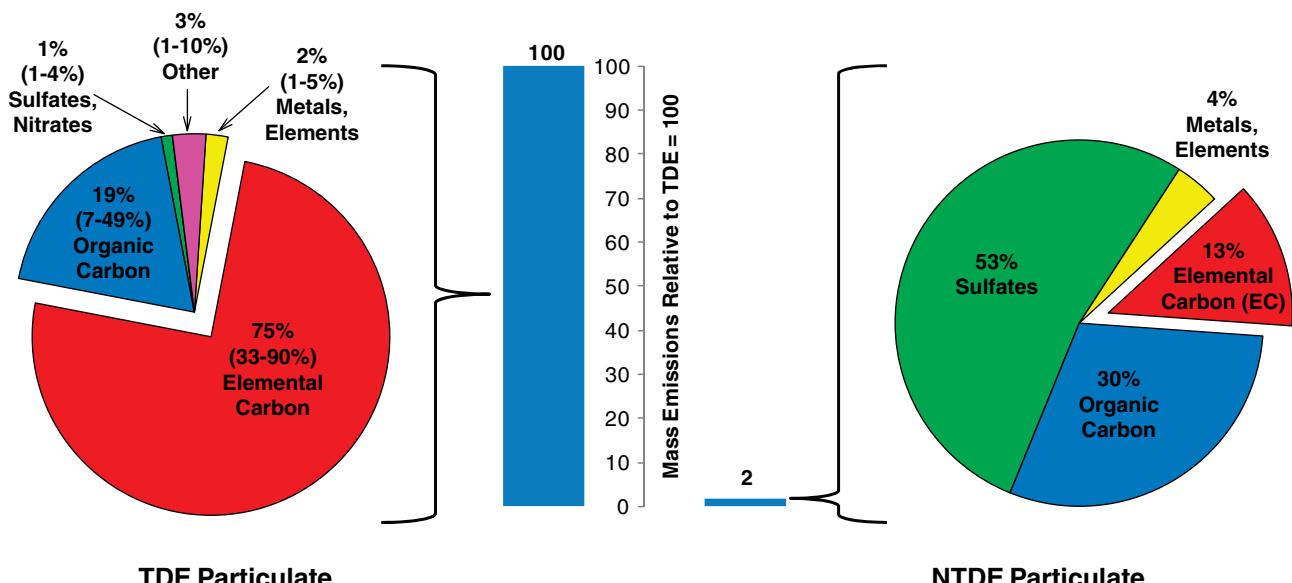

FIGURE 119.1 Quantitative and qualitative differences in the composition of diesel exhaust particulates in TDE (from pre-2000s era diesel engine technology; USEPA, 2002) versus NTDE (average data from four 2007-model-year heavy-duty diesel engines; Khalek et al., 2011) PM mass emissions derived from Hesterberg et al. (2008). Figure reproduced from Hesterberg et al. (2011).

constituents should be evaluated separately. For example, emissions of inorganic compounds, such as SO_x and NO_x , may contribute to the acidification of rain (Winer and Busby, 1995). Similarly, it has been hypothesized that the increased absorbance of solar radiation by black carbon aerosol particles, including diesel particulate matter (DPM), may influence climate change (Roberts and Jones, 2004).

MAMMALIAN TOXICOLOGY

Acute Effects

Due to the variability of diesel exhaust constituents and the lack of consistent exposure assessment methods; there exists limited information for quantifying the exposure-response relationship in acute diesel exhaust studies. In general, however, reports indicate that short-term exposure to TDE can elicit irritant (e.g., conjunctivae, nasal, and bronchial), neurophysiological (e.g., headache, dizziness) and respiratory (e.g., tightness of chest) symptoms (Battigelli, 1965; Gamble et al., 1987a; OSHA, 2013; Rudell et al., 1994; Wade and Newman, 1993). Some individuals may exhibit an unpleasant taste in the mouth (Battigelli, 1965). These symptoms are transient in nature, and can sometimes be present when levels of individual constituents in diesel exhaust are below their respective threshold limit values (TLVs) (Morgan et al., 1997).

Description of the irritant and neurophysiological symptoms, as noted above, together with reports of the

characteristic odor of diesel exhaust, are often the most sensitive method of determining if an individual has been exposed to a high level of TDE. Literature indicates that the presence of general symptoms, as well as increased airway inflammatory responses, are more sensitive indicators of excessive diesel exhaust exposure than pulmonary function tests (Battigelli, 1965; Gamble et al., 1987a; Rudell et al., 1994; Salvi, 2001). A single report describes the development of asthma following exposure to high levels of diesel exhaust (Wade and Newman, 1993). It remains inconclusive as to whether or not individuals with previous allergic or respiratory problems may be more susceptible to developing acute effects (Hesterberg et al., 2009).

Chronic Effects

Noncarcinogenic Effects While limited by a number of variables (i.e., sample size, exhaust composition, etc.), several long-term human epidemiological investigations have examined the chronic noncancer respiratory effects of TDE in occupational settings. Several studies report an increased incidence of respiratory symptoms, including cough, phlegm, and/or dyspnea (Attfield et al., 1982; Gamble and Jones, 1983; Reger et al., 1982); however, others observed a notable absence in diesel exhaust-exposed groups (Ames et al., 1984; Battigelli et al., 1964). Although not consistent across all epidemiological investigations, two studies indicate statistically significant alterations in pulmonary function (FVC, FEV_1 , PEF, FEV_1/FVC , FEF_{50}) (Gamble et al.,

1987b; Purdham et al., 1987). In respect to the epidemiological investigations reported, the USEPA (2002) stated that “*the absence of reported noncancerous health effects, other than infrequently occurring effects related to respiratory symptoms and pulmonary function changes, is notable*” (USEPA, 2002).

Due to the many uncertainties in diesel exhaust epidemiological investigations and the general inadequacies for characterizing potential noncancer health effects associated with long-term diesel exhaust exposure, chronic animal bioassays with well-defined and highly controlled diesel exhaust atmospheres provide health-effects evidence for chronic diesel exhaust exposure (Hesterberg et al., 2009). While a variety of toxicological endpoints have been assessed *in vivo* (e.g., cardiovascular, growth, immunological, neurological, and reproductive) the USEPA has determined that adverse respiratory effects are the most sensitive endpoint for chronic toxicity studies of diesel exhaust (USEPA, 2013); thus, further discussion on this topic will be limited as such. Using concentrations greater than those found in the ambient environment, laboratory studies undertaken in several animal species (rat, hamster, cat, and monkey) indicate that chronic exposure to traditional diesel exhaust may lead to chronic lung inflammation, pulmonary function impairment, and histological changes during the actual exposure to diesel exhaust, but these changes returned to normal levels following cessation of exposure (Hesterberg et al., 2009; USEPA, 2002). However, as will be discussed in the Modes of Action section, there is a general consensus in the scientific literature that “overload” levels of any particle, including diesel exhaust particles, can result in lung cancer in rats that may not be relevant to humans (ILSI, 2000).

Highlighted in the derivation of the USEPA reference concentration (RfC), Ishinishi et al. (1988) exposed Fisher 344 rats to exhaust from either light- or heavy-duty diesel engines for 30 months (16 h a day; 6 days a week) at DPM concentrations ranging from 110 to 3720 $\mu\text{g}/\text{m}^3$, dependent upon emission source. In addition to a dose-dependent decrease in body weights (females) at a DPM concentration of 3720 $\mu\text{g}/\text{m}^3$, significant alterations in liver and kidney function were noted. At DPM concentrations of 960 $\mu\text{g}/\text{m}^3$ or higher, significant histopathological observations were made, including shortened and absent cilia in the tracheal and bronchial epithelium, marked hyperplasia of the bronchiolar epithelium, and swelling of the Type II cellular epithelium (USEPA, 2013). Thus, the authors identified no-observable-adverse-effects-level (NOAELs) in this study of 410 and 460 $\mu\text{g}/\text{m}^3$ for light-duty and heavy-duty engines, respectively.

More recently, Ishihara and Kagawa (2003) reported on the results of rats exposed to diesel exhaust emissions for 24 months (16 h a day; 6 days per week) at doses of 210, 1180, and 3050 $\mu\text{g}/\text{m}^3$. A significant increase in mortality was observed at the highest dose examined. Indications of a localized chronic pulmonary response, including, alterations

in the bronchoalveolar lavage (BAL) fluid composition (e.g., increased protein, increased LDH activity, decreased alveolar macrophages, increased neutrophils, and elevated fructose, phospholipids, and sialic acid) were observed. As no significant physiological changes were observed in the low exposure group (210 $\mu\text{g}/\text{m}^3$) the authors determined that a NOAEL for DEP in the rat lung seems to lie between 200 and 1000 $\mu\text{g}/\text{m}^3$.

As highlighted in Hesterberg et al. (2009), current literature indicates a limited understanding of the impacts of diesel exhaust composition as it pertains to the 2007 and later regulatory environment. For example, McDonald et al. (2004) observed a significant reduction in diesel exhaust-induced lung toxicological endpoints when comparing TDE emissions to an emission-reduced exhaust, characteristic of NTDE (e.g., ultralow SO fuel, catalyzed ceramic trap). Hence, as a majority of the chronic noncancer endpoints literature is derived from TDE, it is uncertain as to the applicability of these endpoints for current and future diesel exhaust exposures.

Carcinogenicity In 2012, the International Agency for Research on Cancer (IARC) updated the carcinogenicity classification of diesel exhaust from Group 2A “probable human carcinogen” to Group 1 “known human carcinogen” (Benbrahim-Tallaa et al., 2012). One of the key studies that provided a basis for the revised IARC classification of diesel exhaust was that by Attfield et al. (2012), which suggested that the “*results of this study indicate a higher lung cancer mortality risk associated with traditional diesel exhaust exposure among [those workers with the greatest diesel exhaust exposure].*” Similarly, Silverman et al. (2012) concluded that their study “*showed a strong and consistent relation between quantitative exposure to diesel exhaust and increased risk of dying of lung cancer.*” However, issues with historical exposure reconstruction (i.e., measurement of CO using colorimetric tubes and establishing the relationship between CO, horsepower and respirable elemental carbon (REC), data interpretation, and potential confounders (e.g., smoking), have led several investigators to question the validity of these conclusions (Boffetta, 2012; Borak et al., 2011; Hesterberg et al., 2012c; McClellan, 2012; Mohner et al., 2012).

The USEPA and the National Toxicology Program (NTP) have designated diesel exhaust and DEP as “*likely to be carcinogenic to humans*” and “*reasonably anticipated to be a human carcinogen*,” respectively. However, the USEPA has not developed a quantitative risk assessment for carcinogenicity for reasons discussed elsewhere (see Risk Assessment); albeit their carcinogenicity classification was based on the findings of (1) strong, but sufficient evidence for a causal association between diesel exhaust exposure and lung cancer risk in occupational studies, (2) extensive data on the mutagenicity of organic compounds adhered to the surface of the DPM, (3) evidence of carcinogenicity of DEP and

adsorbed organic compounds via other routes of study (e.g., dermal) and (4) evidence of DPM carcinogenicity in animal studies (USEPA, 2013).

CHEMICAL PATHOLOGY

The use of controlled-exposure studies with human volunteers provides the most appropriate data set for evaluation of adverse pathology of clinical biochemical parameters. Of important note, however, is the potentially limited applicability of these measurements to the clinical environment, through which the American Thoracic Society has suggested that “*not all changes in biomarkers related to air pollution should be considered as indicative of injury that represents an adverse effect*” (ATS, 2000). Endpoints of specific interest with regards to diesel exhaust exposure often involve markers of pulmonary inflammation and carboxyhemoglobin measurements in addition to objective qualitative endpoints (i.e., mucomembranous irritation).

A number of studies have evaluated airway inflammatory response in a variety of media (e.g., sputum and/or bronchoalveolar wash) following acute exposure to whole diesel exhaust or DEP. Nightingale et al. (2000) and Nordenhall et al. (2000) exposed healthy individuals to diesel exhaust particulate concentrations of 200 and 300 $\mu\text{g}/\text{m}^3$, respectively. Compositional analyses of sputum content indicate an increase in percentage neutrophils, interleukin-6 (IL-6), methylhistamine, and myeloperoxidase (MPO) over baseline (Nightingale et al., 2000; Nordenhall et al., 2000). Salvi et al. (1999, 2000) observed similar markers of pulmonary inflammation (e.g., increased IL-8, neutrophils, and MPO) in the bronchoalveolar lavage following exposure of healthy human volunteers to 300 $\mu\text{g}/\text{m}^3$ DEP. The authors noted similar observations for neutrophils and platelets in the blood. At lower diesel exhaust concentrations, however, results are conflicting; with some reports indicating that lower DEP ($\sim 100 \mu\text{g}/\text{m}^3$) exposures are well tolerated (Behndig et al., 2006; Mudway et al., 2004) while others report extensive DE-induced airway inflammation (Stenfors et al., 2004).

Carbon monoxide poisoning from diesel exhaust is unlikely; however, in certain instances (e.g., significant acute exposure in enclosed areas) carboxyhemoglobin (COHgb) measurements may be evaluated. As a variety of factors (e.g., smoking status, administration of oxygen, and time since exposure) may influence the result, it is important to document such factors.

HYPOTHESIZED MODES OF ACTION

Diesel exhaust is a complex mixture of particulates and gases, all of which retain the potential to influence the toxicological profile through varying modes of action. While the following

discussion is focused on effects of the DEP, additive or synergistic effects caused by the gaseous phase cannot be discounted. To date several mechanistic hypotheses exist (see paragraphs below). However, as most animal studies have been conducted at diesel exhaust concentrations well above those that are observed in an occupational or environmental setting, the mechanistic understanding of diesel exhaust exposure in humans remains limited.

Diesel exhaust particulates, while containing a relatively insoluble carbon core, are surrounded by a solvent-extractable organic layer containing a number of known carcinogenic and mutagenic chemicals adsorbed to their surface (USEPA, 2002). Early literature suggested that desorption of organics (including PAHs) following exposure likely played a role in diesel exhaust-induced carcinogenesis in the rat. However, more recent studies suggest that these organic compounds, which can only be extracted under laboratory conditions (e.g., strong solvents and sonication), are of limited use in predicting the bioavailability and mutagenicity of the organic compounds on DEP in the aqueous environment of the lung (Enya et al., 1997; HEI, 1995; Hesterberg et al., 2012a; NTP, 2011). This line of thinking lead Heinrich et al. (1994) to examine the carcinogenic effects of a carbonaceous particle (carbon black) alone and in combination with a PAH-laden coal tar pitch. These authors suggested that it is the carbonaceous core of diesel exhaust, and not the adsorbed PAHs, that is likely responsible for the induction of lung cancer in high level diesel exhaust-exposed rats (Heinrich et al. 1994).

Similar studies in laboratory rats repeatedly observed an increased prevalence of lung tumor formation following lifetime exposure to high level diesel exhaust ($>2200 \mu\text{g}/\text{m}^3$ as DEP) (Heinrich et al. 1995; Mauderly et al., 1987). However, this tumorigenic response at high particulate levels is not limited to diesel exhaust; as a variety of relatively inert particulates, including carbon black, titanium dioxide, and talc elicited a similar effect. As noted by Heinrich et al. (1995), “*lung tumor rates in the rats increased with increasing cumulative particle exposure independent of the particle employed.*” As these effects have neither been observed with consistency in other species (i.e., mice, hamster, monkeys), nor do they occur at lower DEP levels ($<600 \mu\text{g}/\text{m}^3$ as DEP), this specific response is commonly described as a rat “lung overload” effect (Valberg and Crouch, 1999). As proposed by Driscoll et al. (1996) and Oberdorster and Yu (1990), the formation of lung tumors through the rat “lung overload” may be driven by a progression of events, including (1) particle phagocytosis and release of inflammatory mediators, (2) pulmonary inflammation, (3) epithelial hyperplasia, and (4) neoplastic transformation (Driscoll et al., 1996; Oberdorster and Yu, 1990). Due to the aforementioned reasons, this nonspecific tumorigenic response in the rat lung should be considered of little relevance to humans exposed to diesel exhaust in either occupational or nonoccupational (i.e., ambient environment) settings (Hesterberg et al., 2012b).

A considerable body of evidence suggests that diesel exhaust exposure may induce pulmonary and systemic inflammation; albeit at concentrations significantly greater than those observed in ambient and most occupational settings. Hesterberg et al. (2009) reviewed over 100 studies on the noncancer health effects of diesel exhaust and concluded that, with few exceptions, human controlled-studies largely support the proinflammatory role of diesel exhaust (Hesterberg et al., 2009). For example, Salvi et al. (1999) noted an increase in inflammatory response endpoints in both the airway (e.g., increased neutrophils, mast cells, and lymphocytes) and the blood (e.g., increased neutrophils and platelets) following an acute exposure to high levels of diesel exhaust (Salvi et al., 1999). As proposed by Behndig et al. (2006), this inflammatory response may be due to diesel exhaust particle-induced oxidative stress resulting in the activation of redox-sensitive transcription factors (e.g., NF κ b) and ultimately the release of proinflammatory cytokines; however, the authors suggest that acute human exposures of 100 $\mu\text{g}/\text{m}^3$ or less are insufficient to induce such an inflammatory response.

Current mode-of-action understanding at environmentally or occupationally relevant exposures remains limited. Additionally, the applicability of these mechanistic studies, driven largely by the presence of DEP, to current and future research is largely unknown as emissions studies of 2007 and later diesel exhaust technology (NTDE) show dramatic reductions in all components, especially the particulates, compared to TDE, which was examined in the previously discussed studies.

SOURCES OF EXPOSURE

The quantification of diesel exhaust exposure in ambient environments has been problematic, largely due to the confounding presence of airborne gases and particulates emitted from non-diesel sources. While there is no absolute marker for distinguishing diesel exhaust emissions particulates from other sources, a variety of analytes (e.g., total and respirable dust, CO, NO_x, benzene soluble fractions, specific PAHs, respirable combustible dust, elemental carbon) have been utilized as surrogates (Verma et al., 2003). Of these, however, the development and use of elemental carbon as an indicator of diesel exhaust exposure provides enhanced specificity and sensitivity over previously utilized total carbon or organic carbon methods (Verma et al., 2003).

Occupational

Occupational exposure to diesel exhaust may occur in any workplace where a diesel engine is utilized. In addition to various manufacturing operations, this includes workers in the mining, transportation, construction, agriculture, and

TABLE 119.1 Diesel Exhaust Exposure in Ambient and Occupational Settings

maritime industries (OSHA, 2013). Historical estimates suggest that approximately 1.35 million workers (1981–1983) and 3 million workers (1990–1993) were exposed to diesel exhaust in the United States and European Union, respectively (NIOSH, 1983; Kauppinen et al., 2000). However, current practice includes the use of applicable administrative (e.g., restricted engine idling) and engineering controls (e.g., local exhaust ventilation, diesel exhaust filters) to limit occupational exposure. Table 119.1, above, compares the elemental carbon concentration (as a surrogate for diesel exhaust exposure) of various occupational settings to that of the ambient air in the United States.

Environmental

Due to the ubiquitous on- and off-road uses of diesel in technology in modern society, exposure to diesel exhaust is not limited to the occupational setting. As data suggests that diesel particulate contributes to the nationwide ambient PM_{2.5} load, the general population may be exposed to diesel exhaust through the inhalation of ambient air (USEPA, 2002). In this respect, Liukonen et al. (2002) reported background elemental carbon concentrations ranging from <1 to 8 $\mu\text{g}/\text{m}^3$ (geometric mean of 3.1 $\mu\text{g}/\text{m}^3$) at numerous background locations throughout the United States. Similar ambient elemental carbon estimations have been observed by the USEPA National Air Toxics Assessment (2005). As modernization of the on-road diesel engine fleet progresses, the contribution of DPM to ambient PM_{2.5} is likely to be significantly reduced.

INDUSTRIAL HYGIENE

Neither the Occupational Health and Safety Administration (OSHA) nor the American Conference of Industrial

TABLE 119.2 Occupational Standards for Major Components of Diesel Exhaust^a

Chemical	OSHA-PELs		ACGIH TLVs	
	TWA	STEL/CEIL (c)	TWA	STEL/CEIL (c)
Carbon dioxide (ppm)	5000	—	5000	30,000
Carbon monoxide (ppm)	50	—	25	—
Nitrogen dioxide (ppm)	—	5 (c)	0.2	—
Nitric oxide (ppm)	25	—	25	—
PNOC (mg/m ³)	15 ^b ; 5 ^c	—	—	—
Sulfur dioxide (ppm)	5	—	—	0.25

^aAs dictated by OSHA Partial List of Chemicals associated with Diesel Exhaust (www.osha.gov).

^bTotal Dust.

^cRespirable Dust.

Hygienists (ACGIH) have established standards for diesel exhaust exposure in the general workplace. In this regard, it is emphasized that individual constituents of diesel exhaust are regulated as such (see Table 119.2).

From a historical perspective, the ACGIH has published various threshold limit values (TLV) for diesel exhaust in their Notice of Intended Changes list. The first proposed diesel exhaust specific standard, drafted in 1995, suggested a TLV of 150 µg/m³ measured as submicron particles; with a carcinogenicity classification of A2 (suspected human carcinogen). In 1999, it was proposed that this value be decreased to 50 µg/m³ measured as submicron particles. More recently (2000), however, the ACGIH recognized the appropriateness of elemental carbon as an “analytical surrogate” for diesel exhaust, which prompted a reanalysis of the proposed TLV. As such, the TLV of 50 µg/m³ measured as submicron particles, was expressed as the elemental carbon equivalent of 20 µg/m³. However, following the release of the USEPA Health Assessment Document on Diesel Exhaust in 2002, the ACGIH felt the need to reassess these values. As such, there is not ACGIH value for diesel exhaust at this time (ACGIH, 2013).

In contrast to OSHA and the ACGIH, the U.S. Mine Safety and Health Administration (MSHA) has established a diesel exhaust permissible exposure limit (PEL) of 160 µg/m³ measured as total carbon in metal and nonmetal mines. Additionally, the mine operator must install, use, and maintain feasible engineering and administrative controls to reduce a miners exposure. In the event that these engineering and administrative controls are not effective in reducing an exposure to below the MSHA PEL, they must be supplemented with an appropriate air purifying respirator.

RISK ASSESSMENTS

Multiple agencies have reviewed the human health and diesel exhaust literature in an attempt to qualitatively assess potential noncancer and cancer risks (CALEPA, 1998a; HEI, 1995, 1999; USEPA, 2002). In the 2002 Health Assessment

Document for Diesel Exhaust, the USEPA defined a RfC (a continuous exposure level for all individuals that is not likely to cause harmful effects) of 5 µg/m³ DEP. This value has also been adopted by the California EPA (CALEPA). This RfC was set 30-fold lower than the human equivalent concentration (HEC) of the NOAEL (460 µg/m³) observed in Ishinishi et al. (1988), and has been suggested to be quite conservative (Hesterberg et al., 2009).

At the current time, neither the USEPA nor the Health Effects Institute have developed quantitative risk assessments for carcinogenic endpoints citing, among other things, the lack of reliable exposure estimates in epidemiological studies and the invalidity of the rat model to characterize a tumorigenic response to particulates at relatively high exposure levels. However, the California Air Resources Board (CARB) felt, in relation to cancer risk assessment, that the “epidemiological data are available upon which one can base risk estimates for humans” (CALEPA, 1998a). In this respect, the Cal EPA has established an Inhalation Unit Risk (IUR) of 3.0×10^{-4} (3 excess cancers in 10,000 individuals if exposed daily to 1 µg/m³ DEP). This IUR places diesel exhaust as one of the most potent carcinogens known to the State of California (CALEPA, 1998b; CALEPA, 2013). Because the CALEPA’s quantitative carcinogenic risk assessment was derived from past epidemiological data that the USEPA and the HEI felt inappropriate for evaluation, combined with the fact that the diesel exhaust was of the traditional type, the applicability of such an assessment to current and future derivations of risk is of little practicability.

SPACEFLIGHT OPERATIONS

MICHAEL A. CARDINALE, PHILIP J. SCARPA, JAMES R. TAFFER, AND DANIEL WOODARD

The space industry today is a multibillion dollar international network of government and commercial enterprises associated with designing, fabricating, processing, testing, launching, and landing of crewed and uncrewed spacecraft (Monti and D'Angelo, 1993). It includes operations common to general industry, but also many that are unique to spaceflight or even unique to single industrial sites. The industry is notable for the use of large quantities of reactive and/or toxic materials, as well as the size, complexity, and cost of major launch systems. Contingencies can be very costly and attention to detail in industrial hygiene has proven vital.

INDUSTRY OVERVIEW

The era of spaceflight began with the launch of the first satellite in 1957; competing national programs in the United States and USSR (now Russia) led to the first human landing on the moon only 12 years later. The following years have seen hundreds of launches supporting human spaceflight, numerous scientific satellites and space probes, and a myriad of satellites serve practical applications, primarily in communications and earth imaging for both commercial and military customers. An important change in the industry in recent decades has been the shift from space programs that are funded and closely managed by governmental entities to an industry in which commercial enterprise operates with increasing autonomy, launching uncrewed and ultimately crewed spacecraft.

Spaceflight is supported by an array of industrial, government, military, academic, and research organizations around the world. Major space launch facilities maintain a range of industrial and base support functions, which may be

comparable to those of a small city. Physical boundaries may encompass hundreds of square miles and house dozens of government and contractor organizations. These tenant organizations are responsible for the launch of the vehicle and payload processing operations, as well as the maintenance of the infrastructure, grounds, and facilities.

The mission of any space launch facility is the preparation, test, and checkout of launch systems, spacecraft, payloads, and experiments for launch, while ensuring mission safety. For crewed spacecraft the mission also includes landing recovery operations, including postlanding evaluation, refurbishment, repair, and servicing of the space vehicle, as well as returned scientific experiments and payloads.

The diverse workforce of a space operations facility is engaged in a wide variety of unique industrial processes and operations. This workforce includes the engineers and laborers in the aerospace industries who design, manufacture, and test the spacecraft, and the technicians and specialists who process the payloads and rocket boosters and ready the vehicle for launch. Many design, logistics, construction, and maintenance activities also take place to support the infrastructure itself. These services include management of electrical power distribution, water and sewage systems, waste management, communications, buildings and structures, security and law enforcement, fire protection, grounds maintenance, and food services.

Because of the extraordinary challenges involved in reaching space, it is often necessary to choose designs and materials that achieve the highest possible performance, even if this requires accepting risks. The extremely large quantities of hazardous materials that are used contribute to the unique occupational hazards associated with this work.

employees with a safe and healthful workplace. To accomplish this task, a comprehensive, well-organized occupational medicine and environmental health plan must be in place. The management of such a far-reaching system requires a team of specialists representing diverse fields. Box 120.1 lists the components of a comprehensive occupational medicine and environmental health program.

These programs provide a basis for the management of hazardous operations and processes, the support elements required for the recognition and assessment of new hazards, and the evaluation of control measures used for the protection of personnel.

HAZARDOUS MATERIALS USED IN SPACE OPERATIONS

Space launch processing operations present some unique industrial hygiene problems. Of greatest concern is the safe use and handling of cryogenic liquid propellants, storable propellants, and solid rocket motor propellant. Table 120.1 lists some of the common propellants used in launch-processing operations.

Liquid hydrogen or nitrogen present hazards, such as frostbite from the extreme cold and potential asphyxiation from oxygen displacement. The rapid vaporization from spilled cryogenic liquids can result in oxygen deficiency in enclosed areas if the cryogen is an asphyxiant, such as nitrogen, or in excessive oxygen levels and consequent fire hazard if oxygen is spilled. Cryogenic oxygen presents special hazards from the creation of oxygen-rich atmospheres. Special ventilation and monitoring for oxygen level in air may be required, particularly in confined spaces. In addition to engineering controls, protective clothing and written procedures are used to manage cryogen hazards.

OCCUPATIONAL MEDICINE AND ENVIRONMENTAL HEALTH PROGRAM

Workers in this industry are exposed to a variety of hazardous substances, and many of these employees are involved in potentially dangerous operations. Some hazards are inherent to spaceflight and launch activities and cannot be easily eliminated. Consequently, strong environmental health and occupational medicine programs are required to provide all

TABLE 120.1 Common Propellants

Name	TLV (ppm) ^a	OSHA PEL (ppm) ^a	Use
Aerozine 50 ^b	0.01	1	Hypergolic fuel

^cCeiling limit.

American Conference of Governmental Industrial Hygienists; TLV, threshold limit value (ACGIH, 2014); Occupational Safety and Health Administration; PEL, permissible exposure limit (OSHA, 1995); NA, not available.

Hypergolic propellants include monomethyl or dimethyl hydrazine, which serves as fuels, and nitrogen tetroxide, used as an oxidizer, and are discussed in detail below. They are both toxic and reactive, but are used where liquid propellants must be stored at ambient temperature for extended periods.

Solid rocket propellants commonly contain a mixture of powdered aluminum fuel and ammonium perchlorate oxidizer. When ignited, these components produce large volumes of gas, which contain aluminum oxides, carbon monoxide, and hydrogen chloride gas. Hazard controls require evacuating the immediate launch area during launch in addition to the downwind corridors. Monitoring for toxic gases is performed as a part of postlaunch reentry before unprotected personnel are allowed access to the launch pad.

Although much attention is directed to the propellants associated with spacecraft, oversight is also required to manage the hazards associated with the maintenance of the facilities, grounds, infrastructure, and ground support equipment. The widespread use of asphyxiant gases, used as pressurants and for inerting propellant systems, carries a significant risk of creating oxygen-deficient atmospheres. Significant attention is also required to control exposures to asbestos, which is frequently encountered during construction and building renovations, and to silica and toxic metals that are present during the maintenance of steel structures at the launch facility when abrasive blasting is performed.

With the end of the Space Shuttle program in 2011 and the beginning of NASA's new mission to commercialize space flight, emphasis is being placed on low toxicity or "green" propellants (NASA Press Release, 2012). Green propellants, such as ammonium dinitramide (ADN) and hydroxylammonium nitrate (HAN), are being considered as low toxicity alternatives to hydrazines. With reduced handling hazards come reductions in processing costs, hazardous waste, systems complexity, and launch processing times. As reliability concerns are addressed, the use of green propellants will be expected to see more widespread use.

HYDRAZINES

Hydrazines are used in rocket engines, reaction control thrusters, the auxiliary power unit, chemical and pharmaceutical production processes, catalysts as inorganic solvents, and plastic synthesis. Hydrazine is a clear, colorless, and corrosive water-soluble liquid. Their vapors are heavier than air and have an ammonia or fishy odor.

INDUSTRIAL HYGIENE

Employees may be exposed to hydrazine via skin or eye contact, inhalation, or ingestion. During the 1990s, the American Conference of Governmental Industrial Hygienists

(1996) reduced its published threshold limit value (TLV) for hydrazine fuels to a common level of 10 ppb in air, a level that required research and development of new detection methods for workplace monitoring. The NASA utilized its unique research and development resources to develop a technology enabling rapid and accurate field measurements of this air contaminant with sensitivities previously considered infeasible (Marmaro et al., 1992).

HEALTH EFFECTS

Hydrazines are caustic and produce local chemical irritation on the skin or lungs, but their primary toxic effects are the result of systemic absorption, usually after inhalation, and effects on target organs. Because spilled hydrazine frequently ignites, an acute exposure often includes combustion products as well. Systemic absorption of hydrazine can result in hypotension, irritation of the pulmonary tract mucosa, coughing, dyspnea, pulmonary edema and respiratory failure, headache, dizziness, narcosis, central nervous system depression, muscle tremors, and seizures. Hydrazine can also cause irritation of the gastrointestinal tract, nausea and vomiting, hematemesis, conjunctivitis, corneal damage, and chemical burns. Skin contact may result in irritant dermatitis and chemical burns, facial edema, and allergic sensitization after prolonged contact. Kidney and liver damage and hyperglycemia or hypoglycemia may also be observed. Red blood cell hemolysis and methemoglobinemia may result from excessive exposure to monomethylhydrazine (MMH) (NIOSH, 1994).

MEDICAL TREATMENT OF SIGNIFICANT EXPOSURES

The patient should be decontaminated by disrobing and washing, and airways, breathing, and circulation should be evaluated. If necessary, oxygen should be administered via a nonrebreather mask. An intravenous (IV) line with normal saline should be started. If the patient is hypotensive, IV fluids should be given and then the patient should be reassessed.

Hydrazines are GABA agonists and can cause seizures or central neuropathies by a mechanism similar to isoniazid toxicity. In significant exposures, or where neurologic abnormalities are seen, pyridoxine can be given at a loading dose of 25 mg/kg IV. In case of seizures, standard treatment with parenteral benzodiazepines (e.g., lorazepam or diazepam) should be administered. Based on experience with isoniazid, if seizure activity continues despite these measures, barbiturates, paralytics, and intubation should be considered.

Laboratory work, even in limited exposures, should include complete blood count, serum electrolytes, methemoglobin,

liver function tests, renal function tests, chest X-ray, arterial blood gases, and pulmonary function tests. If methemoglobin is >30%, 1–2 mg/kg methylene blue can be given IV in a 1% solution (Bronstein and Currance, 1994).

NITROGEN TETOXIDE/NITROGEN DIOXIDE

Nitrogen tetroxide is used as an oxidizer for hydrazine propellants in both launch vehicles and spacecraft reaction control systems. Nitrogen tetroxide is the dimer of nitrogen dioxide (NO_2). At temperatures between -9.3°C (15°F) and 135°C (275°F), NO_2 and nitrogen tetroxide coexist as a gaseous mixture. These vapors are clear to orange-brown with a sweetish, acrid, or bleach odor and are heavier than air. In their liquid phase, they are green to brown, highly corrosive, and water soluble.

INDUSTRIAL HYGIENE

Workers may be exposed to nitrogen tetroxide and NO_2 by inhalation, skin and eye contact. It evaporates quickly and leaves little or no residue. In 2012, American Conference of Industrial Hygienists (ACGIH) lowered its TLV for nitrogen dioxide to a concentration of 0.2 ppm in air. Detection methods and monitoring equipment are commercially available at this level.

HEALTH EFFECTS

Nitrogen dioxide absorbs water readily, becoming nitric acid. Consequently it reacts immediately on contact with human tissue and cannot be absorbed; it produces only local toxicity. It can produce significant skin and eye burns; however, life-threatening injuries are almost exclusively due to inhalation and pulmonary toxicity, which can range from mild chemical pneumonitis to frank pulmonary edema. Life-threatening exposure will generally produce immediate symptoms, but inhalation of NO_2 may produce mild effects initially, followed by a symptom-free period of approximately 5–12 h and subsequent worsening. In severe cases tachycardia, bradycardia, irritation of the pulmonary tract mucosa, coughing, dyspnea, chemical pneumonitis, pulmonary edema, respiratory failure, and severe spasm of the airways or larynx may be seen. Headache, narcosis, vertigo, somnolence, fatigue, and loss of consciousness may also be observed. Burning and irritation of the gastrointestinal tract, nausea and vomiting, as well as conjunctivitis, corneal damage, and chemical burns of the eye may be manifested. Irritant dermatitis and chemical burns of the skin, as well as methemoglobinemia, may result from excessive exposure.

MEDICAL TREATMENT OF SIGNIFICANT EXPOSURES

The patient should be decontaminated by disrobing and washing, and airways, breathing, and circulation should be evaluated. If necessary, oxygen should be administered at high concentration, i.e., by nonrebreather mask. Intravenous steroids should be administered to prevent chemical pneumonitis. Baseline laboratory studies should be performed as well as complete blood count, serum electrolytes, chest X-ray, pulmonary function tests, and arterial blood gases. Close follow-up is required during the first 24–48 h because pulmonary edema may be delayed at least 6 hours. Bronchiolitis obliterans may occur up to 6 months postexposure (Bronstein and Currance, 1994; Clayton and Clayton, 1994).

HISTORICAL TOXIC HAZARD INCIDENTS IN GROUND OPERATIONS

Operations are particularly hazardous at the launch site, where all the hazardous materials are brought together during the complex and precise procedures, which is required to prepare a rocket and spacecraft for flight. The majority of hazardous materials incidents causing injuries and fatalities at launch sites around the world have involved fires or explosions as well as chemical releases and spills. Often these contingencies have occurred while servicing rockets being prepared for launch or making repairs after a problem develops. A comprehensive program of safety, industrial hygiene, waste management, and contingency response has been essential in preventing significant health impacts.

The most serious hazards are posed by toxic propellants, particularly nitrogen tetroxide and hydrazines, generally either unsymmetrical dimethylhydrazine (UDMH) or MMH. Perhaps the first major toxic release incident in the industry occurred on 4 October, 1960 at the Baikonur launch site in the USSR, during preparations to launch an uncrewed rocket designated the R-16. A technician erroneously plugged the first stage umbilical cable into an incompatible umbilical socket on the second stage, causing a premature ignition command. The fuel tanks ignited and ruptured, releasing more than 100 tons of UDMH and nitrogen tetroxide propellants. There was a massive fire, but witnesses also described victims overcome by toxic fumes; there were about 100 fatalities (Oberg, 1988).

An even more disastrous incident occurred at the Xichang Satellite Launch Center in western China on 15 February, 1996. A Long March 3B rocket went off course almost immediately after launch and crashed a few seconds later into an area near the facility gate where a large crowd had gathered to watch. The rocket carried a nearly full load of propellants at the time of impact, including over 200 tons of UDMH and nitrogen tetroxide. While hydrazine fuels tend to

burn in such a situation, the nitrogen tetroxide is largely released as nitrogen dioxide and may well have caused a significant fraction of the casualties. Although the official death toll released by the Chinese government was listed at only six, Western sources and observers at the scene estimated those killed numbered in the “hundreds” and as many as 1000 people were injured (Ferster, 1996).

In April 1994 an incident involving the spill and release of nitrogen tetroxide occurred at NASA’s Johnson Space Center (JSC) at the thermochemical test area (TTA). The leak occurred while a small rocket was being readied for a test in the TTA. The total release was approximately 16 gallons of both liquid and vapor through a 25-foot-tall vent stack. The leak generated a brownish-red cloud that drifted into nearby occupied areas of the center. There were no life-threatening injuries; however, more than 80 people sought medical help for symptoms they believed were related to this exposure (Caylor, 1995).

Oxygen is essential to life, but also carries the risk of toxicity. Atmospheres containing 100% oxygen were used frequently in the early years of human flight to simplify vehicle design and avoid decompression sickness. In 1960 the USSR was conducting a 14-day test of oxygen toxicity with a human subject, a member of their cosmonaut corps, when a flash fire in the chamber left him with burns that proved fatal (Oberg, 1990). A similar hazard resulted in the most serious incident of the Apollo program, now designated Apollo 1. During a ground communications test prior to the first crewed launch, the capsule was filled with an atmosphere of 100% oxygen and pressurized to a total pressure of about 18 PSI; this was a condition that had not been anticipated in the design. A source of ignition was provided by an electrical short in the capsule, probably involving wires that were partially installed and subjected to abrasion. In the pressurized oxygen-rich atmosphere, nonhazardous materials in the cabin were ignited, including fabric netting, Velcro, polyurethane foam insulation and even ethylene glycol coolant fluids. The resulting flash fire and carbon monoxide accumulation killed all three crew members. This tragedy led to substantial modifications in materials and procedures used on Apollo and subsequent spacecraft (NASA, 1970).

Confined spaces are sometimes filled with dry nitrogen gas to reduce hazards from flammable gasses and prevent ice accumulation on cryogenic systems. This poses a significant hazard since an individual entering such an oxygen-deficient atmosphere can become hypoxic and lose consciousness in a matter of seconds. One such incident occurred at the Kennedy Space Center on 28 February, 1981 just after a 20-s engine test of the Space Shuttle Columbia on the launch pad prior to its first flight. Due to a procedural error technicians were cleared to enter the aft compartment of the Shuttle after the firing, but while the compartment was still filled with 100% nitrogen. All collapsed in the compartment before the problem was recognized; three ultimately died due to anoxic

injury (Wilcut and Harkins, 2011). On 5 May, 1995, two European Space Agency technicians died in a similar accident at the Guiana Space Center when they entered an umbilical mast which had become filled with nitrogen gas due to a leaking heat exchanger (ESA, 1995).

PREVENTION AND TREATMENT OF TOXIC HAZARDS IN GROUND OPERATIONS

Hypergolic fuels for rocket propellant systems consist primarily of hydrazine, MMH, UDMH, and Aerozine-50, which is a 50:50 mixture of hydrazine and UDMH. These hydrazine derivatives present vapor inhalation and skin contact hazards. Hypergolic oxidizer for rocket propellant systems consists of nitrogen tetroxide, which breaks down into NO₂ upon release into the atmosphere. Nitrogen tetroxide is an extremely corrosive liquid and may cause severe eye and skin burns. Nitrogen dioxide gas produces primarily alveolar pulmonary toxicity but may produce irritation to the eyes and mucous membranes as well.

When using or handling hypergolic fuels or oxidizers, the preferred method for preventing personnel exposures is to keep the toxic material fully confined in a closed system. This may not be possible when the chemicals are being transferred from a storage drum to a transport cart, during spacecraft loading procedures, or while connecting or disconnecting systems containing the liquids or vapors. In these situations personnel use fully encapsulating impermeable suits called propellant handler’s ensembles (PHEs). Propellant handler’s ensembles are composed primarily of butyl rubber and protect personnel by supplying clean air either from a breathing air supply located outside the hazardous area or from a tank worn on the back of the user. Propellant handler’s ensembles also preclude skin contact with hypergols. Routine exposure monitoring is also performed to ensure that personnel are using adequate protection. Because of the engineering controls and protective clothing used, personnel exposures to hypergolic propellants are in most cases short term, low in concentration, and transient.

The Emergency Medical System at the Kennedy Space Center (KSC) deploys mobile medical triage and treatment forces for prelaunch and postlanding contingencies and ground mass casualty incidents. These forces are positioned upwind of hazardous exposures, assess, and monitor patient contamination, and provide onsite water-based decontamination and exposure treatment when needed.

A general strategy for exposure to a major toxic propellant release is presented in Box 120.2.

Hazardous materials can be handled safely in spaceflight and launch operations; however, the most effective risk reduction strategy remains finding less toxic alternatives. Several programs are underway in the United States to investigate less toxic storable propellants such as ammonium

BOX 120.2 GENERAL STRATEGY FOR INITIAL TREATMENT OF MAJOR EXPOSURE TO HYPERGOLIC PROPELLANTS

- Respiratory protection if source still present
- Move across wind or upwind away from vapor cloud to fresh air
- Remove clothing
- Oxygen administration
- Respiratory support if required
- Flush exposed areas (skin, eyes) with water for 20 min
- Treat trauma if present
- Pyridoxine 25 mg/kg for seizure prophylaxis in significant hydrazine exposures
- Consider corticosteroids for respiratory injury
- Control seizures with IV benzodiazepines
- Monitor condition and transport to definitive care facility

dinitramide (Talawar et al., 2009), and to develop refrigeration methods for storing cryogenics such as liquid oxygen for long periods in space. In China, the new generation of launch vehicles will abandon hypergolic propellants and utilize kerosene, liquid hydrogen, and liquid oxygen instead.

TOXIC HAZARD INCIDENTS DURING SPACEFLIGHT

The most obvious and visible personnel in the spaceflight industry are the astronauts and cosmonauts who travel into the hostile environment of space to live and work. The time they spend in space ranges from a few minutes during suborbital flights to a year or more aboard the International Space Station. The launch into orbit and the return to the earth from space entail particularly complex and hazardous tasks.

There have been four incidents in which fatalities have occurred during spaceflight; however, all were due to mechanical failures of the spacecraft or launch vehicle rather than toxic hazards. In two of these cases, the Space Shuttles Challenger in 1986 and Columbia in 2003, there were toxicological concerns during the recovery of vehicles as recovery and reconstruction workers were exposed to friable fibrous materials and residuals of toxic chemicals (Scarpa, 2014).

On the fourth day of the Apollo 13 mission, an electrical short circuit in one of the Service Module's oxygen tanks led to an explosion and subsequent crippling of the Apollo spacecraft. The explosion terminated the mission to the moon, and the resultant loss of breathing oxygen presented

an acute emergency. The crew was faced with multiple problems, including rising carbon dioxide levels, which required adapting carbon dioxide absorbent cartridges from the Apollo Command Module to a different environmental system in the Lunar Module (NASA, 1970).

The most serious toxic exposure during a spaceflight occurred in 1975 at the end of Apollo–Soyuz, the first international space mission. Shortly after the Apollo capsule began its descent to Earth, a human factors-related error left the attitude control thruster rockets firing after the parachutes were deployed. As the craft descended into the atmosphere, the cabin vent opened and thruster exhaust was drawn into the cabin. The primary toxin was nitrogen dioxide gas, although a variety of combustion products were also present. Respiratory protection was aboard (oxygen masks with eye protection); unfortunately it had been assumed it would only be needed when the crew was weightless, so the masks were stowed in an area well above the crew seats. When the incident occurred, the spacecraft was suspended by its parachutes under normal gravity, and the masks were inaccessible. The crew almost immediately displayed signs of chemical pneumonitis, including coughing and shortness of breath, as well as burning of the eyes and exposed skin. All remained conscious until the impact with the ocean, unfortunately the capsule then rolled upside down, making it impossible to open the hatch. Two of the three crewmen were incapacitated by that time, and a lethal exposure could have occurred. Fortunately the commander, who remained conscious, was finally able to reach the masks and put them on his crewmates and himself. After recovery, the crew was treated for chemical pneumonitis with oxygen and IV steroids; they were essentially free of symptoms by the following day but were hospitalized for several days as a precautionary measure (NASA, 1976; DeJournette, 1977).

There have been numerous less serious incidents involving hazardous properties of materials aboard spacecraft, including both inhalation and skin exposures. During Apollo 10, loose pieces of fiberglass insulation produced clinically significant skin, eye, and upper respiratory tract irritation. Several inhalation exposures occurred during missions of the Space Shuttle. Eye irritation from lithium hydroxide canisters has been reported on at least six separate shuttle missions. There have also been reports of nausea and headaches from outgassed ammonia and formaldehyde (Coleman and James, 1994). There have been numerous reports of hand desquamation, boils, and contact dermatitis from chemical irritants (Toback, 1991).

Exposures to toxic gases such as ethylene glycol and excessive carbon dioxide were frequent occurrences in the aging Russian space station MIR. In 1997 the life support system normally supported only three crewmembers but six were aboard the station during a crew exchange period and so supplemental breathing oxygen was needed. This was produced using a solid-fuel oxygen generator in which a

cartridge containing lithium perchlorate is ignited and burned slowly, releasing oxygen. A defective cartridge ruptured, emitting a meter-long jet of flame, sparks, and particles of molten metal and rapidly filled the station with smoke. The crew was able to locate smoke masks and managed to use water from several small fire extinguishers to keep the spacecraft wall cool until the device burned itself. One crewman suffered a small third-degree burn (Morgan, 2001; Oberg 1998).

PREVENTION AND TREATMENT OF TOXIC HAZARDS DURING SPACEFLIGHT

Any toxic substance released into the sealed volume of a spacecraft can become a persistent respiratory hazard, consequently a comprehensive toxicology program has been developed to assess every material brought onto human-carrying spacecraft or used aboard the International Space Station.

The program is managed by the Space Toxicology Office at the Johnson Space Center (JSC) in Houston, Texas. Every material to be brought onboard the Space Station is assessed for toxic hazards. Spacecraft Maximum Allowable Concentrations (SMACs) are determined for each chemical constituent and used in material selection and the planning of containment procedures. In addition, air samples are collected aboard the Space Station and spacecraft during each mission, and actual concentrations of a wide range of hazardous materials are measured. Detailed documentation, including the sources for determination of maximum allowable levels, is provided in detail on the website of the JSC Space Toxicology Office, and has been published in a series of reference books which provide a useful resource for toxicology in other industrial environments (National Research Council, 1994-present).

A major concern on all spaceflights continues to be the potential presence of contaminants in the atmosphere of the cabin. Toxic substances in spaceflight can come from a number of different sources, including leaks or spills from storage containers, volatile metabolic waste products of the crew, particulate pollutants that are not easily removed from the air under weightless conditions, components of spilled food, leaks from environmental or flight control systems, thermodegradation of spacecraft materials and products produced by small electrical fires or contaminated removal systems, and outgassing of cabin materials.

The management of toxic hazards in crewed spacecraft, such as the materials selection program, is based on experiences gained during the Apollo Program. The material selection program includes a thorough screening of candidate materials for flammability, applicability, and the evaluation of the contaminant compounds that are outgassed into the crew cabin environment. All of the interior nonmetallic

materials are known to outgas contaminants into the crew compartment. Some specific sources are electrical insulation, paints, lubricants, adhesives, and degradation of nonmetallic console and equipment structures. Approximately 400 compounds have been identified in the atmosphere of the shuttle cabin. Many of these compounds can be found in normal terrestrial air, but when they become part of the confined atmosphere of the spacecraft, they can concentrate to toxic levels over time (James and Coleman, 1994).

The environmental control and life support systems utilized on the Soyuz spacecraft uses an activated charcoal filter to remove most trace contaminants. This approach, although reliable, does not provide the long-term removal of volatile organics needed on the International Space Station. In the Space Station a trace contaminate control system utilizes a charcoal bed followed by an electrically heated high temperature catalytic oxidizer. Any over-oxidized chemicals are then removed by a lithium hydroxide bed (Locke, 2008). Real-time atmospheric monitoring is performed on both the US and Russian segments of the Space Station by spectroscopy which provides partial pressures of oxygen, nitrogen, carbon dioxide, hydrogen, water, and methane (Locke, 2008).

Permissible levels of a wide range of contaminants are also specified for potable water aboard the spacecraft; this becomes more important as the duration of spaceflight increases and water is to be recycled multiple times (National Research Council, 2004).

CONTINGENCY RESPONSE TO SPILLS OR SIGNIFICANT EXPOSURE

The NASA has developed equipment and procedures for the crew to follow in case a serious toxicological event occurs on orbit, and the crew receives extensive training in the effects of toxic materials, both those carried on the spacecraft and those which could result from a fire, in which toxic fumes are generated. Most of the materials selected for use in the Space Shuttle were chosen on the basis of their ability to resist combustion at elevated temperatures. This requirement resulted in the selection of many materials that contain halogenated or nitrogenated hydrocarbons. However, in many cases these materials contribute to increased combustion toxicity (Rippstein and Coleman, 1983). The potential toxic hazards associated with even small fires were demonstrated during an incident on the Shuttle in 1989, in which an electrical cable overheated, releasing a variety of chemical contaminants.

The crew has respirators that provide oxygen and eye protection for quick use in an emergency. A combustion products analyzer, now in use on the Space Station, was developed to detect and measure concentrations of some of the important contaminants released by heating or combustion of these materials, including carbon monoxide,

hydrogen chloride (from polyvinyl chloride), hydrogen fluoride, and carbonyl fluoride (from Teflon), and hydrogen cyanide (from Kapton). Finally, the crew is trained in procedures for purging combustion products from the spacecraft atmosphere and cleaning up spills involving toxic materials. As with chemical exposures on the ground, the crew is provided with an extensive medical kit and training in recognition and medical treatment of crewmembers exposed to toxic materials (Hale et al., 2011).

RADIATION SAFETY CONSIDERATIONS WHEN PLANNING FOR AND SUPPORTING MAJOR RADIOLOGICAL SOURCE SPACE LAUNCHES

Radioisotope power sources (RPSs) use the heat from the radioactive decay of plutonium-238 to generate electricity the spacecraft can utilize to power science instruments, communications equipment, and general spacecraft or surface rover operations for spacecraft that cannot generate electrical power using solar panels. Typical external radiation dose rates from the gamma ray and neutron particles are approximately 100 mrem per hour 3 feet from the external surfaces of the power source with radiation areas of 2 mrem per hour dose rates extending out 16 feet in all directions from the power sources. Power source handlers must also be cognizant of the high surface temperatures of these power sources that are typically around 100 °C.

Another radiation safety issue that must be considered includes the inhalation exposure of the workforce or public to radioactive dust particles that could potentially be released as a result of a launch accident. Because plutonium-238 is an alpha particle emitter, the retention of radioactive dusts trapped in the lungs could lead to potential cancers in exposed people. In order to minimize this risk the plutonium, as plutonium-238 oxide is embedded in a ceramic matrix to help preclude formation of respirable particles. The fuel is placed into iridium capsules to help withstand crushing pressures that in turn are encased in several layers of a carbon–carbon material to absorb the heat generated from an accident environment.

Supporting major radiological source launches such as the Cassini, Pluto, and Mars Science Laboratory missions is no small task. Radiation safety management of ionizing radiation hazards must provide oversight of every step in the launch process from source receipt, ground processing, and radiological contingency launch readiness. Planning takes considerable time to outline, prepare for, and execute. Usually planning starts about 3 years prior to launch, with approximately 5–6 months involved in ground processing. Overlapping at the end of ground processing is approximately 2–3 weeks for radiological contingency preparations, training, and drilling of the contingency elements prior to launch to insure readiness to respond, as well as, have the

capability to support any protracted period postlaunch should a launch mishap occur.

Beginning 3 years prior to launch, radiological contingency planning meetings are held with appropriate federal, state, and local officials. Follow-up meetings are scheduled to status preparations, plan development, equipment procurements, and planning contingency exercises. A core planning working group meets more frequently to conduct detailed planning, submit and track procurements, develop radiological contingency plans and procedures, maintain budget tracking and forecasting, and track action items from the radiological contingency planning meetings.

Ground processing support planning typically starts 1 year out from launch. It is kicked off by a high fidelity practice dress rehearsal by the spacecraft builders. At this 1–2 day rehearsal draft procedures for ground processing source handling are walked through to validate and/or identify any issues that need resolution. During the rehearsal, health physics support is identified and time and motion studies are conducted with the source handling and support personnel in order to identify opportunities to use time, distance, or shielding to reduce radiation exposure. Data from the walk-through are also used to define likely radiation exposures that would be received during the actual handling procedures. Prior to source arrival, all personnel involved with source handling operations are provided radiation safety training and health physics managers issue radiation work permits spelling out who is cleared to handle the sources, what source handling procedures must be used, where the activity will take place, and what radiation safety steps to follow. Radiation safety surveillance is provided for all ground processing activities involving radioactive sources. Appropriate radiation safety monitoring surveys insure compliance with issued radiation work permits, document workplace radiation exposure levels, and monitor for the presence of any radioactive contamination levels. Personnel radiation dosimeters are worn and exposures tracked usually on a monthly basis to insure radiation exposures are kept as low as reasonably achievable (ALARA). For workers who are identified as source handlers, additional direct reading electronic dosimeters are worn daily to track this potentially higher exposure work group. In order to keep exposures ALARA the RPS is loaded onto the spacecraft as late in the flow as possible. This usually means loading the power source at the launch pad.

During the radiological contingency planning period the size and scope is defined, and project milestones are established. Key exercise and rehearsal dates are established and detailed planning occurs. Specialized radiation monitoring equipment to measure air concentrations and ground deposition must be defined, procured, and tested during this period. Two to three weeks prior to launch a radiological contingency task force composed of radiation safety personnel from several Federal, state, and local agencies assemble

for site-specific training and conduct appropriate level of exercises to validate readiness for launch support. A radiological contingency capability must address the following:

1. Notify appropriate organizations and agencies in the event of an accident involving potential release of radioactive material
2. Generate public information releases on the status of the launch accident that are accurate, timely, consistent, and easily understood
3. Assess whether a release of radioactive material has occurred
4. Quantify the magnitude and character, and predict the dispersion of any radioactive material released to the environment
5. Formulate appropriate and prudent protective actions to be taken onsite and provide recommendations for offsite agencies' consideration
6. Support smooth transition to Federal response model per National Response Framework
7. Address out-of-launch area accidents resulting in suborbital or orbital reentry of the spacecraft

A radiological control center is activated to coordinate radioactive material plume modeling, direct deployed ground monitoring assets, collect and analyze monitoring data, formulate and coordinate appropriate protective actions, and keep management, the media, and general public informed in a timely manner of the state of conditions, actions, and assessments that are underway.

Sufficiently in advance of any planned launch developed radiological contingency plans are briefed to various federal, state, and local officials to inform them and help allay any concerns about the specific launch. Briefings and readiness status to launch site management, and launch agency leadership is required to proceed toward launch. Finally, the White House Office of Science and Technology Policy are briefed and must grant launch approval.

In summary start planning early, develop thorough ground processing radiation safety support plans, insure development of comprehensive radiological contingency plans that are tested, and deploy an appropriately instrumented radiological contingency taskforce capable of making prompt and comprehensive radiological assessments and timely coordinated protective actions in order to protect workers and the general public.

FUTURE SPACEFLIGHT TOXIC HAZARDS

Future spaceflights will involve longer durations, the need for self-sufficiency and autonomy, and closed life support cycles. Also, effects of long exposure to the spaceflight

environment, including microgravity and space radiation could generate unforeseen exposure hazards such as microbiological increased virulence and resistance already observed in spaceflight microbial payloads.

Project Apollo marked the first exposure of humans to a nonterrestrial material, lunar dust, and a potential exposure concern for future lunar explorers as well (Khan-Mayberry et al., 2011). In many respects lunar dust presents irritant and respiratory hazards similar to silicate dusts on Earth; however, in the reduced lunar gravity the deposition of inhaled dust in the lungs may follow different patterns than on earth (Darquenne and Prisk, 2008). Human travel to Mars and other natural bodies within the solar system will further expand the range of potentially toxic materials that must be considered in mission planning.

Future space missions will need to continuously monitor and respond to the long-term buildup of potentially high levels of chemical, physical, and biological contaminants. To relieve the human crews of such a burden, "smart" computer systems are being investigated to continuously monitor the spacecraft environment and automatically activate warnings and countermeasures if hazardous conditions occur.

REGULATORY TOXICOLOGY

DAVID M. POLANIC AND MAREK BANASIK

BACKGROUND

Health and safety data are used for evaluating specific endpoints focused at identifying potential hazards to human health and the environment. These data are used in support of regulatory submissions and for identifying various types of potential hazards (e.g., explosivity, carcinogenicity), establishing occupational exposure limits, determining vulnerable receptors in the environment, and communicating hazards. The data requirements for regulatory submissions vary based on the type of substance being registered. For example, the requirements for industrial chemicals range from only those data in the submitter's possession to required testing based on the intended production volume.

Regardless of the jurisdiction in which a submission is made, there are two standard requirements for generating data, which include performing studies under good laboratory practice (GLP) standards and in accordance with validated testing guidelines. These requirements were established to ensure the quality, reliability, and integrity of the underlying data. Submitters and regulatory agencies may also use non-GLP, non-guideline studies for informing decision-making activities. For example, manufacturers may use this information for guiding research and development on alternative substances. On the other hand, regulatory agencies may use such information for evaluating regulatory submissions or making subsequent decisions on registered substances, which are already in the stream of commerce (e.g., bisphenol A).

The discussion that follows provides an overview of GLP standards and validated testing guidelines, followed by a discussion on various laws where these types of data

are used, including chemical control laws, laws aimed at protecting workers, and hazard communication laws.

TESTING STANDARDS

GLP Standards

Good laboratory practice standards were first proposed by the United States (US) Environmental Protection Agency (EPA) in April 1980 and have since been adopted globally by inter-governmental agencies such as the Organisation for Economic Co-operation and Development (OECD) (EPA, 1983). On the OECD website, it states that the principles of GLP "... ensure the generation of high quality and reliable test data related to the safety of industrial chemical substances and preparations" (OECD, 2014a).

Historically, GLP standards were needed based on EPA's own experience, along with that of the US Food and Drug Administration (FDA), in dealing with the integrity of data submitted in support of the health and safety of regulated products and pesticides. Inspections by EPA and FDA of several laboratories led to the discovery of unacceptable practices that called into question the validity of submitted data. Some studies had been performed so poorly that the resulting data could not be relied upon in EPA's regulatory decision-making process (EPA, 1989a). Many studies did not adhere to specified protocols, were conducted by unqualified personnel, or were not adequately monitored by study sponsors. In some instances, results were selectively reported, underreported, or fraudulently reported. One of the most notable examples was the fraud committed by executives at

the Industrial Bio-Test (IBT) Laboratories (Northbrook, IL, USA) (United States v. Keplinger, 1985).

Industrial Bio-Test Laboratories was a contract research laboratory that conducted animal toxicology studies of various chemicals, drugs, and pesticides on behalf of the manufacturers in order to determine the safety and effectiveness of their products. Managers and executives of IBT Laboratories were convicted of various counts of fraud and making false statements, including suppression of relevant information and falsification of data, in connection with studies performed by IBT Laboratories. Specifically, the infractions included: (1) underreporting mortality of research animals and commingling of original and later-started research animals; (2) omission of histopathological data on research animals; (3) omission of data on post-mortem examinations; (4) failure to report the original opinion of a doctor that trichlorocarbanilide had a significant effect on research animals; and (5) failure to disclose a pathology report. Additionally, IBT Laboratories wholly fabricated blood and urine data pertaining to a study of an anti-inflammatory drug used to treat arthritis, as well as making false statements to the FDA in a written report.

The trichlorocarbanilide study performed by IBT Laboratories was plagued by an unusually high mortality rate, which resulted in the defendants commingling new animals, those that had not been fed the test material for as long as the original animals, with the existing test animals. This practice, although unacceptable because it compromises the validity of the study, was done to ensure that a sufficient number of animals survived to the end of the study so IBT Laboratories could claim a valid evaluation. At trial, the government provided evidence showing that in at least one test group the total number of animals used exceeded the number of animals that started the study by 30%. The government further proved that the defendants were aware of the commingling before the reports were submitted and, as a result, that the reports contained false statements.

After these actions, EPA needed rules to ensure the quality and integrity of data. In enacting the final rule, and keeping with its policy to reduce the burden on the regulated public, EPA found no legal or scientific reason for promulgating GLP standards that differ substantially from those of the FDA. The EPA's Toxic Substances Control Act (TSCA) GLP standards specify minimum requirements for conducting studies relating to health effects, environmental effects, and chemical fate testing to ensure the quality and integrity of data submitted under Section 4 of TSCA.

As part of the GLP standards, a testing facility is required, among other things, to permit an authorized employee of EPA or FDA to inspect the facility and all records and specimens regarding the study, or EPA will not consider the data developed by that facility as reliable. Additionally, a testing facility is required to set forth standard operating procedures, as well as specific protocol for each study being

performed. Data collection, reporting, and record retention requirements are also outlined in the GLP standards to preserve the integrity of the studies performed (for discussion, see Huntsinger, 2008). Of particular note, GLPs require the retention of "raw" data, which are defined as: ". . . any laboratory worksheets, records, memoranda, notes, or exact copies thereof, that are the result of original observations and activities of a study and are necessary for the reconstruction and evaluation of the report of that study [emphasis added]." A failure to comply with the GLP standards may result in study rejection and possibly civil and criminal penalties (EPA, 1989a).

Compliance with GLP standards represents the first of the two major requirements, which are placed on manufacturers, who are conducting health and safety studies as part of a regulatory submission for a new chemical or as part of a testing rule issued by a regulatory agency. The second requirement consists of following the validated testing guidelines. These guidelines play a critical role in product registration testing and regulatory decision-making because they have been designed to ensure that the endpoints being evaluated (e.g., developmental neurotoxicity) are accurately assessed during the experimentation (Makris et al., 2009). In the following subsection, we discuss the available test guidelines and the process that a study design must undergo to eventually become a validated test guideline.

Validated Testing Guidelines

Validated testing guidelines provide requisite information for designing, conducting, interpreting, and reporting the results of studies. In combination with GLPs, validated testing guidelines are intended to ensure that study data are of the highest quality and reliability possible. Testing guidelines go through a rigorous validation process, which includes supporting data, commenting rounds, independent replication of results from multiple laboratories, workshop consultations, etc. Several entities issue validated testing guidelines; however, those issued by the OECD often serve as the basis for organization-specific test guidelines. For example, both the EPA's *90-Day Oral Toxicity in Rodents* test guideline and the EU's *Repeated Dose 90-Day Oral Toxicity Study in Rodents* test guideline are based on the OECD's *Repeated Dose 90-Day Oral Toxicity Study in Rodents* test guideline (EC, 2001; EPA, 1998).

Validated testing guidelines have been issued on physicochemical properties (e.g., density of liquids/solids and vapor pressure), effects on biotic systems (e.g., fish sexual development), degradation and accumulation (e.g., photo-transformation of chemicals in water and bioaccumulation in fish), and health effects (e.g., skin sensitization and developmental neurotoxicity) (EPA, 2013; OECD, 2014b). Additional guidelines are available depending on the substance under evaluation (e.g., spray drift test guidelines for pesticides) (EPA, 2013).

As indicated in the foregoing discussions on GLP standards and validated test guidelines, the stringent standards placed on manufacturers and importers for testing their products are to ensure that informed decisions about the potential hazards of a chemical are realized before being placed on the market. However, manufacturers and importers are not the only sectors that perform human health or environmental effects testing on chemicals. A large portion of research on chemicals is performed in academic laboratories, which are not required to perform studies in compliance with GLP standards or in accordance with validated test guidelines. As noted earlier, GLP standards came about in part because some companies were fabricating research data, which was ultimately used in support of product registrations. However, research misconduct (e.g., data fabrication) permeates all sectors of the research community, including academic laboratories (PubMed, 2014).

Given that research on industrial chemicals is conducted by all sectors of the scientific community, it is imperative that an assessment of the quality of data from such studies be assessed. The discussion that follows provides a brief background on the differences between data generated by manufacturers and importers of chemicals versus academic and government laboratories.

Data Quality

Good laboratory practices/guideline data submissions are the primary source of experimental information from which regulatory decisions are made on a particular chemical, although basic exploratory research data from academic or government research laboratories are sometimes available to inform regulatory decision making. There are, however, several caveats with using exploratory research data, because they are typically not conducted under GLP or in accordance with a validated guideline. Rather, these data are typically reported as published summaries in the peer-reviewed literature, but the underlying raw data are difficult or sometimes impossible to obtain from the investigators (EPA, 2008a–d). Therefore, assessing the quality and reliability of basic exploratory studies is a complicated but essential requirement for the regulatory risk assessment process.

Disputes often arise between manufacturers who perform GLP/guideline studies and researchers who publish the results of exploratory studies and report hazards that were not identified in the GLP/guideline studies (Tyl, 2009). The crux of such disputes is typically focused on data quality and gaining access to the underlying “raw” data. For example, OECD’s validated test guideline for a *Developmental Neurotoxicity Study* recommends using the rat as the test species with a total of 20 litters for each dose level (OECD, 2007). It states further that “[t]he statistical unit of measure should be the litter (or dam) and not the pup.” However, several exploratory

studies on decabromodiphenyl ether (Chemical Abstracts Service Registry Number: 1163-19-5), a brominated flame retardant, reported that this compound caused developmental neurotoxicity in mice and rats (Viberg et al., 2003, 2007). The study authors utilized from three to five litters of mice or rats at each dose level, and used the pup as the statistical unit of measure, an approach that increases the likelihood of obtaining false positives (Holson et al., 2008; Moser et al., 2005). Based on these data, the manufacturers of decabromodiphenyl ether were required to perform a GLP/guideline developmental neurotoxicity study (Biesemeier et al., 2011); no evidence of developmental neurotoxicity was identified; however, regulatory agencies initiated several measures that ultimately led to the market phase out of this substance.

When regulatory agencies utilize disputed exploratory studies for decision-making activities, administrative/legal challenges and congressional inquiries often ensue (Vitter, 2014). The standard argument proffered by impacted stakeholders is that regulatory agencies require manufacturers to follow stringent testing standards (i.e., GLP standards and validated testing guidelines) and to provide the underlying “raw” data for their studies. In contrast, the same regulatory agencies may use exploratory studies as a basis for initiating rule-making or other market deselection activities, even when the underlying “raw” data are unavailable (EPA, 2008a–d; Vitter, 2014). The US Senate’s Committee on Environment and Public Works chastised EPA for this type of “. . . double standard . . .” and likened it “. . . to somebody being criminally prosecuted based on data that the defense is not allowed to see” (Vitter, 2014).

Several regulatory agencies have issued formal guidance for evaluating the quality, reliability, and integrity of data (ECHA, 2011; EPA, 2003, 2012). The European Chemicals Agency’s (ECHA’s) guidance is based on the approach proposed by Klimisch et al. (1997), which described the following numerical codes and descriptive categories for evaluating the quality and reliability of studies:

Reliable without Restrictions. This includes studies or data from the literature or reports which were carried out or generated according to generally valid and/or internationally accepted testing guidelines (preferably performed according to GLP) or in which the test parameters documented are based on a specific (national) testing guideline (preferably according to GLP) or in which all parameters described are closely related/comparable to a guideline method.

Reliable with Restrictions. This includes studies or data from the literature, reports (mostly not performed according to GLP), in which the test parameters documented do not totally comply with the specific testing guideline, but are sufficient to accept the data or in which investigations are described which cannot be subsumed under a testing guideline, but which are nevertheless well documented and scientifically acceptable.

Not Reliable. This includes studies or data from the literature/reports in which there are interferences between the measuring system and the test substance or in which organisms/test systems were used which are not relevant in relation to the exposure (e.g., unphysiologic pathways of application) or which were carried out or generated according to a method which is not acceptable, the documentation of which is not sufficient for an assessment and which is not convincing for an expert judgment.

Not Assignable. This includes studies or data from the literature, which do not give sufficient experimental details and which are only listed in short abstracts or secondary literature (books, reviews, etc.).

The ‘Klimisch codes,’ as they have since become known, are similar to the tiered approach used by the EPA for evaluating data under the High Production Volume (HPV) Challenge Program, and the OECD proposed their use in the OECD HPV program, along with the EPA’s tiered approach. The ECHA recognized the importance of establishing a formal system for evaluating data quality and noted that “[t]he knowledge of how a study was carried out and consequently its relevance and reliability, is a prerequisite for the subsequent evaluation [and use] of information” (ECHA, 2011).

INDUSTRIAL CHEMICAL REGULATIONS

Regardless of the data source(s) used, regulatory agencies are tasked with administering laws that provide specific frameworks for evaluating new and existing substances. These are typically country or region specific and have different data requirements for new and existing substances. For example, in the US, manufacturers are only required to submit health and safety data in their possession at the time of filing a pre-manufacture notice (PMN) under the TSCA, whereas in European Union (EU), specific tests are mandated based on the intended production volume under the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) law. Unlike the US, however, REACH requires manufacturers to submit regulatory submissions for new and existing substances. A general overview of TSCA and REACH is provided in the following section.

TSCA

After finding that human beings and the environment are exposed to large numbers of chemical substances and mixtures each year (15 USC § 2601 et seq.), Congress-enacted TSCA with the purpose of preventing “unreasonable risks of injury to health or the environment associated with the manufacture, processing, distribution in commerce, use, or disposal of chemical substances” (S. Rep., 1976). The TSCA

defines a “chemical substance” as “. . . any organic or inorganic substance of a particular molecular identity . . .,” which includes “. . . (i) any combination of such substances occurring in whole or in part as a result of a chemical reaction or occurring in nature and (ii) any element or uncombined radical” (15 USC § 2601 et seq). However, “chemical substance” does not include, any mixture; any pesticide; tobacco or any tobacco product; any source material, special nuclear material, or byproduct material; any article, the sale of which is subject to the tax imposed by the Section 4181 of the Internal Revenue Code of 1954 or any other provision of such Code; and any food, food additive, drug, cosmetic, or device (15 USC § 2601 et seq). The regulation of chemicals under TSCA is based on the chemicals status as an existing substance or a new substance.

The TSCA defines an existing chemical substance as any chemical substance that is included in the chemical substance list compiled and published under Section 8(b) of TSCA, which includes those chemicals that were “grandfathered” in when TSCA was enacted (15 USC § 2601 et seq). Any individual who intends to manufacture or process a chemical published on this list does not need to notify EPA, so long as the use of the chemical does not constitute a significant new use. A determination by EPA that a use qualifies as a significant new use must be made by a rule promulgated after considering all relevant factors. The relevant factors include: (1) the projected volume or manufacturing and processing; (2) the extent the use changes the type or form of exposure of humans or the environment to a chemical substance; (3) the extent the use increases the magnitude and duration of exposure of humans and the environment to the chemical substance; and (4) the reasonably anticipated manner and methods of manufacture, processing, distribution, and disposal of a chemical substance. If a significant new use rule has been issued, any individual who wishes to manufacture or process for that use must submit a significant new use notice to EPA (40 CFR § 721.5).

The TSCA defines a “new chemical substance” as “. . . any chemical substance which is not included in the chemical substance list compiled and published under section 8(b)” of TSCA. Prior to manufacturing or importing, these new chemical substances are subject to specific notification requirements. However, exemptions to the notification requirements include, a showing that the substance will not present any unreasonable risk of injury to the health or the environment, or if the chemical is to be manufactured or processed only in small quantities. Any person who intends to manufacture or import a new chemical substance, which is neither exempt nor on the inventory list of existing chemicals, must submit a PMN to EPA at least 90 days prior to manufacturing.

Once EPA receives a PMN, it goes through a series of steps to make a determination of whether the substance may present an unreasonable risk to human health or the environment. The first step includes a review of the PMN to ensure that

all of the required information is included. If the PMN is complete, EPA convenes a meeting known as the Chemical Review and Search Strategy (CRSS), which focuses on confirming the identity of the notified substance, evaluating the industrial synthesis process to identify by-products or impurities, evaluate or estimate physicochemical properties, and to understand the intended function and use of the substance.

After the CRSS meeting, EPA's Structure-Activity Team (SAT) performs an initial assessment of the substance's potential human health and environmental hazards. The SAT members utilize any data submitted with the PMN substance, data from previously submitted substances that may serve as analogs for informing potential hazards of the substance under review, modeling, and expert judgment to make the initial hazard calls. Thereafter, an Exposure Analysis Meeting (EXAM) is held, where the nature and magnitude of occupational exposures, environmental releases, consumer and general population exposures, and environmental fate are assessed. As with the SAT meeting, the EXAM members utilize data submitted with the PMN substance, data from previously submitted substances, modeling, and expert judgment to inform these areas.

Once the members of CRSS, SAT, and EXAM have completed their initial review, an initial risk assessment/risk management meeting is held, which is called the Focus Meeting. During the Focus Meeting, the overall potential risk of the PMN substance is discussed and a determination is made that either no further review is needed or that the substance requires a more in-depth review in a process known as Standard Review. As part of the Standard Review, EPA's scientists develop recommendations on the potential hazards and exposures that may present an unreasonable risk. These recommendations are presented at a Disposition Meeting where a decision is made to require further testing on the PMN substance (e.g., production volume based triggers or a ban pending upfront testing) or potentially to prohibit the manufacture of the PMN substance.

Once a chemical is approved under the PMN process, it is added to the TSCA inventory and is then considered an existing chemical substance. Unlike EPA's authority to regulate new chemical substances, once a chemical is designated as an existing chemical substance, EPA's options for subsequent regulatory activity are limited. For example, under TSCA Section 4, EPA must make a statutory finding of "data insufficiency" and "testing is necessary" in order to require manufacturers, by rule, to perform hazard or exposure testing. Test rules are, however, time consuming and often take years to prepare and finalize, with the subsequent testing taking additional months or years to complete before EPA obtains the required data.

Under TSCA Section 6, if EPA finds a "reasonable basis to conclude" that the manufacture or importation of a chemical substance presents or will present an unreasonable risk of injury to health or the environment, EPA shall take one or

more of the following required actions: (1) prohibiting or limiting the amount of the chemical substance to be manufactured, processed, or distributed in commerce; (2) prohibiting or limiting the manufacture, processing, or distribution in commerce for a particular use or a particular use in excess of a level specified by EPA; (3) requiring that such substance be marked with or accompanied by clear warnings and instructions; (4) requires manufacturers and processors to make and retain records of the processes used to manufacture such substance; (5) prohibiting or otherwise regulating any manner or method of commercial use; (6) prohibiting or otherwise regulating any manner or method of disposal of such chemical; (7) directing manufacturers or processors to give notice of unreasonable risk of injury to distributors in commerce (15 USC § 2601 et seq). The EPA previously attempted to issue a TSCA Section 6 rule that would have effectively banned asbestos; however, on appeal, the Appellate Court overturned EPA's proposed rule for failing to consider a number of factors, including, for example, the benefits of asbestos, alternatives, and least burdensome measures (*Corrosion Proof Fittings v. EPA*, 1991).

The limitations on EPA's ability to regulate existing chemical substances have formed the basis for TSCA reform initiatives. Many proponents of TSCA reform favor the regulatory paradigm enforced in the EU under REACH. As discussed in the following section, REACH offers a clear advantage with regulating existing substances because it captures substances, which were grandfathered in under EU's previous chemical control law. However, it also has limitations, primarily of which, REACH does not require the submission of full study reports in support of regulatory dossiers. Rather, it requires the submission of robust data summaries, which lack the underlying "raw" data.

REACH

In December 2006, the EU enacted a new chemical control law known as the REACH (REACH, 2006). The REACH places the responsibility of assessing risks on companies that produce, import, and use chemicals, and it requires companies to take the necessary risk management measures when appropriate. In addition to regulating new chemicals (i.e., non-phase-in substances), REACH is unique in that it also requires retrospective safety evaluation of existing chemicals (i.e., phase-in substances). A phase-in system lasting up to 11 years is planned for the approximate 150,000 phase-in substances, which were pre-registered with the ECHA between June 1, 2007 and December 1, 2008 (ECHA, 2008a). Higher tonnage phase-in substances [$\geq 1,000$ tons per annum (t/a)], as well as lower tonnage phase-in substances that are very toxic to the aquatic environment (≥ 100 t/a) or classified as CMRs (i.e., carcinogens, mutagens, or reproductive toxicants; ≥ 1 t/a), must be registered

before December 1, 2010. All other phase-in substances manufactured or imported in quantities ≥ 100 t/a or ≥ 1 t/a must be registered by June 1, 2013, or June 1, 2018, respectively (REACH, 2006). Non-phase-in substances will be evaluated on an ongoing basis and must be registered before being manufactured or imported into the EU.

The REACH employs a tiered-testing approach, meaning that the data required are dependent on the tonnage manufactured or imported into the EU, so that a higher production volume means that more information is needed. A technical dossier is required for all registered chemicals; however, only chemicals with a production volume ≥ 10 t/a require a chemical safety assessment documented in a chemical safety report (REACH, 2006). A chemical safety report is a risk assessment, which must follow the general provisions of Annex I of REACH, as well as the ECHA's guidance for preparing a chemical safety report (ECHA, 2008b). No new toxicological information is required for substances between 1 and 10 t/a, unless they are considered a priority substance (e.g., CMR).

The REACH requires companies that produce or import the same substance to participate in a Substance Information Exchange Forum (REACH, 2006). Substance Information Exchange Fora are intended to facilitate data exchange, avoid duplication of studies, and reduce the number of studies on experimental animals. The basic data requirements for REACH are provided under Column 1 of the REACH Annexes, labeled "Standard Information Required," for substances produced or imported in quantities of ≥ 1 t/a (Annex VII), ≥ 10 t/a (Annex VIII), ≥ 100 t/a (Annex IX), and $\geq 1,000$ t/a (Annex X). Column 2 provides specific rules for interpretation of Column 1 for when a particular study may be omitted, replaced, or performed at a later stage. For each of these data requirements, Article 10 of REACH only requires the submission of robust data summaries, which as noted previously, may present issues with evaluating the underlying quality and reliability of the submitted information.

WORKER PROTECTION LAWS

US Occupational Safety and Health Administration (OSHA)

In the US, the OSHA Act of 1970 (29 USC § 651–678) was created as a result of Congress' findings that "... personal injuries and illnesses arising out of work situations impose a substantial burden upon, and are a hindrance to, interstate commerce . . ." In defining the duties of employers and employees, the OSHA Act requires employers to: (1) provide each employee with a place of employment free from recognized hazards that cause or are likely to cause death or serious physical harm; and (2) comply with occupational safety and health standards promulgated

under the OSHA Act. In turn, each employee is required to comply with the rules, regulations, and orders issued under the Act, which are applicable to the employee's own actions.

The Act also delegates broad authority to the Secretary of Labor (Secretary) to promulgate "standards to ensure safe and healthful working conditions for the Nation's workers." "... [O]ccupational safety and health standard . . ." is defined as a standard, which is "... reasonably necessary or appropriate to provide safe or healthful employment and places of employment" (Industrial Union Dept. v. American Petrol. Inst., 1980). In promulgating standards dealing with toxic materials or harmful physical agents, the Secretary shall, using the best available evidence and to the extent feasible, set standards, which most adequately assure that no employee's health or functional capacity will be materially impaired, even if employees have regular exposure to the hazard [29 USC § 655(b)(5)]. Development of standards shall be based upon research, experiments, demonstrations, and other information as appropriate. When developing standards, in addition to attaining the highest degree of health and safety protection for the employees, other considerations shall be the latest available scientific data in the field, the feasibility of the standards, and experience gained under this and other health and safety laws.

Pursuant to this granted authority, the Secretary has promulgated standards regulating the exposure limits to hazardous chemicals, known as permissible exposure limits (PELs) (29 CFR § 1910.1000). Permissible exposure limits limit the acceptable level of an employee's exposure to a particular substance. The levels for each substance are defined as an 8-h time-weighted average (29 CFR § 1910.1028), with some chemicals also having a ceiling concentration [29 CFR § 1910.1000(a)(1)] or short-term exposure limit, which are measured as an average over any 15-min period [29 CFR § 1910.1028(C)(2)].

Because PELs go through a time-consuming formal rule making process, many of the existing values may not represent the current state of the science for potential workplace hazards from chemicals. In addition, PELs do not exist for most chemicals in the workplace. Therefore, OSHA may recommend other non-binding values, such as the US National Institute for Occupational Safety and Health's (NIOSH's) recommended exposure limits or the American Conference of Governmental Industrial Hygienists' threshold limit values, as alternatives to PELs for ensuring protection of worker health (OSHA, 2014).

European Agency for Safety and Health at Work

In Europe, the European Agency for Safety and Health at Work was established by Council Regulation (EC) No 2062/94 with the aim of providing "... Community bodies, the Member States, the social partners and those involved in the

field with the technical, scientific and economic information of use in the field of safety and health at work" (EC, 1994). European Agency for Safety and Health at Work disseminates information, including occupational exposure limits (OELs), developed by the Scientific Committee on Occupational Exposure Limits (SCOEL). The SCOEL was given formal status in 1995 and consists of 21 members from all Member States, who are tasked with evaluating risks in the workplace and developing harmonized OELs (EC, 1995). Once the SCOEL develops a recommended OEL, the Advisory Committee on Health and Safety at Work makes a feasibility determination on the recommended OEL.

For chemical substances with a clear threshold for toxicological effects, indicative OELs are established, which Member States may adopt or establish a higher or lower OEL at the national level. In contrast, binding OELs must be implemented at the established level or at a lower national level by Member States (Schenk, 2009). Under REACH, manufacturers develop worker exposure limits known as derived no effect levels for specific chemical substances; Member States may use these values at the national level in lieu of indicative OELs or binding OELs when they are lower.

HAZARD COMMUNICATION

US Hazard Communication Standards (HCS)

In addition to developing PELs, OSHA initially promulgated a HCS on November 25, 1983 to further protect employees from workplace hazards (OSHA, 1983). This standard requires chemical manufacturers and importers to "assess the hazards of chemicals, which they produce or import[.]" Originally, all employers in the manufacturing division (Standard Industrial Classification codes 20 through 39) were required to provide information to their employees concerning hazardous chemicals by way of labels, material safety data sheets, training, and access to written records. However, in 1987 OSHA revised its HCS to cover all employers with employees exposed to hazardous chemicals in their workplaces; thus expanding the scope to non-manufacturing employers as well (OSHA, 1987).

In March, 2012, OSHA modified its HCS to conform to the United Nations' Globally Harmonized System of Classification and Labelling of Chemicals (GHS) (OSHA, 2012; UNECE, 2011). This modification was made to enhance the effectiveness of the HCS in ensuring that employees are apprised of the chemical hazards to which they may be exposed, and in reducing the incidence of chemical-related occupational illnesses and injuries. This update also intends to facilitate global harmonization of standards, and includes revised criteria for classification of chemical hazards; revised labeling provisions that include

requirements for use of standardized signal words, pictograms, hazard statements, and precautionary statements; a specified format for safety data sheets; and related revisions to definitions of terms used in the standard, and requirements for employee training on labels and safety data sheets.

The EPA also has a HCS, which it adopted from OSHA (EPA, 1989b). At that time, EPA did not adopt certain sections of OSHA's HCS because they either were covered in other sections of EPA rules or were not applicable. However, as a result of changes to OSHA's HCS and changes to NIOSH respirator requirements, it is likely that EPA will initiate rule making activities to make several changes to its significant new use rule regulations under 40 CFR (Code of Federal Regulations) subparts A, B, and C. The standard designations in the sections titled "Protection in the Workplace" (40 CFR § 721.63) and "Hazard Communication Program" (40 CFR § 721.72) were modeled on OSHA regulations that were in force at the time EPA's rule was issued in 1989.

EU HCS

In 2008, the European Commission adopted parts of GHS into its classification, labeling and packaging of substances and mixtures (CLP) regulation (EC, 2008). With the exception of transport, the CLP governs hazard communication within the supply and use sectors. Mandatory compliance began on December 1, 2010 for individual substances and will begin on June 1, 2015 for mixtures. As with OSHA's HCS, the CLP sets forth specific criteria for the classification and labeling of substances based on physicochemical properties and human health hazards. However, unlike OSHA's HCS, the CLP established classification categories for aquatic toxicity, which include information on environmental fate (e.g., degradability and bioaccumulation) for classifying chronic aquatic toxicity. As part of regulatory submissions under REACH, manufacturers must classify and label their substances according to the CLP requirements at the time of submission.

 Auranofin 124
 Aurum paradoxum 234
- Bagassosis 294, 971, 976–978
 Baker's asthma 970, 978–979
 Barite 57–58
 Baritosis 59, 62, 296, 298, 929, 931–932
 Barium 25, 57–62, 295–296, 364, 782, 931–932, 934, 950
 Barytes 57, 59
 Bastnasite 200
 Bauxite 36, 68, 115
 Beer drinker cardiomyopathy 103
 Benzene 10, 47, 262, 341, 358, 450, 492, 494, 497, 501, 509, 511, 514, 520–521, 523, 525, 533, 560, 568–569, 581–593, 595–596, 599–601, 603, 605–607, 611, 616, 626, 629, 633–635, 637, 648, 663, 669–670, 672–675, 770–771, 835, 901, 912, 1133, 1137, 1157, 1216, 1234, 1238–1239, 1243, 1271, 1306, 1328
 Benzin 669–670, 672, 674, 676
 Benzo(a)anthracene 605
 Benzo(a,h)anthracene 607
 Benzodiazepines 923, 1269, 1271–1272, 1274, 1313, 1316
 Benzo(a)pyrene (BaP) 605
 Bertrandite 63–64, 67–68, 71
 Beryl 63–65, 67–68, 70–71
 Beryllium 6–7, 10–11, 23, 62–65, 67–71, 110, 200, 285–286, 290, 292, 295–298, 300, 1157
 Beryllium hydroxide 63, 68
 Beryllium sensitization 68, 70–71
 Bioavailability 35, 37, 58, 62, 68, 86, 96, 164, 175–177, 180–181, 194, 241, 259, 266, 271, 285, 767, 870, 918, 923, 1204, 1210, 1280, 1301, 1305
 Biomonitoring 50, 54, 105, 118, 170, 321, 440, 450, 459, 475, 481, 585–586, 591, 598–599, 603, 624, 693, 695–696, 703–704, 706, 709, 716, 765, 768, 770, 772, 774, 777, 780, 788, 908, 913, 1178, 1187, 1238, 1286, 1289, 1292
 Bird breeder's disease 981
 Bird handlers disease 971
 Bis-chloromethyl ether 494–495
 Bismuth salts 74–75
 Bisphenol A 538–539, 760, 775–776, 795–796, 798, 800, 802–807, 828, 835, 1199, 1216, 1221, 1223, 1225, 1227, 1321, 1330
 Blackfoot disease 48–49, 52
- Blood pressure 46, 48, 59–60, 133–134, 137–140, 209, 250, 268–269, 273, 305, 318, 321–322, 357, 363, 536, 674, 912, 1115, 1125, 1211, 1295
 Borate dust 80
 Borax 79–83, 1203, 1224
 Boric acid 79–83, 946, 961, 1203, 1221, 1223–1224
 Boron 79–83, 180, 239, 290, 782, 1203, 1224
 Bovine corneal opacity and permeability (BCOP) 1256
 BPA 760, 775–776, 795–807, 1199, 1210, 1216, 1227
 Brain cancer 634, 744, 1034, 1038, 1064, 1079, 1081, 1083
 1-Bromopropane 677–682, 1202, 1210, 1222, 1227
 Bronchiolitis obliterans 368–369, 683, 686–687, 980
 Buehler test 1249, 1251–1252
 1,3-Butadiene 500, 588, 769–771, 786–787, 1157, 1195–1196, 1210, 1221, 1226, 1302
 Butane 408–409, 698, 719
 Butylbenzyl phthalate 816, 819
 γ-Butyrolactone 723, 1275
 Byssinosis 970, 982–985
- Cacodylic acid 49, 51, 56
 Cadmium 6, 11, 21, 23, 55, 76, 85–94, 113, 138, 142, 151, 182, 207, 231–232, 239, 244, 275, 277, 279–280, 290–293, 295–299, 782, 901, 950, 1026, 1047, 1157, 1195–1196, 1204–1205, 1210–1211, 1219–1227
 Cannabinoids 1276–1278
 Caprolactam 477, 774–775
 Carbamate insecticides 859–861, 871
 Carbofuran 861–862, 875
 Carbon bisulfide 317
 Carbon dioxide 25, 29, 51, 174, 305–309, 313, 328, 358, 369, 371–372, 376, 404, 424, 426, 432, 512, 514, 517, 520, 533–534, 557, 581, 694, 715, 719, 763, 809–810, 949, 1047, 1279, 1301, 1307, 1316–1317
 Carbon disulfide 317–323, 468, 478, 525, 792–793, 901, 1116, 1243
 Carbon monoxide 3, 127, 174, 309–315, 326, 334, 336–338, 345, 357, 366, 372–373, 423, 534, 556–557, 643, 651, 670, 694, 715, 719, 762, 949, 977, 1116, 1242, 1301, 1307, 1313, 1315, 1317
 Carbonic acid gas 305
 Carbonic anhydride 305
 Carbonic oxide 305, 310, 361
 Carboxyethyl germanium sesquioxide 120
 Carboxyhemoglobin 3, 313, 336, 555–558, 1305
 Carcinoma 49, 55, 92, 97, 103–104, 221, 413–417, 458, 460, 463, 502, 570, 607, 622, 630, 639, 653, 659–660, 680, 697, 723, 745–746, 777, 779, 833–834, 836, 842, 929, 937, 972, 993, 995, 1000, 1018, 1047, 1056, 1116, 1137, 1142, 1145, 1149, 1161–1164, 1166–1168, 1285, 1290, 1293
 Cassiterite 247
 Catalyst 33, 46, 74, 97, 101, 110, 142, 150, 159, 173, 183, 188, 190, 193, 195–197, 199–200, 206, 229–230, 240,

- 257–258, 262, 270, 345, 385, 497, 500, 543, 569, 761–762, 779, 781, 785, 787, 1008, 1296
- Catalytic converter 188, 194, 197
- Causation 4, 7–8, 10–11, 117, 578, 994, 1053, 1133, 1265
- Caustic 25–26, 28–30, 47, 278, 320, 333, 1313
- Cell phone 1034, 1075, 1081, 1083, 1201
- Cellular response 99
- Cellulose acetate 509, 511, 773, 791, 960
- Cement 25, 29–31, 57, 98–99, 101, 112, 277–278, 297, 660, 722, 724, 767, 785, 935–937, 940–941, 954, 957–958, 961, 998, 1007
- Cement copper 112
- Centers for Disease Control and Prevention (CDC) 667, 738, 1250
- Centrilobular hypertension 653–654, 832–833
- Ceramic fibers 285, 930, 959–964, 966–967, 1157
- Cerium 21, 186, 199–204
- Chemical burns 26, 28, 31, 284, 329, 345, 354, 396, 422, 460, 522, 528, 705, 713, 1313–1314
- Chemical intermediate 33, 317, 358, 421, 435, 453, 458, 465, 467, 474, 477, 497, 500, 520, 526, 541, 553, 562, 657, 660, 1296
- Cheyne-Stokes respirations 318
- Chlordecone 866–867, 873, 1199
- Chloromethyl methyl ether 494–496, 1157
- Chloroprene 786–787, 1157
- Chlorpyrifos 861–864, 873–876
- Chromate 46, 96–99, 277–278, 290
- Chromic acid 95, 97
- Chromite 96–97
- Chromium 21, 23, 54, 56, 64, 95–99, 102, 104, 106–107, 174, 180–182, 200, 204, 231, 257, 262, 275, 283, 285, 289, 292–293, 296–297, 299, 950, 1017, 1157, 1217
- Chronic beryllium disease 65, 70–71, 295
- Chronic progressive nephropathy 653, 655, 723
- Chrysene 605, 607, 1151
- Chrysotile 935–937, 940–941, 946, 964, 998–1008, 1011–1012, 1018, 1159, 1168
- Cirrhosis 49, 55, 111–112, 210, 280, 469, 544, 1158
- Cisplatin 23, 195–197, 1157, 1243, 1245
- Clays 51, 83, 942, 955–956
- Clothianidrin 871–872
- CN 110, 331–333, 522, 746
- CO poisoning 311, 313, 555
- Coal 37, 46, 51, 58, 68, 70, 82, 87, 206, 208, 229, 233, 243, 260, 264, 267, 270–271, 273–274, 279, 295–297, 305, 310, 325, 331, 364, 383, 393, 398, 404–405, 458, 461–462, 592, 594, 605–608, 663, 665, 667, 929–930, 944–945, 949–954, 956, 1015, 1059, 1136, 1150, 1157–1158, 1218, 1247, 1305–1307, 1310
- Cobalt 21, 23, 101–107, 110, 118, 174, 182, 193, 200, 231, 258–260, 274, 285, 289–290, 292–293, 295–297, 300, 336, 338, 762–763, 792, 1157, 1274
- Cocaine 240, 1271–1275, 1278–1279
- Coffee workers disease 985
- Confidence interval 9, 213, 378, 1019, 1034, 1064, 1079
- Contact dermatitis 29–30, 33, 37, 97, 102, 104–106, 116–117, 173, 175, 177, 180, 182, 185, 190–191, 232, 275, 285, 352–353, 413–415, 428, 431, 433, 446, 449, 451–452, 460–463, 467–468, 470, 472–473, 478, 485, 490, 522–523, 534, 536–537, 539–540, 547, 549, 604, 738–739, 751, 759–763, 767–768, 774–775, 783, 785–787, 789–790, 792–793, 869, 880, 898–899, 902, 904–911, 962, 966–967, 976, 1026, 1248–1250, 1253, 1316
- Control banding (CB) 16
- Controlled environment 1036, 1038, 1082, 1265
- Controlling exposures 15–17
- Copper 21–23, 36, 46, 48–51, 54–55, 63–65, 68, 71, 73, 80, 83, 85, 89, 93, 97, 101, 103, 109–114, 132, 142, 150, 160, 167–169, 174, 176–178, 180, 182, 188, 193, 206–207, 221, 223, 225, 229, 233, 247, 249, 274, 277–282, 289–290, 293, 295, 298–299, 334, 366, 383, 543, 584, 739, 779, 792, 901, 904, 1047, 1096, 1123, 1218, 1298
- Copper fume 109, 111, 113
- Cresol 507, 591–595, 598–600, 761
- Critical effect 327, 818
- Crocidolite 935–936, 938, 998–999, 1001–1002, 1004, 1009, 1011–1013, 1159, 1164, 1167–1168, 1170
- Cupric 109–111, 455
- Cuproenzymes 109
- Cutting oils 412–416
- Cyanide 5, 48, 54, 110, 112, 124, 229, 231, 278, 328–329, 331–339, 453, 741–742, 746–747, 749, 754, 763, 775, 1242, 1245, 1318
- Cyanogen 332, 334–335, 338
- Cyanosis 47, 59, 202, 236, 306, 336–337, 373, 434, 443, 526, 528, 572, 611, 617–618, 620, 623, 627, 632, 635, 663, 672, 747, 860, 890, 947, 987, 989
- Cyhalothrin 868–869
- Cytotoxicity 5, 186, 204, 251, 254, 259, 284, 286, 457, 546, 552, 561, 563, 568, 570, 602, 604, 606, 664–665, 699, 723–725, 885, 892, 903–904, 907, 909, 935, 951, 964, 966, 1012–1013, 1020, 1022, 1131–1133, 1154, 1156, 1165, 1171, 1177, 1211, 1255
- 2,4-D 887–889, 896–897
- DDT 92, 865–867, 873–875, 1199, 1212, 1226
- Decabromodiphenyl ethane 821–825
- Detergent workers disease 987
- Diacetyl 683–687
- Dibutyl phthalate 782, 816
- Dichlobenil 892–894
- Diieldrin 865–867, 873, 875, 1199
- Diesel emissions 202, 1307–1310
- Diesel exhaust 306, 308, 457, 1157–1158, 1301–1310
- Diethylhexyl phthalate 816, 1204, 1227, 1235

- Diisobutyl phthalate 537, 816, 819
 Diisononyl phthalate 538, 816, 819
 Dimethylarsinic acid 47
 Dioxane 500–503, 525, 725, 1157
 Dioxin 575, 712, 858, 887–889, 1157, 1216, 1221–1222, 1226–1227
 Dipentyl phthalate 816, 819
 Diquat 883–885
 Dopamine receptor 834
 Draize testing 1251, 1254
 Dry ice 305–307
 Durability 96, 791–792, 929–930, 937–938, 961, 963–964, 966–967, 1159, 1301
 Dysprosium 200, 202
- Elastomers 255, 719, 766, 769, 782, 785–788, 790–791, 845, 946
 Electric 83, 129, 179, 188, 199–201, 229, 250, 252, 271, 374, 587, 897, 934–935, 946, 956, 1031–1032, 1035–1036, 1039–1041, 1057, 1059–1060, 1069–1078, 1083–1085, 1118
 Electrodiagnostic studies 1092, 1097
 Electroplating 30, 89, 96–98, 110, 124, 173, 188, 278, 297, 331, 333, 345, 955, 1204
 Elemental carbon 1303–1304, 1306–1307
 Emissions 35, 43, 55, 63, 86–87, 91, 94, 136, 150, 188–189, 191–192, 194, 196, 202, 243, 259, 270, 272, 274, 306–307, 309–310, 312, 315, 328, 331, 338, 364–365, 388, 405, 424, 457, 500, 542, 598, 607, 636, 644, 651, 666, 670, 686, 704, 730, 747, 751–754, 764, 817, 1034–1035, 1042, 1054, 1057, 1069, 1077, 1157, 1204, 1209, 1215, 1218, 1296, 1301–1304, 1306–1310
 Endocrine 139, 144, 160, 210, 214, 249–250, 252, 319, 333, 539, 574, 577, 592, 645, 649, 700, 705, 735, 795, 797, 799–800, 803–804, 806–807, 819, 835, 867, 878–879, 895, 1090, 1155, 1189, 1194–1196, 1198–1199, 1204–1205, 1208–1209, 1212, 1216, 1220–1223, 1225–1226, 1235
 Endocrine disruptor 806, 835, 895
 Engineering and administrative controls 170, 945, 1052, 1119, 1307
 EpiOcular 1257–1258
 Epoxy resins 294, 547–548, 550, 760–761, 775, 795–796, 798, 800, 962, 1210, 1216
 Erbium 200, 202, 204, 1047
 Ergonomics 1087, 1095–1097, 1112

 Oxocarbon 310
 Oxygenate 618, 643, 651, 670
 Ozone 240, 364, 366, 371–372, 374–382, 388, 398, 451, 508, 521, 543, 553–554, 567, 573, 643, 651, 677, 681, 785–786, 868, 1046, 1052–1053, 1201, 1223, 1302
- Painting 43, 97, 136, 409, 476, 480, 518, 598, 641, 931, 1137, 1151, 1233
 Palladium 21, 187–193, 292–293, 298, 455
 Paraquat 875, 881–885
 Parkinsonism 152, 339, 412, 885
 Particle deposition 929
 Particulate matter 80, 150, 174–175, 189, 192, 264, 271–272, 276, 377, 381, 395, 828, 942, 946, 954, 1301–1303
 Peripheral neuropathy 48, 54–55, 117, 242, 480–482, 488, 554, 597, 768, 779–780, 865, 1092, 1219
 Permethrin 867–869
 Peroxisome proliferator-activated receptors 578, 654
 Personal protective equipment (PPE) 17, 153, 325, 360, 367, 373, 730, 940, 1124, 1298
 Petrol 417, 669–670, 672, 674–676, 1326, 1329
 Petroleum products 173, 188, 271, 371, 410, 465, 593, 605, 1025
 Phenol 366, 448, 451–452, 505, 533, 581, 583–586, 588–596, 598, 601, 611–612, 673, 761–762, 835, 962
 Phosgene 357–362, 436, 520, 529, 546, 558–560, 563, 764, 775
 Phosphine 384, 387–389, 915–916, 1295–1300
 Phosphorus 38, 88, 92, 265, 279, 383–389, 412, 533, 535, 792, 837, 841, 845, 857, 874, 924–925, 1296, 1298–1300
 Phosphorus anhydride 384, 386–387
 Phosphorus oxychloride 384, 386, 533
 Phosphorus pentachloride 384–386, 389
 Phosphorus pentasulfide 384, 386
 Phosphorus trichloride 384–385
 Picloram 896–897
 Plasticizer 530, 533, 782–783, 800, 1199, 1225, 1238
 Platinum salt sensitivity 194, 196
 Pleural plaque 1011
 Pneumoconiosis 40, 42–43, 59, 61–62, 103, 107, 128, 130, 168, 170, 178, 201–202, 204, 249, 252, 267, 279, 295–296, 298–299, 776, 778, 929, 931–934, 937, 943, 947–948, 950–957, 999–1000, 1015–1016, 1019, 1022
 Polyamides 760, 774, 792
 Polyaromatic hydrocarbons 605
 Polycyclic organic matter 605
 Polydimethylsiloxane 766–767
- Polyester resins 386, 763, 782
 Polyethylene terephthalate 762
 Polyethylenes 785
 Polyisobutylene 787
 Polyisoprene 787
 Polynuclear aromatics 605
 Polystyrene 551, 758, 761, 763, 767–768, 770, 809–812, 821, 827
 Polysulfide elastomers 788
 Polytetrafluoroethylene 204, 545, 773–774
 Polyurethane 294, 358, 497–498, 616, 719, 760, 763, 765–766, 789, 792, 796, 845, 960
 Polyvinyl chloride 345, 347, 386, 450, 758, 776, 778, 796, 816, 1218, 1223, 1225, 1318
 Polyvinylpyrrolidone 781
 Popcorn 455, 468, 683–687
 Power-line EMF 1069, 1072–1073, 1075, 1080–1081
 PPAR- α 578, 1189, 1192–1193, 1195
 Praseodymium 199, 201, 204
 Prevention through design 16–18
 Promethium 199–201
 Propane 42, 310, 406–407, 409, 473, 476, 640, 805, 1157
 Propanil 890–892
n-Propyl bromide 678, 681–682
 Prussian blue 239, 241–242, 245, 353
 Pulmonary irritant 80, 254, 1259–1260
 Pyrene 456, 467, 469, 593, 595, 605, 607–611, 898–899, 951, 1157–1158, 1160, 1162–1163, 1168
 Pyrethrin 867–869
 Pyrethrioids 867–869
- Radiofrequency 1039–1043, 1045, 1069, 1077, 1079, 1081–1085
 Radio-frequency radiation 1031–1032, 1034, 1036, 1038, 1040, 1042, 1085
 Rare earth 199–204
 Raynaud's disease 1110
 Rayon 317–323, 326, 397, 752, 791–793, 960
 Reactive airways dysfunction syndrome 975, 1259–1261
 Reactive oxygen species 49, 97, 104, 106, 135, 138, 164, 177, 243, 259, 373, 376, 454, 595, 665–666, 697, 702, 704, 708, 717, 938, 944, 951, 964, 967, 1013, 1025, 1150, 1152, 1177, 1243–1245
 Recommended exposure limit 41, 52, 113, 129, 173, 178, 185, 219, 231, 243, 247, 313, 321, 325, 341, 343, 367, 384–385, 394, 420, 493, 505, 542, 666, 681, 686, 737, 748, 764, 932, 952, 1298
 5 α -Reductase 646, 1192–1193
 Reference dose (RfD) 16, 41, 52, 90, 105, 114, 137, 153, 164, 173, 219, 341, 385, 420, 596, 661, 670, 721, 729, 735, 816
 Refrigerants 341, 407–408
 Reinforced plastics 760, 763, 772–773, 791, 793, 810–811, 813, 962, 967

- Renal toxicity 94, 142, 165, 273, 319, 322, 434, 546, 597, 603, 649, 674–675, 694, 716, 728, 737, 739, 783, 944, 1132, 1243
- Reproductive toxicant 236, 634, 798, 896, 1200, 1203
- Reproductive toxicity 60, 81, 103, 242, 394, 441, 517, 528, 597, 630–631, 648, 680, 694–695, 716, 735, 744, 752, 797, 802–805, 807, 824, 864, 878, 1198, 1202–1204, 1206–1207, 1209, 1211–1212, 1217, 1219–1225, 1227
- Resin 43, 446, 452, 474, 477–478, 507, 547–549, 590, 639, 748, 758–764, 770, 773–776, 789–790, 796, 802, 809, 821, 835, 845, 961, 966, 1005, 1277
- Resonant vibration frequencies 1100
- Respiratory damage 168, 175
- Respiratory disease 27, 36, 48, 71, 103, 128, 299, 342, 344, 497, 510, 685, 760, 930, 934, 943, 958, 973–974, 976, 978, 984, 994, 1007, 1016, 1019, 1022, 1259, 1266
- Respiratory toxicity 107, 114, 639, 664, 668, 687, 725
- Retinal toxicity 425
- Rhodium 21, 187–193
- Rock wool 959, 961–962, 965–966
- Rodent tumors 712, 1195
- Rodenticide 62, 277–278, 636, 915–917, 919–920, 922–925, 1249, 1295, 1298
- Rotenone 869–870, 874–875
- Ruthenium 187–188, 190–193
- Samarium 200–204
- Scandium 199–202, 204
- Sedation 554, 720, 722, 1276, 1279
- Semiconductor 39, 41, 43, 46, 116, 119, 204, 233, 297, 386, 439, 543, 1047, 1202, 1210, 1222, 1225
- Shaver's disease 36
- Significance level 9
- Silica 59, 128, 249–251, 255, 286, 295–296, 371, 782, 790, 929–932, 936, 941–949, 951–957, 959–962, 964, 967, 1001, 1008–1009, 1015, 1017, 1019, 1023, 1026, 1157, 1164, 1313
- Silicosis 36, 59, 62, 128, 249, 251, 296, 937, 941–945, 949, 952–957, 978, 1019, 1167
- Silver 21–22, 40, 43, 45, 47, 57, 73, 82, 86, 114, 131–132, 137, 142, 158, 160, 178, 201–202, 229–233, 248, 290, 331, 334, 385, 388, 494, 497, 534, 588, 591, 931–932, 1026, 1136, 1212, 1227
- Silver nitrate 229–231
- Simazine 879–881, 890, 892
- Skin irritation 74, 143–144, 178, 233, 235, 267–268, 410, 419, 431, 436, 438, 457, 460, 464, 466, 470, 477, 511, 514, 523, 534, 582, 612–613, 621, 658, 663, 677, 692, 705, 713, 730, 734, 741, 743, 782, 785, 795, 809, 878, 918, 921, 933, 942, 962, 974, 1082, 1247–1248, 1250–1252, 1254
- Skin prick 189–190, 194–197, 975, 979, 988, 1265
- Skin sensitization 102, 173, 194, 235, 293, 470, 534, 786, 798, 986, 1248–1250, 1254, 1322
- Slag wool 959–962, 964–965
- Slate 221–222, 229, 942, 946, 957, 1012
- Smart meter 1035
- Sodium hydroxide 25–26, 29–31, 387, 792, 1275
- Soluble molybdenum 168–170
- Soyuz 367, 1316–1317, 1319
- Space station 1316–1317
- Spandex 789, 792–793, 960
- Species concordance analysis 1133
- Specific absorption rate 1031, 1039, 1077
- S-phenylmercapturic acid (SPMA) 581
- Spore 989, 1283
- Stannosis 59, 249, 252, 296, 299, 929, 932, 934
- Steroidogenesis 539, 716–717, 818–819, 1190–1191, 1195–1196, 1219
- Steroids 105, 293, 368, 540, 704, 973, 984, 1053, 1190, 1211, 1261, 1265, 1267, 1270–1271, 1314
- Stibine 40–42, 116
- Strategies for controlling exposures 17
- Styrene 273, 461, 667, 742, 760, 762–763, 769–773, 787, 789, 792, 809–813, 827, 1116, 1157, 1242–1243, 1291
- Styrene-butadiene rubber 789
- Sulfidic nickel 174, 176
- Sulfur 48, 109, 132, 145, 169, 206–207, 217–218, 262, 278, 284, 325–326, 328, 334, 336, 348, 384, 386, 391–398, 412, 414, 450, 455, 460, 462, 491, 526, 581, 629, 668, 683, 689, 694, 702, 785–786, 789, 933, 950, 1158, 1260, 1301, 1307, 1309
- Sulfur compounds 169, 391–392, 394–398, 491, 950
- Sulfur dioxide 145, 207, 262, 328, 348, 386, 391–396, 398, 450, 581, 683, 785, 1307
- Sulfuric acid 142, 174, 262, 275, 320, 328, 334, 347–348, 353, 391–393, 395–397, 468, 491–492, 505, 511, 523, 525–527, 657, 767, 791, 1157
- Surveillance 70, 181, 196, 227, 295, 298, 314, 344, 351, 455, 472, 478, 496, 499, 502, 686, 701, 704, 712, 714, 751, 793, 798, 975–977, 979, 984, 988, 1007, 1034, 1042, 1089, 1091, 1093–1094, 1096, 1135, 1169, 1244, 1292, 1318
- Synthetic fibers 791–792, 966–967
- 2,4,5-T 858, 887–889, 898
- Talc 782, 938, 945–948, 1016–1023, 1081, 1126, 1305
- Telloy 234
- Tellurium 206, 233–237
- Tellurium dioxide 233, 235–237
- Terbium 200, 202–203
- Tert-butyl alcohol 518, 643, 646, 654, 657–662
- Thallium band 242
- Thallotoxicosis 242, 245
- THF 424, 719–724
- Thiamethoxam 871–875
- Thulium 200, 203

- Tin 21–22, 39, 47, 55, 73, 110, 116–119, 233, 247–252, 257, 277, 283, 290, 296, 299–300, 345, 929, 932, 934, 1193
- Tinnitus 144, 306, 995, 1115, 1241
- Titanium dioxide 253–256, 792, 948, 1016, 1022, 1026, 1075, 1081, 1305
- Toluene 10, 358, 366, 411, 459, 476, 483, 485, 583, 585, 587–589, 592, 594–601, 603, 632, 648, 667, 670, 672–674, 763–766, 789, 1090, 1097, 1116, 1157, 1215, 1225, 1227, 1233–1234, 1236–1239, 1242–1243, 1245
- Toluene abusers 596–599
- Toluene diisocyanate 763–766, 789
- Traditional diesel exhaust 1302, 1304
- Transverse carpal ligament 1092–1093
- Triaxial vibration measurements 1100
- Tributyltin 248–249, 251
- Triethyltin 249
- Trimethyltin 249
- Tris[2-chloro-1-(chloromethyl)ethyl] phosphate 837–838, 840, 842–843, 848
- Tris(2-chloro-1-methylethyl) phosphate 845–846, 848, 850, 852–853
- TSCA 57, 73, 77, 171, 637, 648, 1249, 1322, 1324–1325, 1328
- Turpentine 341, 612–614
- Ultrafine 101–102, 104, 106–107, 254–256, 299, 306, 793, 1027, 1302
- Ultraviolet radiation 1045–1047, 1049, 1053–1054, 1152, 1157
- Uncertainty factor (UF) 219
- Uncertainty/variability factors 9
- United States Environmental Protection Agency (USEPA) 309, 315, 463, 485, 489, 508, 527, 539, 600, 696, 704, 707
- Urea-formaldehyde resins 759
- Vibration 530, 779–780, 1088, 1090, 1097, 1099–1113, 1116–1117
- Vinyl chloride monomer 776, 778, 1224
- Vinyl cyanide 741
- Visible light 1045–1046, 1048, 1050–1052, 1054, 1056, 1071, 1077
- VOC 375–376, 409, 412, 643, 742, 754
- Water-soluble nickel 174–177, 179
- Weight-of-evidence 665, 799, 805, 833, 1258
- Weight of evidence approach 806, 1245, 1255
- Welding 33, 35–36, 60, 62–63, 76, 96–97, 99, 129, 145, 154–155, 169, 173, 177, 180, 230, 255, 267, 280–281, 289–291, 293, 295–299, 312, 314, 345, 367, 371, 380, 387, 931–932, 934, 943, 1041, 1046–1048, 1050–1053, 1264
- White phosphorus 383–385, 388, 1299
- Witherite 57–58
- Wood dusts 969–973, 994–995, 1264
- Xenotime 200
- Ytterbium 200–204, 1047
- Yttrium 185, 199–204
- Zeolite 1009–1015
- Zinc 6, 21–22, 36, 41, 73, 85, 88–89, 93–94, 107, 110, 115, 132, 135–136, 151, 158, 160, 180, 182, 221, 225, 244, 249, 277–282, 289–296, 298–300, 387–388, 424, 551, 585, 789, 792, 904–906, 915–916, 961, 1026, 1096, 1206, 1219, 1238, 1295, 1297–1299
- Zinc oxide 22, 277–278, 280–282, 289, 291, 296, 299–300
