Immunoglobulin (Ig) E or G antibodies have not been identified as being present in some conditions (i.e.,

occupational asthma and contact dermatitis) associated with formaldehyde exposure (Kramps et al., 1989; Grammer et al., 1990; Liddn et al., 1993). This indicates that the signs and symptoms associated with these conditions may not be immunologically mediated but that they occur through an irritation mechanism. The occurrence of membranous nephropathy is hypothesized to be induced by formaldehyde in genetically susceptible persons with a common amino acid sequence, but clear evidence for this mechanism is unavailable (Breysse et al., 1994).

SOURCES OF EXPOSURE

Occupational

Formaldehyde has a variety of uses in the occupational setting. It is a constituent of many formaldehyde-based resins which may be used in particle board, furniture, plastics, rubbers, and other textiles. Formaldehyde is also used as an intermediate in the synthesis of other chemicals and in dyes, animal feeds, and a wide range of commercial products, such as perfumes and vitamins. The funeral, veterinary, and medical industries use formaldehyde as a disinfectant and preservative of biological tissues. Studies have even shown concentrations of formaldehyde as a pyrolysis product in grill kitchens (Vainiotalo and Matveinen, 1993).

Environmental

Environmentally, this compound is found in combustible engine exhaust and cigarette smoke and as a natural product of photooxidation. An emerging environmental source of formaldehyde exposure is through the use of electronic cigarettes. Electronic cigarettes have become mainstream as an alternative to tobacco cigarettes. Researchers are investigating whether or not exposure to formaldehyde is possible from this route. While formaldehyde was detected in one chamber study, it was below established exposure limits. In addition, researchers were unable to determine if the formaldehyde was the result of endogenous production by the participant or that of the electronic cigarette itself (Burstyn, 2014). In order to make a more concrete determination of a link between formaldehyde exposure and electronic cigarettes, more investigation is needed.

INDUSTRIAL HYGIENE

Humans are exposed to formaldehyde every day since it is part of our environment and bodies. Occupational exposure to excessive amounts of formaldehyde can occur. Formaldehyde is mainly encountered in the workplace as a gas, making inhalation the primary route of exposure. Some compounds,

such as carbamide formaldehyde resins and bromonitropropanediol, are known to release gaseous formaldehyde during decomposition. Inhalation exposure to dusts-containing formaldehyde is also an occupational hazard. In settings where the formalin solution is used, dermal contact with the liquid becomes a concern as well. Production of industrial formaldehyde is accomplished by the catalytic oxidation of methanol, through a variety of techniques. The Occupational Safety and Health Administration (OSHA) requires a permissible exposure limit (PEL) of 0.75 ppm with a short-term exposure limit (STEL) of 2 ppm. A concentration of 0.5 ppm calculated as an 8 h time-weighted average (TWA) has been established by OSHA as the action limit in which increased monitoring should be initiated to prevent unnecessary exposure. The National Institute for Occupational Safety and Health (NIOSH) recommends an exposure limit (REL) of 0.016 ppm and a 15-min ceiling of 0.1 ppm. The American Conference of Governmental Industrial Hygienists (ACGIH) recommends a 0.3 ppm threshold limit value (TLV).

Adequate ventilation and personal respirators are recommended for mitigating inhalation exposures in the occupational environment. Protective clothing, such as aprons, face shields, and gloves, are recommended to prevent dermal contact of formalin. Since each workplace can vary, different control measures will be needed to prevent excessive formaldehyde exposure. Workers in the funeral industry can be exposed to both the gas and liquid form of the chemical. Recommendations for embalmers include all forms of protective equipment. A survey of local exhaust ventilation systems in funeral parlors demonstrated some formaldehyde concentrations exceeding recommended guidelines (Korczynski, 1994). In a gross pathology setting, protective devices, especially respirators, may hinder vision and perspective and therefore may not be a reasonable solution (Akbar-Khanzadeh et al., 1994). Elimination of formaldehyde by substitution with glutaraldehyde or non-aldehyde-containing Kryofix may interfere with embalming techniques. New engineering controls for ventilation, such as a slot hood design with down-draft ventilation or the presence of motors, which cause a down flow of formaldehyde vapors into carbon filtration systems, have been examined and shown to be more effective than air circulation and more cost efficient as well (Gressel and Hughes, 1992; Coleman, 1995). Recent research has focused on hair stylists' exposure to formaldehyde. During a study that simulated use, a popular hair straightening product containing methylene glycol, a hydrated form of formaldehyde, was found to increase formaldehyde levels in the breathing zone above the OSHA 15 min TWA, the NIOSH ceiling limit, and the ACGIH TLV (Stewart et al., 2013). Continued exposure at these levels may require the institution of engineering controls, administrative controls, and/or personal protective equipment.

Protective gloves are necessary to prevent formalin from reaching the surface of the skin. Before selecting protective gloves, it is important to ensure that their construction

material can withstand contact with formalin. Schwope et al. (1988) tested a variety of glove materials for permeability to formaldehyde and reported that neoprene-based gloves are more resistant than natural latex, polyvinyl chloride, and polyethylene gloves without compromising tactility or dexterity.

Air monitoring in the workplace for formaldehyde can be accomplished by the recommended NIOSH 3500 pump and impinger method. Alternative tests may be available, such as a passive bubbler technique that has been shown to meet OSHA +25% accuracy requirements (Kollman, 1994). Personal air monitors may be more effective for measuring actual worker hazards. A study by Nobles et al. (1993) reported that only one of four monitors tested for short-term and TWA sampling was consistent with OSHA performance criteria and the newly revised ACGIH 0.3 ppm ceiling. Chemosorption sampling of formaldehyde in air was found to be reliable for monitoring occupational settings without being compromised by interference from other aldehydes and related compounds (Andersson et al., 1981). Current technology has led to the development of portable new sensors capable of detecting formaldehyde without interferences from other chemical compounds. A handheld formaldehyde detection device has been developed to analyze indoor environments for contamination. The limit of detection for the device was 0.04 ppm during a sampling time of 3 min with no interference from other aldehydes and/or volatile organic compounds (Kawamura et al., 2005). Cataluminescence-based gas sensors have also been developed for online monitoring of formaldehyde in air with satisfactory stability. No interferences from ammonia, ethanol, benzene, carbon monoxide, and sulfur dioxide were found (Zhou et al., 2006).

MEDICAL MANAGEMENT

For accidental formaldehyde exposures, removal from exposure is the primary treatment. Countermeasures should be taken if symptoms and signs emerge.

Species differences in the mechanisms of formaldehyde-induced adverse health effects and in exposure estimates make the risk assessment process for carcinogenicity a daunting task. Animal studies in rodents and nonhuman primates yield conflicting results with respect to observed adverse health effects. Inconsistencies of this nature make the extrapolation of animal data to human responses unreliable. For carcinogenicity, the rates of DNA binding and cell proliferation are both possible predictors of cancer and are important parameters to consider for estimating risk (Heck et al., 1990). Animal studies found lower cancer risks associated with primate exposure when compared with rodent exposure.

An additional uncertainty in formaldehyde risk assessments revolves around the quantification of exposure in

epidemiologic evaluations. It is important for researchers to consider varying exposure estimates in the occupational environment, where they can be relatively low. Low dose chronic health hazards must continue to be investigated. Very low dose cancer risks are not readily measurable. Evans et al. (1994) described a probabilistic approach that takes into account the uncertainty of carcinogenic action for the compound, as well as the low dose confounder. The authors find that their calculated occupational risk estimates are somewhat lower than the Environmental Protection Agency's estimates for excess cancer risks associated with formaldehyde exposure in the environment. Blair and Stewart (1992) examined exposure misclassification in population-based formaldehyde studies and concluded that analyses should be conducted using several exposure measures, while including data such as duration by intensity to avoid exposure misclassification. Whether positive or negative, these methods would enhance the findings of these investigations.

Endogenous formation of formaldehyde makes it difficult to quantify external exposures to the chemical because of ever-present metabolites. Visual blood and tissue concentrations of formaldehyde are often masked due to rapid biotransformation in the human body. Shifts in formic acid concentrations in the urine of occupationally exposed workers did not reliably monitor formaldehyde exposure (Gottschling et al., 1984). Animal studies of urinary metabolites identified formate and a cysteine adduct upon injection of radiolabeled formaldehyde, but these findings have not been replicated by human data (Hemminki, 1984). More recent studies of formaldehyde biomonitoring have shown an increase in DNA–protein crosslink (DPC) frequencies in the white blood cells of workers exposed to formaldehyde (Shaham et al., 1996). The authors also reported a linear correlation between chronic exposure and the amount of DPC observed. Low level exposure in a study of mortuary students was associated with epithelial cytogenetic changes in the mouth and blood lymphocytes, indicating these changes may be useful as markers of biologically effective doses of formaldehyde (Saruda et al., 1993).

ACETALDEHYDE

Target organ(s): Eyes, skin, respiratory system, kidneys, central nervous system

Reproductive system

Occupational exposure limits: NIOSH—not established; OSHA—TWA 200 ppm

ACGIH—STEL ceiling 25 ppm

Reference values: RfC—0.009 mg/m³; TDI—0.1 µg/kg; MRL—1.0 ppm

Hazard statements: H224—extremely flammable liquid and vapor; H319—causes serious eye irritation; H335—may cause respiratory irritation; H351—suspected of causing cancer

Precautionary statements: P210—keep away from heat/ sparks/open flames/ . . . /hot surfaces/ . . . no smoking; P281—use personal protective equipment as required; P305+P351+P338—if in eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P337+P313—if eye irritation persists, get medical advice/attention

Risk phrases: R12—extremely flammable; R36/37—irritating to eyes and respiratory system; R40—limited evidence of a carcinogenic effect

Safety phrases: S2—keep out of the reach of children; S16—keep away from sources of ignition . . . no smoking; S33—take precautionary measures against static discharges; S36/37—wear suitable protective clothing and gloves

BACKGROUND AND USES

Acetaldehyde (acetic aldehyde, ethanol ethyl aldehyde; CASRN 75-07-0) is a low molecular weight aldehyde used as a solvent and chemical intermediate in the manufacturing of compounds. It is also used in the concoction of resins, explosives, fragrances, and flavorings. While widely used in industry, acetaldehyde is regularly found in nature. Higher order plants metabolize acetaldehyde to form an intermediate which can be found in humans after ethanol consumption. It can also be detected in a number of fruits, vegetables, and spices.

PHYSICAL AND CHEMICAL PROPERTIES

Acetaldehyde exists as a colorless liquid or gas with distinct, fruity odor. It is miscible with water and many organic solvents. The chemical has a molecular weight of 44.1 g/mol, a boiling point of 69 °F, and a freezing point of –190 °F. The vapor pressure is 902 mm Hg at 25 °C and the specific gravity is 0.79. The lower explosive limit is 4.0% and the upper explosive limit is 60%. Acetaldehyde may be incompatible with strong oxidizers, acids, and bases. It can also react with hydrogen cyanide and hydrogen sulfide. If acetaldehyde is exposed to air, it has the potential to form peroxides that are explosive.

MAMMALIAN TOXICOLOGY

Acute Effects

Low concentrations of acetaldehyde elicit irritant effects which are primarily a nuisance. Vapor exposure to concentrations of 50 ppm has been shown to cause eye irritation (Sim and Pattle, 1957). Higher concentrations can result in

transient conjunctivitis and mild upper respiratory effects (Brabec, 1994). Similar to other aldehydes, high concentrations of acetaldehyde vapor can have narcotic effects. Segel and Mason noted that acetaldehyde caused depressant effects on cardiac mitochondria which may lead to abnormal cardiac biochemistry and function (Segel and Mason, 1979). Dermal contact with the liquid state may result in erythema and burns if the exposure is of a sufficient duration (Pinnas and Meinke, 1992). Similar to formaldehyde, sensitization, and subsequent dermatitis are potential outcomes for certain individuals. Human volunteers who inhaled acetaldehyde in concentrations likely to be encountered in the workplace (1 ppm) were found to retain an average of 60% of the inhaled dose (Egle, 1970).

Chronic Effects

Chronic effects associated with occupational exposure to acetaldehyde have not been reported. One study has shown that inhaled acetaldehyde was responsible for bronchoconstriction in asthmatic patients (Myou et al., 1995). This is achieved through a histamine-releasing action. Chronic exposure to acetaldehyde, a component of cigarette smoke, was shown to be damaging to cilia and lung cells (Rylander, 1973). Chronic alcohol consumption is believed to lead complications, including cancer of the oral cavity, larynx, liver, and breast due to increases in acetaldehyde formation (Voulgaridou et al., 2011). No convincing studies have demonstrated a clear teratogenic effect similar to fetal alcohol syndrome associated with acetaldehyde exposure in the workplace. Continued epidemiologic investigation is necessary to determine if chronic diseases are possible with excessive acetaldehyde exposure.

Animal exposures to acetaldehyde have resulted in some cancers. Feron et al. (1982) reported increased carcinomas of the tracheal epithelium, nasal passages, and larynx upon inhalation exposure in hamsters. The chronic effects that are elicited by acetaldehyde may be increased when mitochondrial aldehyde dehydrogenase deficiencies exist. A 2010 study involving mitochondrial aldehyde dehydrogenase deficient mice identified a potential link between acetaldehyde exposure and increased risk of nasal epithelium and lung cancers (Oyama et al., 2010). Similar results in other animal species have led the IARC (1985) to assign acetaldehyde to Group 2B, sufficient data in animals that acetaldehyde is a carcinogen, but insufficient data in humans. The ACGIH (2013) classifies acetaldehyde in Group A3: confirmed animal carcinogen with unknown relevance to humans.

Mechanism of Action(s)

Acetaldehyde is formed in the liver after the consumption and biotransformation of ethanol. Since most acetaldehyde activity is concentrated in the liver, it is recognized as a

hepatotoxin. However, animal studies have shown that metabolism of acetaldehyde can occur in the nasal mucosa and brain mitochondria of rats (Casanova-Schmitz et al., 1984; Quintanilla and Tampier, 1995). Aldehyde dehydrogenase, the enzyme responsible for oxidizing acetaldehyde, is present in many different mammalian tissues and varies widely among individuals.

Effects on dorsal root ganglion neurons similar to those seen with ethanol exposure have been observed in chick embryos (Bradley et al., 1995). The carcinogenicity of acetaldehyde is possibly linked to its ability to produce cross linking in DNA and sister chromatid exchanges after repeated injury (Lambert and He, 1988). It has been shown that acetaldehyde reacts, albeit reversibly, with amino groups of nucleic acid bases (Hemminki and Suni, 1984). The stimulatory effects on the cardiovascular system in animals have been linked to a catecholamine-like response, an increase in heart rate and oxygen consumption (Gailis and Verdy, 1971). Varying concentrations of acetaldehyde can be detected in blood samples.

Chemical Pathology

Acetaldehyde enters the body when fumes of the liquid are inhaled. It can also enter the body if food or drink has been contaminated with the chemical. Several factors determine how acetaldehyde will affect the body: amount of the chemical in the body, the duration of exposure, and the frequency of exposure. Once in the body acetaldehyde is broken down by the enzyme aldehyde dehydrogenase. Acetaldehyde metabolism results in the formation of acetate. If the concentration of acetaldehyde in the liver is too great, individuals may develop symptoms of acute acetaldehyde poisoning, including cardiac arrhythmia, nausea, and anxiety. Physiologically based pharmacokinetic models have been developed that consider acetaldehyde concentration–time data which may help to understand the chemical's pathology (Umulis et al., 2005). The National Institutes of Health explain that highly reactive oxygen species are created by acetaldehyde metabolism and this can lead to the damage of proteins and DNA (2007). In addition, the highly reactive oxygen species have the ability to react with other substances in the body to potentially form harmful compounds.

SOURCES OF EXPOSURE

Occupational

Acetaldehyde is used in industry in the formulation of a variety of chemicals. Any individuals that are involved in the packaging, processing, and/or distribution of the chemical may be at risk for possible exposure. Acetaldehyde is produced by the Hoechst-Wacker process, in which 1.

ethylene is oxidized by aqueous palladium chloride to acetaldehyde, 2. the reduced palladium is reoxidized by cupric chloride to palladium chloride, and 3. the reduced cupric chloride created is reoxidized by oxygen (NIOSH, 1991). Most recently researchers have been interested in worker exposure to acetaldehyde and structurally similar compounds in the production of different food flavoring substances. The chemical has been identified in several microwave popcorn production facilities with concentrations being below the established OSHA PEL (OSHA, 2010). While the workers were not exposed to levels above established limits, consistent low level exposure could potentially lead to adverse health effects.

Environmental

Acetaldehyde is a byproduct found in internal combustion exhaust. Individuals living in highly populated areas may be at risk for exposure as a result of air pollution. Acetaldehyde is formed by photochemical reactions resulting in smog in urban areas. Studies have examined the presence of acetaldehyde in both the indoor and outdoor environments. One study found that the mean personal exposure level of acetaldehyde was 7.9 ppb among 15 research subjects (Jurvelin et al., 2001). Acetaldehyde can also be produced by the burning of wood, tobacco, and the incineration of waste. It may also be produced via the respiration of higher order plants. It was determined that plants subjected to sulfur dioxide produced acetaldehyde when stressed (Kimmerer and Kozlowski, 1982). Acetaldehyde may also be found in perfumes and fragrances as well as baked goods and alcoholic beverages.

INDUSTRIAL HYGIENE

Acetaldehyde is commercially produced through an oxidation reaction of ethylene. Industrial use of acetaldehyde is typically confined to a closed system due to the chemical's explosive nature. The use of a closed system helps to prevent occupational exposures. The most likely route of exposure is inhalation of acetaldehyde fumes. Protective clothing such as aprons and eyewear should be worn to prevent dermal contact from accidental spills. Low concentrations of acetaldehyde vapor produce irritant effects alerting employees to potential exposure before serious health effects occur. The human carcinogenicity of acetaldehyde has not been determined; however, animal carcinogenicity is confirmed. Therefore NIOSH (1995) classifies it as a possible occupational carcinogen and recommends the lowest feasible exposure. OSHA has a less stringent PEL of 200 ppm (360 mg/m^3). The ACGIH (2013) has a stricter ceiling value of 25 ppm, noting acetaldehyde as a definite animal carcinogen with unknown relevance to humans.

MEDICAL MANAGEMENT

Workers that have the potential to be exposed to acetaldehyde should be entered into a medical surveillance program. Medical surveillance can prevent workers from encountering occupational injury and disease by early detection, diagnosis, and treatment. NIOSH explains that employees should be educated by employers about the potential hazards in the work environment and they should be placed in jobs that do not compromise safety and health (NIOSH, 1992). If a worker is using acetaldehyde and experiences any type of adverse health effects, they should be evaluated immediately and preventive measures instituted. Preventive measures may include industrial hygiene monitoring, engineering controls, administrative controls, and personal protective equipment. It should be recognized that worker evaluation should be completed before, during, and after termination from the job site. This will ensure that biological monitoring data above baseline will be investigated immediately. Acetaldehyde can be detected in exhaled air, urine, and blood.

Individuals exposed to acetaldehyde should take various first-aid measures. If skin is exposed to the chemical, it should be rinsed thoroughly with copious amounts of water. The area may then be cleansed with a detergent and water. Any clothing or other apparel that has been contaminated should be removed immediately. Special processes to remove contaminated clothing should be considered. Individuals that regularly use acetaldehyde in the work environment should institute a rigorous personal hygiene regimen. This regimen should include regular washing of the upper extremities and face before eating, drinking, or smoking. No eating, drinking, or smoking should take place in environments where acetaldehyde is present.

ACROLEIN

Target organ(s): Eyes, skin, respiratory system, heart

Occupational exposure limits: NIOSH—TWA 0.1 ppm, STEL 0.3 ppm; OSHA—TWA 0.1 ppm; ACGIH—STEL Cicling 0.1 ppm

Reference values: RfD—0.0005 mg/kg/bw/day; RfC—0.00002 mg/m³; MRL—0.003 ppm

Hazard statements: H225—highly flammable liquid and vapor; H300—fatal if swallowed; H311—toxic in contact with skin; H314—causes severe skin burns and eye damage; H330—fatal if inhaled; H400—very toxic to aquatic life

Precautionary statements: P273—avoid release to the environment; P280—wear protective gloves/protective clothing/eye protection/face protection; P303+P361+P353—if on skin (or hair), remove/take off immediately all contaminated clothing; rinse skin with water/shower; P304+P340—if inhaled, remove victim to fresh air and keep at rest in a position comfortable for breathing; P305+P351+P338—if in eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P403+P233—store in a well-ventilated place; keep container tightly closed

Risk phrases: R1—highly flammable; R24/25—toxic in contact with skin and if swallowed; R26—very toxic by inhalation; R34—causes burns; R50—very toxic to aquatic organisms

Safety phrases: S23.3—do not breath gas/vapor/aerosol; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S28.1—after contact with eyes, rinse immediately with plenty of water and seek medical advice; S36/37/39—wear suitable protective clothing, gloves, and eye/face protection; S45—in case of accident or if you feel unwell, seek medical advice immediately (show label where possible); S61—avoid release to the environment; refer to special instructions/safety data sheets

BACKGROUND AND USES

Acrolein (acraldehyde, acrylaldehyde, acrylic aldehyde, allyl aldehyde, propenal, 2-propenal; CASRN 107-02-8) is another important aldehyde. It is used as a chemical intermediate in many industrial synthetic processes, including in the production of acrylic acid and allyl alcohol. Acrolein may also be used as a biocide and in the production of perfumes and colloidal metals. Residue from industrial emissions and the burning of wood and other organic substrates will contain traces of acrolein. Acrolein is also a constituent of diesel exhaust and photochemical smog. It is also formed during the pyrolysis of cotton and polyethylene and found in cigarette smoke. Much of the human toxicity data is obtained from the formation of acrolein *in vivo* as a metabolite of the anticancer drug, cyclophosphamide.

PHYSICAL AND CHEMICAL PROPERTIES

Acrolein can exist as a colorless or yellow liquid with a penetrating, displeasing odor. The chemical has a molecular weight of 56.1, a boiling point of 127 °F, and a freezing point of –126 °F. The vapor pressure is 274 mm Hg at 25 °C and the specific gravity is 0.84. The lower explosive limit is 2.8% and the upper explosive limit is 31%. Acrolein may be incompatible with oxidizers, acids, alkalis, ammonia, and amines. Acrolein has the ability to polymerize unless inhibited with hydroquinone. Shock-sensitive peroxides may be formed over time NIOSH (2010).

MAMMALIAN TOXICOLOGY

Acute Effects

Lacrimation and severe respiratory irritation can result from acute exposure to acrolein vapor. Pulmonary edema can rapidly occur in air levels of 20 ppm. A concentration of 150 ppm is considered lethal in humans exposed for 10 min or longer. Respiratory effects produced by acrolein can persist for long periods. Ciliary action in the upper airways is significantly reduced due to this highly reactive aldehyde. The result is tissue destruction in all parts of the lungs. Acrolein is a likely contributor to smoke inhalation-induced injury and death. Asphyxiation in animals and humans can occur with high concentrations of acrolein. Skin irritation, painful dermatitis, burns, and epidermal necrosis can occur with dermal contact of high concentrations of acrolein. A pesticide worker exposed to acrolein was diagnosed with thermal skin sensitivity 3 weeks after exposure (CDC, 2013). Several other workers suffered from acute acrolein-related

illness with symptoms ranging from eye irritation, headache, and dyspnea.

Acute exposures in animals have resulted in a variety of effects depending on exposure route and concentration. Acrolein was found to have a potent sensory irritant effect in mice after a single exposure (Kane and Alarie, 1977). Spontaneous inhalation of acrolein vapor caused immediate inhibitory effects on breathing rats, bradycardia, and reduced ventilation (Lee et al., 1992). It is a common constituent of smoke, and studies of acrolein-containing smoke in animals produced pulmonary edema and airway damage in both high and low concentration groups (Hales et al., 1988). Excessive exposure to this aldehyde can also impair resistance to bacterial infections in test animals. Astry and Jakab (1983) demonstrated susceptibility to certain bacterial strains that are normally inactivated shortly after contact. Increases in bacterial infections and pneumonia in acrolein-exposed mice were seen. High concentrations of acrolein in tobacco smoke make this of some concern to humans. In addition to sensory irritation, other observations from animal studies include inhibition of protein synthesis and enzyme activity, elevated liver alkaline phosphatase, weight loss, and death. A high concentration of acrolein in the bladder lumen of rats caused acute cytotoxicity and epithelial lesions (Sakata et al., 1989).

Chronic Effects

Similar to acute effects, the chronic effects of acrolein vary as well. Sensitization in some individuals is possible when exposed to acrolein. Since acrolein has such a disagreeable odor, low odor threshold, and strong irritating effects, workers can be alerted to exposure preventing the development of chronic effects. One of the few chronic studies available involves patients treated with cyclophosphamide. Cytotoxicity in the bladder of each patient was noted, although acrolein was not investigated as the causal agent at the time of the study (Beyer-Boon et al., 1978). This type and concentration of acrolein exposure are not likely to occur in the workplace.

Most knowledge about the chronic effects and toxicity of this chemical was generated from animal studies. Subchronic exposures of rats to levels much higher than those likely to be found in the workplace resulted in decreased lung function and suggestive airway obstruction (Costa et al., 1986). In a study by Leach et al., (1987), the adverse effects resulting from excessive exposure were likely to be confined to local nasal tissue pathology, such as exfoliation and erosion of the respiratory epithelium. No human data identifying acrolein-induced adverse developmental toxicity are available, although a study using rabbits completed by Parent et al. (1993) found no adverse developmental effects after ingestion of acrolein.

Animal studies have shown acrolein to be carcinogenic. Acrolein was shown to have initiating activity for bladder carcinogenesis in male rats, but the study was unable to demonstrate promotion or complete carcinogenic action for acrolein (Cohen et al., 1992). This carcinogenic activity is likely a result of the 2,3-epoxy metabolite. Human studies have not explored this link in detail, but it is important to note that cigarette smoking and cyclophosphamide therapy have both been implicated as causes of bladder carcinoma (Seltzer et al., 1978; Auerbach and Garfinkel, 1989). IARC (1987) classification of this compound is a Group 3, inadequate data in humans and animals to classify acrolein as carcinogenic.

Mechanism of Action(s)

The metabolism of acrolein is not well characterized. The first step of acrolein metabolism appears to be a conversion of acrolein to acrylic acid by liver enzymes (Patel et al., 1980). Draminski et al. (1983) proposed the next step as a methylation of acrylic acid to methyl acrylate and then conjugation with glutathione to form its final metabolite, S-carboxymethylmercapturic acid, which was found in the urine of rats exposed to acrolein in the same study. This metabolism is from oral dosing data, which may differ from dermal and inhalation routes. The reaction of acrolein with thiol groups *in vitro* is reported, and this is a detoxification mechanism important for protecting cells and tissues from the toxicity of acrolein.

Many researchers have suspected acrolein as a carcinogenic agent. The carcinogenicity of acrolein is likely related to formation of a 2,3-epoxy metabolite. A study by Wilson et al. (1991) demonstrated DNA adducts produced in human fibroblasts. Wang et al. (2012) found that acrolein not only damages DNA but can also change DNA repair mechanisms resulting in the degradation of the changed repair mechanisms (Wang et al., 2012). The disruption of normal cellular processes by acrolein appears to result in disease manifestation. Acrolein is a highly reactive aldehyde when compared with other aldehydes and their toxicity.

Chemical Pathology

Acrolein is extremely reactive and binds to macromolecules to form thiol ethers. The binding of acrolein to messenger compounds may cause direct cytotoxic effects and interrupts cell signaling (Beauchamp et al., 1985). Disruption of cell signaling pathways can disrupt the normal cellular activity in the human body leading to the generation of different diseases. It is believed that acrolein may have the ability to induce Alzheimer's disease-like manifestations. Huang et al. (2013) found that acrolein caused the inactivation of astrocytes, upregulation of BACE-1, and downregulation of ADAM-10, resulting in Alzheimer's disease-like pathologies both *in vitro* and *in vivo*.

SOURCES OF EXPOSURE

Occupational

Acrolein can be found in industry as a chemical intermediate in the production of acrylic acid and esters. Acrolein itself is prepared commercially by propene oxidation. Acrolein is also used industrially in the manufacture of colloidal metal, plastics, and perfumes. It is also used to control the growth of plants, algae, and other microorganisms making those involved in the plant and wildlife management at risk for exposure. Since acrolein is often a component of smoke, research has focused on firefighter's exposure to the chemical. Materna et al. (1992) found that as a result of wildfires, firefighters may be exposed to harmful components of smoke at or above established occupational exposure limits. Those working in oil or coal fired power plants may also be exposed to acrolein via smoke. Acrolein may be encountered in the food manufacturing industry as a food starch modifier and in the paperboard for the packaging of food products (OSHA, 2013). Individuals in the military or other first responding agencies could be at risk in the event that acrolein is used as a chemical warfare or riot control agent.

Environmental

As previously mentioned, acrolein is a component of smoke. When trees and plants are burned, acrolein exposure can occur if smoke is inhaled. Fireplaces that are indoors may concentrate smoke inside leading to higher exposures. Proper ventilation should be provided. Smoke from oil or coal fired power plants and the burning of tobacco products can contain acrolein. Acrolein levels were found to be elevated in homes that had lower air exchange rate and that housed at least one tobacco smoker (Gilbert et al., 2005). Stevens and Maier (2008) explain that the smoking of tobacco products can equal or exceed the total human exposure to acrolein from other sources. Traces of the chemical can also be found in exhaust from internal combustion engines. Acrolein levels measured at a toll booth during rush hour traffic exceeded established levels in the state of California (Destaillets et al., 2002). Instituted air pollution control measures may have the ability to reduce the potential for acrolein exposure.

INDUSTRIAL HYGIENE

A primary route of exposure is inhalation of acrolein vapor during its manufacture and industrial use. Trace amounts of acrolein, about 0.16 ppm, can normally be detected by a worker because of its strong odor. It is also irritating to the eyes and throat at levels slightly above the odor threshold. Bromination of sampled ambient air followed by gas chromatography analysis is an effective method for monitoring

acrolein with sensitivity for measurement of amounts as low as 5 ppb (Nishikawa et al., 1986). OSHA recommends air sampling with a sorbent tube containing 2-(hydroxymethyl) piperidine on XAD-2 adsorbent using toluene to extract acrolein (OSHA, 1992). Recommendations for protection of workers in contact with acrolein are respirators as needed and prevention of skin and eye contact (NIOSH, 2010). The allowable workplace air standards for acrolein are the same for the TLV of the ACGIH (2013), the PEL of OSHA, and the REL of NIOSH (2010), at 0.1 ppm (0.25 mg/m³) TWA and a skin designation of 0.3 ppm (0.8 mg/m³).

MEDICAL MANAGEMENT

There are no reliable methods for biomonitoring exposure to acrolein; however, some promising techniques have been reported. The inhibition of glutathione-s-transferase in human erythrocytes by acrolein and other chemicals has been used to characterize acrolein exposure (Ansari et al., 1987). The measurement of mercapturic acid metabolites in the urine has also been suggested for biomonitoring, but no reliable quantification of metabolites has been reported as adequate for monitoring industrial exposures. Workers that experience respiratory symptoms should consider investigative chest X-rays (NLM, 2013). Individuals with excessive exposure should be administered blood gases to treat hypoxia. Treatment of exposed persons typically consists of respiratory and cardiovascular support.

CINNAMALDEHYDE

Target organ(s): Eyes, skin, respiratory system

Occupational exposure limits: NIOSH, OSHA, ACGIH—not established; derived no effect level (DNEL); DNEL inhalation, systemic effects, long term: 2.2 mg/m³; DNEL dermal, systemic effects, long term: 2.51 mg/kg/bw/day

Reference values: RfD, RfC, MRL—not established; DNEL inhalation, systemic effects, long term: 0.54 mg/m³; DNEL dermal, systemic effects, long term: 0.625 mg/kg/bw/day; DNEL oral, systemic effects, long term: 2.5 mg/kg/bw/day

Hazard statements: H312—harmful in contact with skin; H315—causes skin irritation; H317—may cause an allergic skin reaction; H319—causes serious eye irritation

BACKGROUND AND USES

Cinnamaldehyde (cinnamic aldehyde, benzylideneacetaldehyde, phenylacrolein, 3-phenylpropenal, 3-phenyl-2-propanal; CASRN 104-55-2) is a saturated aldehyde with an aromatic ring that is a yellowish, oily liquid at room temperature. It is used as a flavoring and aromatic agent in a variety of food products, perfumes, and household products. It has also seen use as a rubber reinforcing agent. A burning taste that produces the odor and flavor of the spice may be found with this aromatic aldehyde. Cinnamaldehyde has also been used as an attractant for insect control, in the preparation of corrosion inhibitors, and as a coating for metals. Although extensively used in industry, it is also a natural constituent of cinnamon leaves and bark, some essential oils, and other plant products.

PHYSICAL AND CHEMICAL PROPERTIES

Cinnamaldehyde exists as yellowish to greenish-yellow oily liquid with a cinnamon odor. The chemical has a molecular weight of 132.15, a boiling point of 487.4°F, and a melting point of 19.4°F. The vapor pressure is 0.0289 mm Hg at 25°C and the specific gravity is 1.049. It is normally insoluble in water and many organic solvents but is miscible with alcohol and other flavoring oils. Exposure to air will result in thickening and oxidation.

MAMMALIAN TOXICOLOGY

Acute Effects

Metabolism of ingested cinnamaldehyde is believed to involve oxidation of the aldehyde to cinnamic acid via ADH. As a result, hippuric and benzoic acids are formed and excreted in urine. As with many other chemicals, this metabolism is thought to occur mainly in the liver. Rat liver glutathione levels were significantly depressed within 30 min after intra-peritoneal administration of cinnamaldehyde (Boyland and Chasseud, 1970). Two urinary metabolites containing sulfur groups, 3-S-(N-acetylcysteinyl)-3-phenylpropyl alcohol and 3-S-(N-acetylcysteinyl)-3-phenylpropionic acid have been identified in a rat model (Delbressine et al., 1980). Non-immunological contact urticaria is likely to involve a non-allergic histamine-liberating response. Animal models have not clearly demonstrated the mechanism involved, but similar effects of dermal edema and erythema are seen following exposure in these models (Lahti and Maibach, 1984). Research conducted by Subash et al. (2007) indicated that cinnamaldehyde had the ability to reduce hypoglycemic and hypolipidemic effects in diabetic rats.

Acute effects of cinnamaldehyde are noticeable at high concentrations. Inflammation and erosion of the gastrointestinal mucosa may occur after ingestion of undiluted essential oils containing cinnamaldehyde. Systemic reactions are not expected from exposure. Mucous membranes may become irritated due to exposure to high concentrations of inhaled cinnamaldehyde. Contact dermatitis and superficial chemical burns are possible with prolonged dermal contact. Delayed contact dermatitis may also be seen. Cinnamaldehyde-induced sensitization has been reported in a non-invasive mouse ear swelling assay, designed for evaluating fragrances and mixtures (Thorne et al., 1991). Nonimmunological contact urticaria, characterized by redness and wheals, may also be an outcome of acute dermal exposure to cinnamaldehyde (Mathias et al., 1980; Seite-Bellezza et al., 1994). Cinnamaldehyde is a strong skin irritant and sensitizer and may cause urticaria. Cinnamaldehyde was found to arouse spontaneous, immediate pain and induce heat and mechanical hyperalgesia, cold hypoalgesia,

and neurogenic axon reflex erythema in human participants (Namer et al. 2005).

Chronic Effects

Chronic effects associated with cinnamaldehyde exposure may result from repeated exposures and subsequent sensitization of atopic individuals. Contact dermatitis has been associated with a number of different occupations, including bakers, chemists, and workers in manufacturing plants (Fisher, 1975; Nethercott et al., 1983). Powered cinnamon contains only 1% of the aldehyde and is not an irritant when ordinarily used. Coal miners provided with a perfumed lotion at their worksite were reported to have a high number of individuals sensitized to cinnamaldehyde (Goodfield and Sainan, 1988). Unfortunately for the affected individuals, reoccurrence of signs and symptoms may develop away from the workplace in response to reexposure to cinnamaldehyde in foods, cosmetics, or other products containing the aldehyde.

Mutagenicity tests have indicated that cinnamaldehyde may actually be an antimutagen, reducing spontaneous or induced mutations (Ohta, 1993). Cinnamaldehyde was found to have a chemoprotective and anti-inflammatory effect on human endothelial cells (Liao et al., 2008). Cinnamaldehyde was also found to have antitumor activity mediated by the inhibition of farnesyl transferase (Moon et al., 2006). However, in high doses administered to rats, cinnamaldehyde did induce some genetic alterations at the chromosomal level (Mereto et al., 1994), suggesting a dose-dependent mutagenic effect. *In vivo* developmental toxicity testing in mice has found no overt health effects among dams or offspring after midterm exposure to cinnamaldehyde (Hardin et al., 1987).

Mechanism of Action(s)

Allergic contact dermatitis may be the result of acute and chronic exposure to cinnamaldehyde. Allergic contact dermatitis occurs when the T-lymphocyte immune response reacts to a chemical allergen that contacts the skin (Smith Pease et al., 2003). The allergen binds to a carrier protein and is processed by antigen-presenting cells. The antigen-presenting cells then present the allergen to the T-lymphocyte. This stimulates the production of memory and effector T-lymphocytes. Later contact with the allergen at a sufficient dose will activate an immune response and result in allergic contact dermatitis symptoms. Protecting the skin from cinnamaldehyde will prevent initial and subsequent exposure of allergens, preventing the development of allergic contact dermatitis.

Cinnamaldehyde is used in the preparation of various fragrances. Their use introduces the chemical into the air where it has the potential to be inhaled. Inhalation of

cinnamaldehyde can produce irritant effects in the upper airways, resulting in cough. Faruqi and Morice (2008) determined that cinnamaldehyde was a specific agonist of the TRPA-1 receptor and induced cough due to chemesthesia in the airways. Another study found that children's toys that were perfumed with fragrances had the ability to emit fragrance chemicals increasing risk for exposure via inhalation (Masuck et al., 2011). Proper ventilation will help reduce indoor concentrations to acceptable levels. In extreme cases, respiratory protection or cessation of fragrances or perfume may be necessary to eliminate exposure.

Chemical Pathology

Cinnamaldehyde exposure results in effects on the skin from dermal contact and in the respiratory tract from inhalation. Sells et al. (2007) found pigmentation of the olfactory epithelium, specifically in the basal cytoplasm, following exposure to cinnamaldehyde via the noninhalation route. While the skin and the respiratory tract are affected by cinnamaldehyde exposure, additional research studies indicate that other sites may be adversely affected by exposure. Rats provided a dose of 73.5 mg/kg/day showed histological changes in kidney tissue trailed by increased renal, serum, and urinary enzymes (Gowder and Devaraj, 2008). An additional study found that rats exposed to cinnamaldehyde had abnormal liver function leading to a prooxidant state which could increase the probability of cancer development (Raveendran et al., 1993). The kidney and the liver may be other cinnamaldehyde target organs but additional research is needed to understand the complete chemical pathology.

SOURCES OF EXPOSURE

Occupational

Occupational exposures to cinnamaldehyde may occur in the industrial environment as a result of chemical preparation, processing, and distribution. The chemical is easily manufactured as a condensation product of benzaldehyde and acetaldehyde in an acidic or basic solvent. The oxidation of cinnamylic alcohol and condensation of styrene with 2-chloroallylbenzene will also result in the creation of this aldehyde. The United States Environmental Protection Agency (USEPA) issued a report in which they believed that mixers, loaders, and applicators of cinnamaldehyde do not pose an unreasonable hazard when using the biochemical fungicide (USEPA, 2000). However, an individual with acute itching on his right hand was patch tested with various concentrations to cinnamaldehyde and developed immediate reactions to the chemical (Cocchiara et al., 2005). Inhalation of cinnamaldehyde is also possible. Once inhaled, the aldehyde irritates the upper respiratory tract and can induce

coughing. Birrell et al. (2009) found that cinnamaldehyde evoked coughing in guinea pig and human volunteers.

Environmental

Cinnamaldehyde can be extracted from natural sources. It is used in many different applications that can be found in an individual's environment. Its use as a flavoring agent is an indication of its low toxicity at levels found in food items. This flavoring agent is used in mouthwashes, dentifrices, throat lozenges, candy, soft drinks, chewing gum, and many other items. This aldehyde is also extensively used in deodorizers, detergents, soaps, and cosmetics. It is also used in the formulation of certain biocides. Cinnamaldehyde appears to have the ability to reduce both Gram-negative and Gram-positive bacterial population, although the mechanism is not completely understood (Gill and Holley, 2004). Inhalation and dermal contact with the aldehyde are possible in different environmental situations. The burning of substrates that contain the aldehyde could cause symptoms, including respiratory irritation and cough. Exposure to cinnamaldehyde and similar compounds may have a relationship with cardiovascular disease (Haberzettl et al., 2011). Increasing ventilation in the indoor environment may help prevent the buildup high concentrations of cinnamaldehyde and other aldehydes.

INDUSTRIAL HYGIENE

A dermal exposure is more frequent and more likely to be a health hazard industrially. Inhalation exposures are not likely to be a source of serious health effects. The strong odor emitted by the chemical serves as a sufficient warning sign of hazardous concentrations. Currently, there are no published guidelines for this aldehyde because concentrations in some items are as high as 5000 ppm (Collins and Mitchell, 1975). Dermal protection is recommended for those individuals who come into contact with high concentrations or who have developed sensitivity to the chemical. Dermal protection may include face protection, gloves, and aprons. Engineering controls and respiratory personal protective equipment may be necessary to further reduce the risk of exposure.

MEDICAL MANAGEMENT

Individuals exposed to cinnamaldehyde who develop symptoms of irritation should be immediately removed from the contaminated environment. The chemical has a strong odor and will alert individuals when concentrations become high making overexposure unlikely. Individuals that are exposed to high concentrations should seek medical assistance if symptoms persist or are troublesome. Individuals that

experience respiratory irritation may require the use of respiratory protection. Those that are exposed to the chemical dermally should be removed from the environment and may require a topical agent to control itching. Covering exposed skin will restrict dermal contact and exposure. Employees should remove contaminated clothing and should cleanse hands and arms thoroughly to remove any chemical that may have contacted the skin. Good personal hygiene measures will prevent unnecessary exposure.

CROTONALDEHYDE

Target organ(s): Eyes, skin, respiratory system

Occupational exposure limits: NIOSH—TWA 2 ppm; OSHA—TWA 2 ppm

ACGIH—STEL ceiling 0.3 ppm

Reference values: RfD/RfC—not established; MRL—0.39 ppm

Risk phrases: R11—highly flammable; R24/25—toxic if contact with skin and if swallowed; R37/38—irritating to respiratory system and skin; R41—risk of serious damage to eyes; R48/22—harmful: danger of serious damage to health by prolonged exposure if swallowed; R50—very toxic to aquatic organisms; R68—possible risk of irreversible effects

Safety phrases: S1/2—keep locked up and out of the reach of children; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S28—after contact with skin, wash immediately with plenty of . . . (to be specified by manufacturer; R36/37/39—wear suitable protective clothing, gloves,

and eye/face protection; S45—in case of accident or if you feel unwell, seek medical advice immediately (show label where possible); S61—avoid release to the environment; refer to special instructions/safety data sheets

BACKGROUND AND USES

Crotonaldehyde (2-butenal, β -methyl acrolein, propylene aldehyde; CASRN 123-73-9) is similar in structure to acrolein, as both are α,β -unsaturated aldehydes. This structural similarity leads to similar sensitizing and irritating properties of the two compounds. Crotonaldehyde is used industrially in the preparation of other chemicals (chiefly sorbic acid), flavoring agents, and can form endogenously and in the environment.

PHYSICAL AND CHEMICAL PROPERTIES

Crotonaldehyde can exist as a water-white liquid with an asphyxiating odor. The chemical can turn pale yellow when it contacts air. The chemical has a molecular weight of 70.1, a boiling point of 219 °F, and a freezing point of –101 °F. The vapor pressure is 30 mm Hg at 25 °C and the specific gravity is 0.87. The lower explosive limit is 2.1% and the upper explosive limit is 15.5%. Crotonaldehyde may be incompatible with caustics, ammonia, strong oxidizers, nitric acid, and amines. It also has the ability to polymerize at high temperatures.

MAMMALIAN TOXICOLOGY

Acute Effects

Several studies have investigated the mammalian toxicology of crotonaldehyde. The chemical has been implicated in the development of vascular-related disease through lipid and protein oxidation (Lee and Park, 2013). It is believed that crotonaldehyde possesses mutagenic and carcinogenic properties by directly reacting with DNA. Hamster ovary cells exposed to crotonaldehyde formed DNA adducts at a level of 75 μ mol/mol deoxyguanosine suggesting potential tumorigenic potential (Foiles et al., 1990). Fernandes et al. (2005) found that mutation yields of DNA adducts were 5–6%, suggesting that adducts could possibly contribute to genotoxicity and carcinogenicity. Jha and Kumar (2006) investigated whether exposure to crotonaldehyde caused an increase in the number of abnormal sperm in mice. They found a statistically significant increase in the percentage of abnormal sperm. Based on available scientific research, crotonaldehyde is suspected to be a cancer causing agent and those individuals that may be potentially exposed to it should use proper protective measures.

Acute exposure to small quantities of crotonaldehyde vapor can result in eye and respiratory irritation. Vapors have been known to cause lacrimation. Higher exposure concentrations result in pulmonary edema and more serious respiratory effects. Skin irritation and chemical burns are possible with dermal contact from this aldehyde. Fatal doses can be delivered through all exposure routes. Acute animal exposures to high concentrations have shown a rapid decrease in respiratory rate with little or no recovery (Steinhagen and Barrow, 1984). A male worker accidentally exposed to a high concentration mixture of ethenone and crotonaldehyde presented with decreased vesicular sounds, opacities in the lung, and acute respiratory distress syndrome (Huang et al., 2013). Crotonaldehyde was found to induce apoptosis of endothelial cells resulting in vascular injury (Ryu et al., 2013). Acute effects resulting from crotonaldehyde can be prevented by identification and control of sources of exposure.

Chronic Effects

Chronic exposures in humans are not well documented; animal studies are a large source of current information on chronic crotonaldehyde toxicity. The most notable is the 1986 study by Chung, Tanaka, and Hecht, which demonstrated the induction of liver tumors in male rats. The potential carcinogenicity of this compound is of some concern to humans because of its endogenous formation. Mutagenic assays in *Salmonella* bacterial strains have shown positive results (Neudecker et al., 1981, 1989); however, the correlation between human carcinogenicity and these tests has not been demonstrated for many chemicals. 1, N²-propanodeoxyguanosine lesions following crotonaldehyde exposure in human and rodent liver DNA have been demonstrated, and these adducts may be related to the carcinogenic effect of crotonaldehyde (Nath and Chung, 1994). This aldehyde has been shown to be tumorigenic in rodents. Clinical cases of sensitization have been observed. Chronic obstructive pulmonary disease (COPD) can result due to chronic exposure to crotonaldehyde by causing lung inflammatory responses by different mechanisms (Yang et al., 2013). Traces of crotonaldehyde that can be found in cigarette smoke play a critical role in inflammatory cytokine production and neutrophilic airway inflammation (van der Toorn et al., 2013). Adequate ventilation to prevent inhalation and personal protective equipment to prevent dermal contact in the occupational workplace and environment can control crotonaldehyde exposure, limiting the potential for chronic disease development. In light of the available evidence, the ACGIH (2013) has placed crotonaldehyde in Group A3: confirmed animal carcinogen with unknown relevance to humans.

Mechanism of Action(s)

The major concern regarding crotonaldehyde exposure is its ability to react with different body systems and with DNA. Boyland and Chasseud (1970) demonstrated that rats injected with crotonaldehyde exhibited subsequent decreased glutathione levels. Crotonaldehyde reacts rapidly with thiol groups. Measurements of urine metabolites in rats have identified 3-hydroxy-l-methyl-propylmercapturic acid as the major metabolite following exposure to crotonaldehyde (Gray and Barnsley, 1971). Wang et al. (1988) found that crotonaldehyde is formed in the liver by metabolic α -hydroxylation of N-nitrosopyrrolidine suggesting that crotonaldehyde is involved in N-nitrosopyrrolidine and macromolecule interactions. Some research indicates that crotonaldehyde can be formed from crotyl alcohol, an unsaturated precursor. Fontaine et al. (2002) demonstrated that crotonaldehyde was formed when crotyl alcohol was oxidized by equine liver alcohol dehydrogenase. This suggests that crotonaldehyde may be encountered in the environment through normal metabolism and biotransformation of other substances in mammals.

Chemical Pathology

The specific chemical pathology of crotonaldehyde is not well understood. What is known regarding the chemical is that it is highly reactive, creates adducts with DNA, and inhibits enzyme activity. Cytochrome P450 and aldehyde dehydrogenase activity is disrupted by crotonaldehyde and human polynuclear leukocytes treated with crotonaldehyde form a dose-related reduction in sulphydryl groups with subsequent inhibition of superoxide production (Witz et al., 1987). Irritation caused by the chemical is typically immediate with the development of pulmonary edema being delayed. Some research suggests that crotonaldehyde disrupts neural transmission. A rise in oxidative stress and crotonaldehyde formation in glial cells may play a role in the mechanism of action for Alzheimer's disease (Kawaguchi-Niida et al., 2006). A study conducted in 2007 found enhanced crotonaldehyde formation in motor neurons and reactive glia of the spinal cord suggesting a possible relationship between crotonaldehyde and amyotrophic lateral sclerosis development (Shibata et al., 2007).

SOURCES OF EXPOSURE

Occupational

Crotonaldehyde exposure can occur in a variety of occupational settings. Crotonaldehyde is used in industry as an intermediate in the manufacture of butyl alcohol, in polymer technology, as a corrosion inhibitor, and as a stabilizer (OSHA, 1978). In order to protect workers from exposure,

processes should be enclosed with the proper ventilation with proper personal protective equipment utilized. Since the chemical is found in smoke from burning wood, fire fighters, forestry workers, and power plant workers are at risk for exposure to crotonaldehyde. Exhaust from internal combustion engines can contain traces of the chemical. Individuals that encounter this exhaust, including truck drivers, heavy equipment operators, and road maintenance workers are at risk to exposure. Individuals that encounter crotonaldehyde are likely to be exposed by way of inhalation or through dermal contact. Proper protective measures should be taken depending on the route of exposure presented. If a worker presents with symptoms indicating exposure, they should be removed from the work environment immediately.

Environmental

Crotonaldehyde, similar to other aldehydes, are emitted by the combustion of petroleum products, wood, and tobacco. Individuals in the population can be exposed to the chemical by inhaling environmental tobacco smoke, petroleum product exhaust, and smoke from wood combustion. Traces of crotonaldehyde found in environmental tobacco smoke can adversely affect mucociliary function, decrease smoke particle removal from the lungs, and serve as a risk factor for the development of asthma in children (Goodwin, 2007). Crotonaldehyde was successfully identified in automobile exhaust gas using gas chromatography with electron-capture detection (Nikshikawa et al., 1987). Environmental exposure to crotonaldehyde is likely to be inhalation of chemical traces from the aforementioned sources. Individuals may experience eye and respiratory irritation if levels are sufficient. If crotonaldehyde levels build up in the indoor environment, increasing the ventilation of the indoor space will help decrease the chemical to acceptable levels. Removal from the contaminated environment may also help improve symptoms.

INDUSTRIAL HYGIENE

Many different chemicals are created using crotonaldehyde as a chemical intermediate. In the occupational environment, exposures to crotonaldehyde are most likely to occur through inhalation, with dermal contact being secondary. Lacrimation and upper respiratory irritation are expected at concentrations slightly above threshold values. The extremely pungent odor and strong irritant properties of crotonaldehyde provide warning signs that make the likelihood of excessive exposure remote. Crotonaldehyde vapors can be detected in air using a solid sorbent technique (Mann and Gold, 1986). Personal respirators and protective clothing to prevent inhalation and dermal exposure are recommended to prevent industrial exposure. Personal air monitoring techniques have been developed using OSHA and the ACGIH exposure

limits (Wu and Que Hee, 1995). NIOSH (2010) and OSHA allowable levels of exposure for this compound are identical at 2 ppm (6 mg/m^3). The ACGIH (2013) has established a STEL ceiling of 0.3 ppm. For industrial hygiene monitoring of crotonaldehyde levels, OSHA uses two glass fiber filters coated with 2,4-dinitrophenylhydrazine and phosphoric acid, in open face mode, with a spacer (OSHA, 2006).

MEDICAL MANAGEMENT

There are currently no blood tests that can identify crotonaldehyde exposure but respiratory function tests and chest X-rays may identify damage to the lungs (ATDSR, 2002). Urinary tests may identify crotonaldehyde exposure if the metabolite 3-hydroxy-1-methylpropylmercapturic acid is present (Scherer et al., 2006). Individuals who were exposed to crotonaldehyde, with inhalation or dermal exposure symptoms should be removed from the contaminated environment. Irritation of the eyes, skin, and respiratory system can result but is unlikely since the chemical has a pungent odor. The strong odor will likely alert individuals when concentrations are above normal levels making overexposure unlikely. Medical assistance should be sought if individuals are exposed to high concentrations and their symptoms do not improve. Respiratory protection may be necessary if individuals experience irritation of the upper airways. Covering exposed skin will restrict dermal contact and exposure. As with other aldehydes, individuals should discard contaminated clothing and should cleanse exposed body parts to remove any chemical that may have contacted the skin. Secondary contamination to other individuals due to off gassing of crotonaldehyde is possible from contaminated clothing. Good personal hygiene practices are recommended.

FURFURAL

Target organ(s): Eyes, skin, respiratory system

Occupational exposure limits: NIOSH—not established; OSHA—TWA 5 ppm

ACGIH—TWA 2 ppm

Reference values: RfD—0.003 mg/kg/day; RfC—0.05 mg/m³; MRL—not established

Hazard statements: H226—flammable liquid and vapor; H301—toxic if swallowed; H330—fatal if inhaled; H315—causes skin irritation; H335—may cause respiratory irritation; H319—causes serious eye irritation; H351—suspected of causing cancer

Precautionary statements: P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking; P301+P310—if swallowed, immediately call a poison center or doctor/physician; P403+P233—store in a well-ventilated place; keep container tightly closed; P305+P351+P338—if in eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P308+P313—if exposed or concerned, get medical advice/attention; P281—use personal protective equipment as required

Risk phrases: R21—harmful in contact with skin; R23/25—toxic by inhalation and if swallowed; R36/37/38—irritating to eyes, respiratory system and skin; R40—limited evidence of a carcinogenic effect

Safety phrases: S1/2—keep locked up and out of reach of children; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S36/37—wear suitable protective clothing and gloves; S45—in case of accident or if you feel unwell, seek medical advice immediately (show label where possible)

BACKGROUND AND USES

The presence of furfural (fural, 2-furancarboxyaldehyde, furfuraldehyde, 2-furanaldehyde; CASRN 98-01-1) can be detected in numerous applications, including lubricating oils, resins, pesticides, fuels, and food products. It is also used as a chemical intermediate and reagent in such reactions as rubber vulcanization. Chemically, furfural can also be classified as a furan because of its dienic ether group. Furfural is a natural constituent of a variety of essential oils and can be produced as a by-product of carbohydrate pyrolysis.

PHYSICAL AND CHEMICAL PROPERTIES

Furfural is a colorless to amber color liquid with an odor similar to almonds and a taste similar to caramel. The chemical darkens when it contacts light or air. The chemical has a molecular weight of 96.1, a boiling point of 323 °F, and a freezing point of –34 °F. The vapor pressure is 2.21 mm Hg at 25 °C and the specific gravity is 1.16. The lower explosive limit is 2.1% and the upper explosive limit is 19.3%. Furfural may be incompatible with strong acids, oxidizers, and strong alkalis. Furfural has the ability to polymerize when it contacts strong acids or strong alkalis.

MAMMALIAN TOXICOLOGY

Acute Effects

Due to the low volatility of furfural, most exposures are dermal in nature; therefore the primary health hazards are associated with this route of exposure. Contact dermatitis and eczema may occur, as well as other sensitization reactions. Irritation of the skin, eyes, and mucous membranes may result with acute inhalation exposure. Respiratory effects associated with furfural at typical occupational exposure levels are mild irritation and slight difficulties in breathing. Removal from the contaminated environment will result in abatement of most, if not all, signs and symptoms. Acute exposure in animal studies has shown a dose-response relationship with signs of toxicity, as well as high LC₅₀ values (Terrill et al., 1989; Mishra et al., 1991). Signs observed in these animals included discoloration of fur, increased secretory responses, lacrimation, and some

respiratory difficulty. Mishra et al. (1991) further examined the biochemical changes in rat tissue after furfural exposure and found mucous membrane irritation and hepatocyte necrosis. Furfural has also been found to cause histopathological changes in rats at low concentrations with increasing incidence and severity at higher concentrations (Arts et al., 2004). A supporting research study found that rats that inhaled furfural above 126 ppm experienced dose-dependent mortality (Malik et al., 2012).

Chronic Effects

Chronic exposure to furfural in humans has not been the subject of any significant scientific investigation. Furfural's presence in foodstuffs and multiple other sources make determining exposure source difficult. Trace amounts of furfural may be detected in combustion smoke. Naeher et al. (2007) explains that continued inhalation of wood-smoke by firefighters led to chronic pulmonary dysfunction. While furfural is not the sole component in woodsmoke, it possibly plays a role in disease development. Much of the information in this area involves animal and *in vitro* studies. Carcinogenicity studies in rodent assays have not yet shown furfural alone to be a potent carcinogen. However, reports by Feron (1972) and Miyakawa et al. (1991) have shown initiation effects with furfural and known carcinogenic compounds such as benzo(a)pyrene and 12-O-tetradecanoylphorbol-13-acetate in different models. Extrapolation of these results to human risk assessment would be questionable. *In vitro* studies have shown associations with furfural exposure and mutagenic effects on plasmid DNA; however, these mutations were not significantly increased beyond the body's natural repair capabilities to counteract these effects (Khan et al., 1995). A 2-year gavage study found some evidence of carcinogenic potential in male F344/N and B6C3F1 mice for hepatocellular adenoma and bile duct dysplasia (Irwin 1990). The ACGIH (2013) ranks furfural as a Group A3 carcinogen: clear evidence in animals with unknown human relevance.

Mechanism of Action(s)

Furfural metabolism is not well established in humans, and few animal studies have been reported. No systemic effects are known to occur in humans. Nomeir et al. (1992) studied furfural disposition and metabolism in rats. After oral administration of the compound, metabolites of furfural were mainly found in urine, up to 88%. The initial step appears to be oxidation to furoic acid and subsequent excretion unchanged or conjugated with compounds such as glycine. Further scientific investigation is needed to get a better understanding of furfural toxicodynamics.

Chemical Pathology

The pathology of furfural is not well established in the literature. There is some evidence that tissue distribution primarily occurs in the liver and kidneys. These and similar results have focused interest on liver and kidney hazards among workers exposed to furfural. Although no known associations have been discovered, as stated previously, compromised individuals should be cautious. Monitoring of urinary excretion of furfural metabolites, such as furoic acid and 2-furoylglycine, has been reported, although not quantitatively (Sedivec and Flek, 1978; Laham and Potvin, 1989). Liver cells exposed to furfural developed cirrhotic changes after 90 days of exposure indicating a potential site of carcinogenesis (Shimizu and Kanisawa, 1986).

SOURCES OF EXPOSURE

Occupational

Similar to other aldehydes discussed, furfural is a component of smoke. Burning of wood, petroleum, and petroleum products may contain traces of the chemical. Recent scientific investigation has focused on furfural levels in electrocautery smoke. A 2004 study found that electrosurgical smoke had furfural concentrations at 24 ppm, 12 times higher than the occupational exposure limit (Hollman et al., 2004). A supporting study also detected electrosurgical smoke with furfural levels at 24 ppm (Lin et al., 2010). Surgeons and medical staff may be at risk for exposure from this route. Ventilation may be necessary in this situation to decrease concentrations back to allowable levels. Furfural can also be found in industry during the production of oils, pesticides, fuels, and foods. Several individuals working at popcorn popping company developed occupational asthma with furfural, present in environmental air samples, implicated as a potential causative agent (Sahakian et al., 2008). This situation indicates the need for exhaust ventilation and personal protective equipment to protect employees from exposure.

Environmental

Since furfural is used in a variety of products, it can be released into the environment through a variety of waste streams. Like other aldehydes presented, it is a component of smoke from wood burning, tobacco burning, and internal combustion engines. Indoor air quality may be impacted if products are burned inside. A 2002 study found that the burning of incense significantly increased concentrations of aldehydes in indoor air (Ho and Yu, 2002). Increasing air exchange rates and ventilation in indoor environments will prevent furfural and other volatile organic compounds from reaching high concentrations. In some situations, furfural can be off gassed from substrates. Furfural, a product of paper

degradation, was found at higher concentrations in library repositories when compared to air-filtered library repositories (Fenech et al., 2010). Clothes exposed to tobacco smoke were found to off gas a significant amount of furfural into the indoor environment (Chien et al., 2011). Irritation of the eyes and respiratory tract may occur at elevated contaminant levels. Removal from the environment is likely to improve symptoms.

INDUSTRIAL HYGIENE

A reaction of agricultural waste residues that contain pentosans with sulfuric acid is capable of producing furfural industrially. Low volatility of furfural vapors makes occupational inhalation exposure rare. Adverse health effects related to furfural are most likely to come from the dermal route. Ingestion of toxic concentrations of furfural is rare. Barrier protection is recommended to protect workers from the irritant properties of furfural. Concentrations from 2 to 14 ppm have caused eye and throat irritation and headaches. Workers who have a history of contact dermatitis, liver maladies, or kidney maladies should be given special consideration. Although liver and kidney effects have not been demonstrated in humans, these organs have been identified as targets in some animal studies, and caution should be taken. Eye, hand, and face personal protective equipment should be worn in case of possible contact with furfural. Respiratory protection equipped with organic vapor cartridges, are recommended for those workers who may be involved in brief work where high concentrations of furfural vapors are present. The use of personal protective equipment coupled with proper exhaust ventilation can keep health hazards to a minimum. The detection of furfural in the workplace can be achieved by adsorption onto activated carbon and desorption with carbon disulfide and 2-propanol followed by GC analysis (Sidhu, 1982). The ACGIH has set TLV guidelines for exposure at 2 ppm (7.9 mg/m³). OSHA has a higher PEL of 5 ppm (20 mg/m³), whereas NIOSH has no established REL for this compound. The immediate danger to life and health level for furfural is 250 ppm.

MEDICAL MANAGEMENT

Diagnostic testing may be necessary to identify frequent or high level exposure to furfural. Urine samples that contain furoic acid may indicate exposure to the chemical (Sedivec and Flek, 1978). In addition, liver function tests above baseline values may be a strong indicator. Chest X-rays may identify damage to the lungs from acute exposure. Patch testing conducted by an allergist may be necessary to determine skin allergies or sensitization from furfural (NJDHSS, 2000). Individuals that experience symptoms resulting from

exposure should be removed from the contaminated environment immediately. If symptoms persist after removal from the environment, exposed individuals should seek prompt medical treatment. Engineering controls are the best way to control exposure by providing exhaust ventilation and/or by enclosing or isolating the source. Because engineering controls are often quite costly and require adequate amounts of planning, the use of personal protective equipment may be necessary. Clothing, including long shirts and aprons, should be worn to protect the skin from chemical contact and face protection should be worn to prevent the chemical from contacting the face. Respiratory protection may be necessary in areas where furfural concentrations are high.

GLUTARALDEHYDE

Target organ(s): Eyes, skin, respiratory system

Occupational exposure limits: NIOSH—ceiling 0.2 ppm; OSHA—ceiling 0.2 ppm; ACGIH—STEL ceiling 0.05 ppm

Reference values: RfD—0.16 mg/kg/day; RfC/MRL—not established

Hazard statements: H290—may be corrosive to metals; H400—very toxic to aquatic life; H411—toxic to aquatic life with long lasting effects; H301—toxic if swallowed; H331—toxic if inhaled; H314—causes severe skin burns and eye damage; H317—may cause an allergic skin reaction; H334—may cause allergy or asthma symptoms or breathing difficulties if inhaled

Risk phrases: R23/25—toxic by inhalation and if swallowed; R34—causes burns; R42/43—may cause sensitization by inhalation and skin contact; R50—very toxic to aquatic organisms

Safety phrases: S1/2—keep locked up and out of reach of children; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S36/37/39—in case of accident or if you feel unwell,

seek medical advice immediately (show label where possible); S61—avoid release to the environment; refer to special instructions/safety data sheets

BACKGROUND AND USES

Glutaraldehyde (Symbol GTA; glutaric dialdehyde, 1,5-pentanediol, glutaral; CASRN 111-30-8) is commonly used in the medical industry in cold sterilization and in the X-ray development process. It can also be encountered in the leather industry as a tanning ingredient and in mortuary workers. There are no reports which indicate that glutaraldehyde is a naturally occurring compound. Cidex and Acusol, 2% buffered solutions, use this aldehyde as an active ingredient. Sodium bicarbonate is required to activate the solution, which then has a shelf life of 1–2 weeks. Despite health hazards involved with its use, glutaraldehyde is one of the most effective biocides used. It is particularly effective against bacteria and viruses, including the human immunodeficiency virus.

PHYSICAL AND CHEMICAL PROPERTIES

Glutaraldehyde is a colorless liquid with a strong, pungent odor. It is miscible in water and organic solvents. The chemical has a molecular weight of 100.1, a boiling point of 212°F, and a freezing point of 7°F. The vapor pressure is 0.6 mm Hg at 30°C and the specific gravity is 1.10. Glutaraldehyde may be incompatible with strong oxidizers and strong bases. It should be noted that alkaline solutions containing glutaraldehyde may react with alcohol, ketones, amines, hydrazines, and proteins.

MAMMALIAN TOXICOLOGY

Acute Effects

A multitude of signs and symptoms may result from acute exposure to glutaraldehyde depending on the exposure route. It is known to irritate the eyes, skin, and upper respiratory tract. Bronchial and laryngeal mucous membrane irritation can result from the inhalation of vapors. A study of the histopathology of rats found a concentration-related acute inflammation and necrosis of the nasal mucosa, larynx, trachea, and bronchi (Ballantyne and Myers, 2001). Vapors of this aldehyde may cause eye irritation, which subsides after exposure is terminated. However, direct contact of glutaraldehyde with the cornea has reportedly been the cause of keratopathy with development of a white plaque that resolved after time (Dailey et al., 1993). Dermal contact with glutaraldehyde solutions used in cold sterilization may

cause a mild skin irritation, but studies report on systemic effects are likely to occur due to low penetration of the skin (Frantz et al., 1993). A study of workers involved in glutaraldehyde sterilization reported general work-related symptoms such as headache and nausea (Norback, 1988). Symptoms of tachycardia and palpitations in workers, which resolve upon discontinued exposure to the chemical, have been reported, although these effects have not been confirmed by others (Connaughton, 1993).

Glutaraldehyde has long been suspected of being a sensitizer with prolonged exposure producing localized edema and other symptoms suggestive of an allergic response. Hilton et al. (1998) conducted a study using the local lymph node assay and demonstrated that glutaraldehyde had a greater potential to cause skin sensitization when compared to formaldehyde. Skin symptoms were 3.6 times more likely to be reported by glutaraldehyde exposed nurses (Waters et al., 2003). Animal studies report that nasal and pulmonary changes occur and persist at exposure levels lower than recommended guidelines (Zissu et al., 1994). Chronic bronchitis and nasal symptoms in humans were noted to be significantly higher at peak concentrations of glutaraldehyde (Takigawa and Endo, 2006). Numerous cases of colitis following endoscopy have been reported (Rosen, 1994; West et al., 1995). These outbreaks have been linked to residual glutaraldehyde on equipment that has not been thoroughly rinsed.

Chronic Effects

Chronic dermal exposure to glutaraldehyde has resulted in many cases of allergic contact dermatitis, particularly among health care workers involved in sterilization of medical equipment (Bardazzi et al., 1986; Nethercott et al., 1988). A study conducted in 2000 found that health care workers were eight times more likely to be allergic to glutaraldehyde when compared to individuals that do not work in the health care field (Shaffer and Belsito, 2000). The hands and arms are the most commonly affected areas. Some cases may take months to resolve and may reemerge with contact outside of the workplace because glutaraldehyde is found in lower concentrations in fabric softeners and hairsprays.

Occupational asthma related to glutaraldehyde exposure has also been reported among health care workers (Chan-Yeung et al., 1993; Gannon et al., 1995). Decreases in the peak expiratory flow (PEF) rate and bronchial challenges have indicated glutaraldehyde as the primary cause of the occupational asthma. There have been some reports of radiography technicians with this illness as well (Cullinan et al., 1992). Other reports include general respiratory irritation and in one case recurrent nosebleeds that subsided after exposure to glutaraldehyde was removed (Wiggins et al., 1989). Recent research indicates that the incidence of occupational asthma resulting from glutaraldehyde has declined

indicating that control measures are properly reducing exposure in the work environment (Bakerly et al., 2008).

Glutaraldehyde has not been the subject of human studies evaluating carcinogenicity and teratogenicity. Carcinogenic studies of glutaraldehyde in rodents have reported lesions in the anterior portion of the nose, but no precancerous lesions similar to those seen in rats exposed to formaldehyde have been reported (Gross et al., 1994). A battery of mutagenicity assays *in vitro* revealed no significant increases in genotoxic effects (Slesinski et al., 1983). Gastric intubation of pregnant rats with glutaraldehyde produced no teratogenic effects among the fetuses (Ema et al., 1992). A 2-year study of rats and mice exposed to varying concentrations of glutaraldehyde produced lesions in the nose, none of which were neoplastic (van Birgelen et al., 2000). The ACGIH (2013) declare glutaraldehyde a Group A4 carcinogen: not classifiable as a human carcinogen.

Mechanism of Action(s)

The mechanism of glutaraldehyde toxicity has not been the subject of many studies, as the health hazards associated with occupational exposure to glutaraldehyde are only of recent interest. A possible explanation for the acute effects involving mild irritation is nonspecific corrosive tissue damage. Glutaraldehyde-induced dermatitis and occupational asthma were reported months and, in some cases, years after primary exposure, demonstrating the lengthy latent period required to cause these effects. The biocidal activity of glutaraldehyde is a product of its ability to crosslink membrane proteins, altering the membrane function of the cell (Munton and Russell, 1973). Glutaraldehyde-induced cross-linking of DNA proteins is the proposed mechanism for the possible mutagenicity of this aldehyde. Studies have shown similar mutagenic potential of glutaraldehyde at concentrations less than formaldehyde (St. Clair et al., 1991). However, no evidence has verified the carcinogenicity of glutaraldehyde. Similar intestinal effects as those in human postendoscopy cases were observed in animals treated with glutaraldehyde via the colon. The diarrhea and other health effects were linked to severe mucosal damage and colonic lesions believed to be effects similarly produced in humans (Durante et al., 1992). Studies of glutaraldehyde metabolism have reported expired CO₂ as a major byproduct.

Chemical Pathology

The specific pathology of glutaraldehyde is not well understood. Rodent tissue studies have shown high metabolism of glutaraldehyde in the kidney and liver. Glutaraldehyde is not as good a substrate for the dehydrogenase enzymes compared to other aliphatic aldehydes. Metabolic biotransformation of glutaraldehyde likely involves oxidation to glutaric acid (Beauchamp et al., 1992). Other urinary metabolites have

been identified but not characterized. Takigawa and Endo (2006) explain that the major route of metabolism of glutaraldehyde is through oxidation by the kidney and liver resulting in several different byproducts. It is possible that pathological manifestations result by the chemical concentrating in these two organs. Additional research is needed to support this thought. As previously mentioned, glutaraldehyde's ability to crosslink DNA is believed to be the potential mechanism for cancer development. Several research studies have been conducted to examine the carcinogenic pathology of glutaraldehyde but up to this point there is no consensus.

SOURCES OF EXPOSURE

Occupational

Glutaraldehyde is commonly found in the healthcare industry as a disinfecting agent. National Institute for Occupational Safety and Health explains that the chemical is used to sterilize equipment that cannot be heat sterilized, including dialysis instruments, surgical instruments, bronchoscopes, and endoscopes (NIOSH, 2012). Physicians, nurses, medical assistants, and patients are at risk for inhalation or dermal exposure to the chemical. Eight hospital staff members working in an endoscopy unit were exposed to 2% glutaraldehyde and reported lacrimation, rhinitis, dermatitis, respiratory irritation, nausea, and headache (Jachuck et al., 1989). Glutaraldehyde has various uses and can also be found in industries, including tanning, petroleum, water treatment, paper manufacturing, and cosmetic manufacturing. Most worker exposure will be through dermal contact with the chemical; however, inhalation of the chemical is possible. Protective equipment, including gloves, aprons, and face protection may be necessary to prevent dermal contact. In occupations where inhalation may be of concern, proper ventilation or respiratory protection should be considered.

Environmental

Glutaraldehyde is used in a variety of industries and has the potential to be released in the environment from multiple sources. Glutaraldehyde has been found to be toxic to warm and cold water aquatic organisms and is slightly more toxic to freshwater fish when compared to salt water fish (Leung, 2001). Substituting glutaraldehyde with other chemicals with similar properties could help reduce impact on surrounding and aquatic environments. Patients undergoing medical procedures may be at risk for exposure from sources in the health care environment. Medical tools not properly cleansed may have residue that may illicit adverse health reactions in patients. Abdominal pain, diarrhea, and rectal bleeding were symptoms of eight patients receiving either an endoscopy or colonoscopy from a scope-containing glutaraldehyde

residue (Stein et al., 2001). Health care professionals should ensure that medical tools are properly sanitized and rinsed prior to patient use. Closed loop systems and engineering controls may be necessary to prevent environmental sources of glutaraldehyde exposure.

INDUSTRIAL HYGIENE

Inhalation and dermal contact are the main exposure routes for this chemical. Manual washing of medical equipment in glutaraldehyde-containing solutions is the most common hazard for all exposures. Mechanical washing and processes in X-ray development are less hazardous for dermal contact, but glutaraldehyde vapors are still released in measurable amounts. Personal respirators and monitors as well as adequate ventilation in and around the work area will provide adequate respiratory protection against chemical vapors. Protective clothing, aprons, and face shields are recommended to protect against dermal contact with glutaraldehyde. Gloves are necessary, but attention should be given to glove materials. Studies have reported glutaraldehyde penetration of glove materials, including latex and nonlatex rubbers (Lehman et al., 1994). Neoprene or butyl rubber gloves are protective. In order to combat this problem, it is recommended that workers frequently replace and/or double glove. Faulty equipment used for sterilization can also be a source of occupational exposure (Lynch et al., 1994).

Workplace standards for glutaraldehyde vary slightly. The ACGIH (2013) has a short-term exposure limit ceiling of 0.05 ppm while OSHA and NIOSH (2010) have short-term exposure limit ceiling values of 0.2 ppm (0.82 mg/m³). A study reported by Leinster et al. (1993) assessed typical exposure levels in a hospital setting and found that occupational exposure is usually within guidelines. Approximately 35,000 employees are occupationally exposed to glutaraldehyde. Formaldehyde is the most commonly used aldehyde followed by glutaraldehyde. A 2% glutaraldehyde solution used for sterilization can produce airborne concentrations that exceed workplace exposure guidelines.

MEDICAL MANAGEMENT

The hazards associated with glutaraldehyde are well known. It is important to understand that glutaraldehyde is a possible cause of occupational illness. Reports of glutaraldehyde-induced dermatitis and occupational asthma have increased the awareness of its occupational hazards. Occurrence of diseases, such as AIDS, has caused more frequent use of glutaraldehyde as a sterilizing agent in health care settings, thereby increasing risks of exposure (Fowler, 1989). In order to assess occupational exposure, medical surveillance programs should be instituted that include physical examination

and pulmonary function testing. For a surveillance program to be successful, it should monitor an employee prior to employment, during employment, and at the termination. Individuals exposed to high concentrations of glutaraldehyde vapors should be removed from the environment. If symptoms persist after removal, medical treatment should be sought. Individuals exposed dermally to glutaraldehyde should remove contaminated clothing and cleanse affected body parts thoroughly. Contaminated clothing should be discarded in an appropriate manner.

KETONES

ACETONE

Target organ(s): Eyes, skin, respiratory system, central nervous system

Occupational exposure limits: NIOSH—TWA 250 ppm; OSHA—TWA 1000 ppm

ACGIH—TWA 500 ppm, STEL 750 ppm

Reference Values: RfD—0.9 mg/kg/day; RfC—not established; MRL—inhalation 13–26 ppm, Oral 2 mg/kg/day

Hazard statements: H336—may cause drowsiness or dizziness; H319—causes serious eye irritation; H225—highly flammable liquid and vapor

Precautionary statements: P403+P233—store in a well-ventilated place; keep container tightly closed; P405—store locked up; P305+P351+P338—if in eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P243—take precautionary measures against static discharge; P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking

Risk phrases: R11—highly flammable; R36—irritating to eyes; R66—repeated exposure may cause skin dryness or cracking; R67—vapors may cause drowsiness and dizziness

Safety phrases: S2—keep out of the reach of children; S9—keep container in a well-ventilated place; S16—keep away from sources of ignition . . . no smoking; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice

BACKGROUND AND USES

Acetone (dimethyl ketone, ketone propane, 2-propanone; CASRN 67-64-1) is the most prominent and simplest ketone

in terms of volume, giving it wide industrial importance. It is used as an industrial solvent and as a chemical intermediate in many processes involving oils, rubbers, and dyes. Non-industrial uses of acetone are omnipresent and it is most notably used in cosmetics such as nail polish remover.

PHYSICAL AND CHEMICAL PROPERTIES

Acetone is a colorless liquid with a fragrant odor, which has been characterized as fruity or mint like. It is miscible with several other solvents. The chemical has a molecular weight of 58.1, a boiling point of 133 °F, and a freezing point of –140 °F. The vapor pressure is 231 mm Hg at 25 °C and the specific gravity is 0.79. The lower explosive limit is 2.5% and the upper explosive limit is 12.8%. Acetone may be incompatible with oxidizers and acids NIOSH (2010).

MAMMALIAN TOXICOLOGY

Acute Effects

Acetone is commonly seen as the least toxic organic solvent used in industry therefore few hazards are associated with occupational exposure. Eye and mucous membrane irritation, nausea, and headache are likely to be caused by exposure to acetone vapor at higher concentrations. Irritation of the trachea, nose, throat, and lungs are likely to be associated with inhalation exposures. Repeated exposures at high concentrations may cause central nervous system (CNS) depression. A study of workers exposed to high concentrations of acetone (average 1000 ppm) over an 8-h work day reported only an increase in a self-reported “annoyance” category of well-being (Kiesswetter et al., 1994). A study in rats found that acetone caused selective damage to olfactory neuroepithelium over a time of exposure (Burton et al., 2009). Skin absorption is not likely to cause systemic effects. Acetone is similar to ethanol in its anesthetic properties and as an inducer of mixed function oxidase enzyme systems. Animal studies have shown that coadministration of acetone with hepatotoxicants has an additive adverse health effect and increased metabolism of cytochrome P450 substrates (Miller and Yang, 1984; Kobusch et al., 1989; Iba et al., 1993). Bruckner and Peterson (1981) evaluated inhalation reactions to acetone in rodents and demonstrated CNS depression and narcosis, as well as a significant 9-h lag time before full recovery, although the levels examined were extremely high (Bruckner and Peterson, 1981). Also known as a defatting agent, acetone may cause skin defatting and dermatitis.

Chronic Effects

Studies of chronic exposures to acetone have been documented. A mortality study of occupationally exposed

workers showed no excess mortality risk when compared with the general population (Ott et al., 1983). At concentrations far exceeding those expected to occur occupationally, some developmental effects were observed in mice (Mast et al., 1989). However, in a study of solvent exposure and pregnancy outcome, acetone exposure was not associated with an increased rate of miscarriage or fetal malformations (Axelsson et al., 1984). Epoxy resin carcinogenicity of the skin was studied in mice using acetone as a solvent. A control group of mice dermally exposed to acetone alone exhibited no excess incidence of skin tumors or decreased fitness (Zakova et al., 1985). Long-term animal exposure studies found damage to the kidney and liver, as well as birth defects (Niziaeva 1982; NTP, 1991).

Mechanism of Action(s)

There are several different ways that acetone is metabolized. Some acetone is excreted in the urine or exhaled unchanged. The lactate, methylglyoxal, and propanediol pathways are the three known routes of acetone metabolism in humans. Acetone metabolism occurs primarily in the liver and begins with the oxidation of acetone to acetol catalyzed by acetone monooxygenase (Casazza et al., 1984). This is the rate-limiting step for all three pathways. Acetol monooxygenase catalyzes the oxidation of acetol to methylglyoxyl, which is converted to glucose directly or by lactate. Acetol may also be converted to 1,2-propanediol, which is converted to glucose or lactate or breaks down to acetate and formate. The first two pathways are more common at low concentrations because the propanediol pathway is used after the first two become saturated. High blood levels of acetone may result in the metabolism of the compound to isopropyl alcohol, but this was found to occur in mostly diabetic individuals who were not known to be exposed to acetone occupationally (Lewis et al., 1984). Recent research has focused on the development of portable acetone detectors for the identification of diabetes. Righettoni and Tricoli (2011) summarized the strengths and limitations of the device in their review article.

Chemical Pathology

Acetone is typically present in the human body as a result of the breakdown of adipose tissue. It is one of the important normal processes that make energy for bodily function. The health effects of acetone have been the topic of scientific investigation. Rabbit eyes exposed to acetone had changes consistent with mild irritation and corneal injury limited to the epithelium and superficial stroma (Maurer et al., 2001). In addition to inducing irritation in tissue, acetone is often detected in the breath of diabetic patients. In severe cases of ketoacidosis, acetone is often elevated as a result of fatty acid breakdown for energy (Keltanen et al., 2013). One study

found that acetone gas emanating from diabetic rat tails was significantly higher (1134 ppb) when compared to a control group (124 ppb) (Yamai et al., 2012). Animals provided large quantities of acetone to drink developed bone marrow hypoplasia, degeneration of kidneys, and abnormal sized livers (NTP, 1988; NTP, 1991).

SOURCES OF EXPOSURE

Occupational

Acetone is a widely used solvent in industry so occupational exposure can easily occur. It is also used in the application of lacquers and varnishes. A study of 157 Romanian coin and medal factory workers found negative effects on human performance and evidence of neurotoxicity when acetone concentrations over an 8-h work shift ranged from 988 to 2114 mg/m³ (Mitran et al., 1997). The values reported were above occupational exposure limits in the country. Acetone is commonly used in nail salons to remove nail polish during manicures and pedicures. One study examining acetone concentrations in nail salons found acetone was present in 96% of 70 environmental samples (Gjolstad et al., 2006). In order to prevent exposure to acetone in the work environment, personal respirators and ventilation should be used if inhalation is of concern. If dermal contact is of concern, protective clothing, including aprons, face shields, safety glasses, and gloves are recommended.

Environmental

Volatile organic compounds are known to contaminate indoor environments. In certain environmental conditions, VOCs can produce gas vapors, leading to occupant exposure. Acetone belongs to this class of chemicals. Air fresheners used in homes oxidize 2-methylpropanol to acetone with emission rates ranging from 530 mg/h to 660 mg/h and an acetone concentration of 700 µg/m³ (Geiss et al., 2014). Increasing the amount of air exchanges or ventilation in the indoor environment can reduce the buildup of acetone vapors. In addition, selecting building materials with low VOCs can also reduce contaminant buildup. Trace amount of acetone can be found in automobile exhaust, tobacco smoke, and landfill material. Acetone-containing waste found in landfills may be a major source of environmental contamination. Soil and water can become contaminated when acetone is leached from landfill waste products. When acetone enters soil or water, it can either evaporate or be removed by microbes (Ramachandriya et al., 2011). Reducing waste or substituting other solvents in place of acetone may reduce the amount that enters the outside environment.

INDUSTRIAL HYGIENE

Exposures to acetone occur mostly via inhalation and dermal contact. This results primarily in an irritant response. Acetone is known to have low toxicity in humans. No known lethaliities are associated with occupational exposure to acetone. The odor threshold, 0.2–1.5 ppm, is significantly lower than any exposure guidelines set for acetone. Therefore detecting odor of acetone does not point to a hazard. Since acetone has irritant properties, casual contact with concentrations high enough to be considered as a health hazard would generally not be tolerated by workers.

Workers exposed to high concentrations of acetone should wear recommended protective clothing and personal respirators. Materials used as a barrier for acetone should be evaluated carefully for breakthrough time. Acetone was shown to pass through neoprene rubber independent of the thickness of the material evaluated (Berardinelli and Meyer, 1988). Monitoring for acetone vapor concentrations in the atmosphere can be achieved. Some polymers of sorbent material were not reliable for acetone in normal solid sorbent assays (Levin and Carleborg, 1987). Adsorption of acetone by an activated charcoal medium followed by gas chromatography analysis produced positive reliable results (Whitehead et al., 1984).

The PEL set by OSHA for acetone is 1000 ppm (2400 mg/m³), with NIOSH having a lower recommendation (REL) of 250 ppm (590 mg/m³). The ACGIH has set guidelines (TLV/ STEL) for acetone exposures at 500 ppm/750 ppm (1780 mg/m³, 2380 mg/m³). Acetone is not designated as a suspected carcinogen.

MEDICAL MANAGEMENT

Studies of biomonitoring have identified detectable amounts of unchanged acetone in the urine of workers occupationally and experimentally exposed via inhalation (Pezzagno et al., 1986). These concentrations paralleled rises in environmental concentrations and the amount absorbed. An analysis of urine, alveolar air, and blood concentrations of acetone further demonstrated urine as the most reliable indicator for monitoring exposure (Fujino et al., 1992). The ubiquitous nature of acetone in the environment and body makes acetone an ever-present constituent of urine in those non-occupationally exposed (Ashley et al., 1994). These normal amounts of acetone in the urine make the relationship between urinary and environmental concentrations curvilinear as opposed to linear (Kawai et al., 1992). Increases in urinary acetone will likely not be detectable until atmospheric concentrations reach a level capable of changing endogenous levels and subsequently leading to increases in urinary acetone levels.

CYCLOHEXANONE

Target organ(s): Eyes, skin, respiratory system, central nervous system, liver, kidneys

Occupational exposure limits: NIOSH—TWA 25 ppm; OSHA—TWA 50 ppm; ACGIH—TWA 20 ppm, STEL 50 ppm

Reference values: RfD—5 mg/kg/bw/day; RfC/MRL—not established

Hazard statements: H226—flammable liquid and vapor; H302—harmful if swallowed; H312—harmful in contact with skin; H332—harmful if inhaled; H315—causes skin irritation; H318—causes serious eye damage

Risk phrases: R10—flammable; R20—harmful by inhalation ($\geq 25\%$)

Safety phrases: S2—keep out of reach of children; S25—avoid contact with eyes

BACKGROUND AND USES

Cyclohexanone (symbol CH; anone, cyclohexyl ketone, pimelic ketone; CASRN 108-94-1) is a primarily used in industry, up to 96%, as a chemical intermediate in the production of nylons 6 and 66. Oxidation or conversion of cyclohexanone yields adipic acid and caprolactam, two of the immediate precursors to the respective nylons. Cyclohexanone can also be used as a solvent in a variety of products, including paints, lacquers, and resins. It has not been found to occur in natural processes.

PHYSICAL AND CHEMICAL PROPERTIES

Cyclohexanone is a colorless liquid with a water-white to pale yellow liquid with a peppermint or acetone-like odor. It is miscible with several other solvents. The chemical has a molecular weight of 98.2, a boiling point of 312°F, and a freezing point of -49°F. The vapor pressure is 5 mm Hg at 26.4°C and the specific gravity is 0.95. The lower exposure limit is 1.1% and the upper exposure limit is 9.4%. Cyclohexanone may be incompatible with oxidizers and nitric acid.

MAMMALIAN TOXICOLOGY

Acute Effects

Exposure to cyclohexanone is known to cause acute effects that are primarily irritation. The most likely areas to be affected by high concentrations of the chemical are the eyes and respiratory system. It has the potential to act as a central nervous system depressant, although its effect is weaker than other ketones. Dizziness and unconsciousness can also result. Mice exposed to extremely high concentrations of cyclohexanone vapors were found to have lung edema and congestion (Gupta et al., 1979). These

concentrations are unlikely to occur occupationally. Neonatal rats were acutely exposed to cyclohexanone intravenously with no adverse health effects reported (Greener et al., 1987). Cutaneous or subcutaneous exposure of cyclohexanone over a period of several days resulted in cataracts in guinea pigs (NIOSH, 1988).

Chronic Effects

There are few available reports on the chronic toxicity of cyclohexanone in humans. Bruze et al. (1988) reported a handful of cases of sensitization contact allergies to a cyclohexanone resin in humans and a follow-up investigation with guinea pigs. Although positive results were found, the resin contained not only cyclohexanone, but other chemicals as well. No associations have been found between cyclohexanone exposure and teratogenicity or carcinogenicity. The ACGIH (2013) has given cyclohexanone an A3 rating, designating this compound is a confirmed animal carcinogen with unknown relevance to humans.

Animal studies involving cyclohexanone exposure are present in the literature. Subchronic intravenous administration of cyclohexanone in rats showed no adverse effects at relatively low doses similar to occupational exposure limits (Greener et al., 1982). A study of rats and mice by Lijinsky and Kovatch (1986) found only a weak carcinogenic effect at extremely high dose levels. There has been some indication that a cumulative toxic effect in mice may occur with cyclohexanone (Gupta et al., 1979). Mitran et al. (1997) conducted a study that showed there may be a relationship between cyclohexanone exposure and neurotoxicity.

Mechanism of Action(s)

The metabolism of cyclohexanone has been characterized in humans and animals. Major metabolites found after exposures to cyclohexanone are cyclohexanol, 1,2- and 1,4-cyclohexanediol, and their glucuronide conjugates (Martis et al., 1980; Sakata et al., 1989; Mraz et al., 1994). These can be detected in breath or in urine by gas chromatography with flame ionization detection. The biological half-life of cyclohexanone is short, leading to a fairly rapid clearance of this compound. Very little, if any, of the parent compound is detectable in plasma or urine.

Chemical Pathology

Research has examined the chemical pathology of cyclohexanone. It has been suspected to cause neurotoxicity in mammals. A study conducted by Koeferl et al. (1981) found that beagle dogs exposed to cyclohexanone developed signs of toxicity, including lacrimation, urination, defecation, stupor, ataxia, and convulsive movements. The chemical is also known to cause skin irritation after contact. It leads to

dermatitis be defatting the skin after repeated contact (NLM, 2005). Itching, redness, and inflammation will be present at the site of exposure. Ingestion is not a typical route of exposure for cyclohexanone; however, it is possible. An individual that ingested the chemical developed an altered mental state, shock, acidosis, hepatitis, a renal dysfunction (Zuckerman et al., 1998). The route of exposure appears to determine what body systems are impacted.

SOURCES OF EXPOSURE

Occupational

Cyclohexanone is used in many different industrial processes that may lead to exposure. The chemical is used as to coat fabrics and plastics, in the cleaning of leathers and textiles, and as a solvent in different chemical formulations (NIOSH, 1988). Occupational exposure can occur by inhalation and skin or eye contact. There are two major methods used to control cyclohexanone concentrations in the work environment. Local exhaust ventilation is one way to control exposure. Contaminated air is captured and exhausted to the outside atmosphere. Personal protective equipment is the other way to control exposure. Personal protective equipment, including aprons, gloves, and goggles, prevent the chemical from contacting exposed body parts. Exposed workers should be removed from the contaminated environment and provide medical care. Skin and eyes should be flushed with large amounts of water if they are contacted by cyclohexanone. Personal respiratory protection may be necessary for work in areas where cyclohexanone concentrations are high.

Environmental

Cyclohexanone exposure can occur during the manufacture, processing, distribution, and disposal of the chemical. The use of a closed system can prevent the release of the chemical into the environment. Cyclohexanone can be emitted into the atmosphere during such industrial processes. Those living in surrounding areas could be at risk of inhaling contaminated air or coming into contact with contaminated water. Since cyclohexanone can be used as a solvent, the chemical can evaporate readily into the air. Environmental contamination of the soil and water is possible if cyclohexanone is not disposed off properly. The chemical can volatilize from both soil and water leading to potential inhalation. The National Library of Medicine estimates that the half-life of cyclohexanone in a model river and model lake is 4.1 and 33 days, respectively (NLM, 2005). Industrial companies utilizing the chemical should follow proper procedures to prevent the release of the chemical into the environment.

INDUSTRIAL HYGIENE

Occupational exposure to cyclohexanone is most likely to occur through inhalation, although dermal contact may also have adverse health effects. With its strong odor, cyclohexanone can be detected well below harmful concentrations. The odor threshold for this compound is 0.480 mg/m³ (Ruth, 1986). Air-supplied respirators and area ventilation may be necessary for workers exposed to cyclohexanone. Skin protection should be used when contact is anticipated. Airborne concentrations of cyclohexanone can be monitored using charcoal tubes and carbon disulfide solvent. Contaminants are extracted with simple adsorption techniques followed by gas chromatography analysis.

The OSHA PEL for atmospheric concentrations of cyclohexanone is 50 ppm (200 mg/m³), the NIOSH (2010) REL is 25 ppm (100 mg/m³), and the ACGIH (2013) TLV is 20 ppm (80 mg/m³). The NIOSH and the ACGIH recommendations also include a skin designation.

MEDICAL MANAGEMENT

NIOSH recommends several practices to protect workers from occupational exposure: medical surveillance, preplacement medical evaluation, periodic screening, biological monitoring, and follow-up medical practices at job transfer or termination of employment (NIOSH, 1988). The development of contact and/or allergic dermatitis should be considered a sentinel health event and should warrant investigation into the cause. If cyclohexanone contacts the eyes or the skin, copious amounts of water should be used to flush the chemical from the affected area. Exposed workers should seek prompt medical attention. The metabolites of cyclohexanone can be used as biomarkers for occupational exposure. Ong et al. (1991) found a significant correlation between urinary cyclohexanol and environmental concentrations ($r=0.77$). A lesser association was found with exhaled breath concentrations of cyclohexanone. Chemical protective clothing should be used to prevent contact with the skin. Face shields or safety glasses should be used to prevent the chemical from splashing into the eyes.

METHYL *n*-BUTYL KETONE

Target organ(s): Eyes, skin, respiratory system, central nervous system, peripheral nervous system

Occupational exposure limits: NIOSH—TWA 1 ppm; OSHA—TWA 100 ppm

ACGIH—TWA 5 ppm, STEL 10 ppm

Reference Values: RfD/MRL—not established; RfC—3 mg/m³

Risk phrases: R10—flammable; R48/23—toxic: danger of serious damage to health by prolonged exposure through inhalation; R62—possible risk of impaired fertility; R67—vapors may cause drowsiness and dizziness

Safety phrases: S1/2—keep locked up and out of the reach of children; S36/37—wear suitable protective clothing and gloves; S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible)

BACKGROUND AND USES

Methyl *n*-butyl ketone (symbol MBK; 2-hexanone, butyl methyl ketone, methyl butyl ketone; CASRN 591-78-6), like most monoketones, is used extensively as an industrial solvent for lacquers, resins, and oils in industries such as plastics, coatings, and leather manufacturing. Methyl *n*-butyl ketone is found in nature in low concentrations and in foodstuffs, such as blue cheese and nectarines.

PHYSICAL AND CHEMICAL PROPERTIES

Methyl *n*-butyl ketone is a colorless liquid with an odor similar to acetone, giving it a low odor threshold. It is slightly soluble in water at 2% by weight and is more soluble in other organic solvents. The chemical has a molecular weight of 100.2, a boiling point of 262°F, and a freezing point of -71°F. The vapor pressure is 11.6 mm Hg at 25°C and the specific gravity is 0.81. The lower flammable limit is 1.2%, and the upper flammable limit is 8%. Methyl *n*-butyl ketone may be incompatible with strong oxidizers.

MAMMALIAN TOXICOLOGY

Acute Effects

Methyl *n*-butyl ketone can be a potent lacrimator at high concentrations and can act as an irritant to the mucous membranes, skin, and eyes. High concentrations of the chemical will be intolerable to the average worker. Central nervous system depression may result from repeated exposures to high concentrations. DiVincenzo et al. (1978) demonstrated methyl *n*-butyl ketone is readily absorbed in humans through the skin (between 75 and 92%), the lungs, and the gastrointestinal tract. Methyl *n*-butyl ketone may also result in coughing, wheezing, headache, dizziness, lightheadedness, and passing out (NJDOH, 2009). Individuals suffering from acute exposure to the chemical should be removed from the area of exposure immediately.

Chronic Effects

Chronic occupational exposure to MBK may be a hazardous to worker health. Unlike other ketones of low toxicity, methyl *n*-butyl ketone has been found to be a potent neurotoxin. Sentinel cases of peripheral neuropathy resulting from solvent exposure dating back to the early 1970s. This prompted epidemiological investigations in populations exposed to, among other solvents, methyl *n*-butyl ketone. Reports by Billmaier et al. (1974) and Allen et al. (1975) were among the first to identify the relationship between methyl *n*-butyl ketone and the polyneuropathies seen among workers in plastic coating factories. Populations of workers were screened with a variety of neurological tests and rated according to the severity of the disease. Muscle weakness, sensory and motor dysfunction, and distal electromyographic abnormalities were the most common health effects noted in investigations. Reflex loss was minimal. No relevant human or animal data existed to suggest a causal association with methyl *n*-butyl ketone. Methyl *n*-butyl ketone along with other solvents has been associated with motor neuron disease in the leather industry and in association with spray painting (Mallov, 1976; Hawkes et al., 1989). The association between exposure to methyl *n*-butyl ketone and the development of neurological abnormalities was discovered in subsequent animal studies.

Mendell et al. (1974) reported data from chickens, rats, and cats exposed to 200, 600, and 600 ppm methyl *n*-butyl ketone, respectively. Clinical weakness was found in all species with cats experiencing some slowing of nerve conduction. Inhalation studies in a rat population showed clinical weakness in the hindlimbs and pathological examination revealed a degeneration of nerve fibers (Spenser et al., 1975). Another study exposed monkeys and rats to 1000 ppm and 100 ppm for up to 10 months 5 days a week for 6 h (Johnson et al., 1977). A progressive decrease in motor conduction velocity developed in monkeys from the high-dose group. Similar but less pronounced effects were found lower exposure groups. Some behavioral effects and weight loss were also noted, although no effects were observed in other neurological tests such as visual effects, electroencephalogram readings, or absolute refractory time. No investigations concerning the carcinogenicity or teratogenicity of this compound have been documented.

Mechanism of Action(s)

The identification of neurotoxic properties has made the study of methyl *n*-butyl ketone metabolism a topic of interest to researchers. The main metabolites of methyl *n*-butyl ketone identified in animal systems are 5-hydroxy-2-hexanone, 2-hexanol, and 2,5-hexanedione, a diketone that is also a metabolite of *n*-hexane (DiVincenzo et al., 1976; Granvil et al., 1994). 2-Hexanol is created through a reduction

reaction with the oxidative pathway first producing 5-hydroxy-2-hexanone, followed by a further oxidation to 2,5-hexanedione. Both methyl *n*-butyl ketone and *n*-hexane cause similar neuropathies, and this common 2,5-hexanedione metabolite became the focus of methyl *n*-butyl ketone toxicity studies.

A study of rodents by Couri et al. (1978) demonstrated that oxidation of methyl *n*-butyl ketone to 2,5-hexanedione occurred in the microsomal fraction of the liver and that the reduction of 2-hexanol takes place in the cytosol. It has been shown in mice that, although 2,5-hexanedione appears not to be metabolized further, 2-hexanol may be oxidized back to methyl *n*-butyl ketone or to 2,5-hexane-dione (Granvil et al., 1994). Formation of 2,5-hexanedione is initially slower than 2-hexanol, but the total concentration of 2,5-hexanedione produced may be greater. Krasavage et al. (1978) found a significant relationship between relative neurotoxicity and serum levels of the 2,5-hexanedione metabolite in rodents.

Chemical Pathology

Methyl *n*-butyl ketone research has determined that there is an association between chemical exposure and the development of neuropathies. A prominent feature of these neuropathies is a portion of the axons in the nervous system undergo a “dying back” phenomenon. Distal to proximal dying back axonopathy results when the metabolite 2,5-hexanedione inhibits rapid axon protein transport and glutaraldehyde-3-phosphate dehydrogenase. Neurofilament accumulation, axonal enlargement, and retraction of the myelin sheath can result when the neuropathy is mainly associated with long distal myelinated nerves. A distal motor neuropathy may be formed in the upper and lower extremities. Weakness and loss of sensation of touch and temperatures are insidious in onset and typically symmetrical. Symptoms may progress even after exposure ceases. Confusion, incoordination, and changes in color vision may also be observed when the central nervous system is affected. Reclamation of both central nervous system and peripheral losses may be slow and take several years.

Examination of nerve biopsies from workers with peripheral neuropathy thought to be the result of methyl *n*-butyl ketone exposure revealed accumulation of neurofilaments and enlarged axons (Davenport et al., 1976). Chronic intoxication of cats with methyl *n*-butyl ketone also showed axon swelling with neurofilaments and changes in myelin sheaths and overt fiber breakdown (Spenser and Schaumberg, 1976). Axonal transport is blocked by these accumulations. Dorsal neural tubes were found to be malformed in chick embryos exposed to 2,5-hexanedione, the metabolite of methyl *n*-butyl ketone, indicating a direct effect on nervous system development (Cheng et al., 2012). *n*-Hexane neuropathies are known to have similar pathological findings.

SOURCES OF EXPOSURE

Occupational

Methyl *n*-butyl ketone is widely used as a solvent in industry. It can be found in paints, varnishes, lacquers, and waxes. There are two primary techniques used for methyl *n*-butyl ketone synthesis. The first is a 75% yield reaction of acetyl chloride with butyl magnesium chloride. The second reaction involves a catalyzed reaction of acetic acid and ethylene followed by a distillation reaction to purify the product. Synthesis and industrial application can lead to occupational exposures of methyl *n*-butyl ketone. Occupational exposure to methyl *n*-butyl ketone is likely to occur primarily through vapor inhalation. Dermal exposure is considered as a secondary route and can occur if the chemical is splashed on the skin and not removed. Unintentional ingestion of this compound is not likely. The probability of acute overexposure is remote since the chemical has a strong odor. The strong odor helps to indicate hazardous concentrations of methyl *n*-butyl ketone.

Environmental

Similar to other solvents, methyl *n*-butyl ketone can be released into the environment by a variety of different waste streams. Because of its volatility, vapors are easily released into the atmosphere. The half-life of methyl *n*-butyl ketone in air is estimated to be 2 days (NCBI, 2014). Individuals using the chemical should do so in an area with adequate ventilation. The use of personal respiratory protection may also be necessary. Methyl *n*-butyl ketone volatizes from both soil and water as well. The volatilization of the chemical from the soil is directly dependent on its vapor pressure and the half-life in a model river and a model lake is 7 h and 164 h, respectively (NCBI, 2014). The chemical is not believed to bioaccumulate in aquatic organisms. Those using methyl *n*-butyl ketone should ensure that the chemical is not spilled. If it is spilled, the chemical should be cleaned up immediately to prevent it from negatively impacting the surrounding environment.

INDUSTRIAL HYGIENE

Engineering controls for methyl *n*-butyl ketone should include adequate ventilation to limit inhalation exposures. Proper ventilation will also prevent exposure of the compound to excessive heat and/or sparks, as this compound is flammable. Workers who come into contact with methyl *n*-butyl ketone should be provided with adequate protection, including protective clothing and a supplied-air respirator with a full face piece. The NIOSH (2010) guideline (REL) of 1 ppm (4 mg/m^3) for airborne concentrations of methyl *n*-butyl ketone is significantly lower than the OSHA PEL

of 100 ppm (400 mg/m^3). The ACGIH (2013) has set the TLV for methyl *n*-butyl ketone at 5 ppm (mg/m^3) with a STEL of 10 ppm (41 mg/m^3).

MEDICAL MANAGEMENT

Workers diagnosed with peripheral neuropathy in these cases were observed to have a similar pattern of distal motor and sensory disorder with insignificant reflex loss (Allen et al., 1975). Muscle weakness and atrophy, decreased nerve conduction velocities, and loss of body weight are classic signs and symptoms indicating methyl *n*-butyl ketone exposure. For suspected cases of peripheral neuropathy, abnormal electromyogram, and nerve biopsies are useful diagnostic tools. There is no direct treatment for this condition, although cessation of exposure to methyl *n*-butyl ketone is required. A majority of animal and human subjects experienced total recovery from methyl *n*-butyl ketone-induced peripheral neuropathy after a period of discontinued exposure.

Few studies have developed reliable tests to measure worker exposure to methyl *n*-butyl ketone even with its positive association with neuropathies. Plasma and tissue concentrations of methyl *n*-butyl ketone in rats were found to correlate with exposure concentrations in a dose-dependent manner (Duguay and Plaa, 1995). Detection of significant levels of the metabolite 2,5-hexanedione were found to relate to exposure route, particularly via inhalation. Urinary concentrations of 2,5-hexanedione are more readily measurable than unchanged methyl *n*-butyl ketone (DiVincenzo et al., 1978).

The presence of 2,5-hexanedione in the metabolic pathway of *n*-hexane confounds the detection of this compound to indicate exposure to only methyl *n*-butyl ketone. In addition, the extremely low levels of exposure (1–5 ppm) that occur in the workplace have not been shown to correlate with current biomonitoring techniques (Bos et al., 1991). Occupational exposure to methyl *n*-butyl ketone should be carefully monitored because of its direct effect on the central and peripheral nervous system. Methyl *n*-butyl ketone also interacts with other industrial chemicals and may affect the biotransformation of these same materials. Other ketones, such as methyl ethyl ketone, have been shown to potentiate the effects of the neuropathy (Abdel-Rahman et al., 1976).

METHYL ETHYL KETONE

Target organ(s): Eyes, skin, respiratory system, central nervous system

Occupational exposure limits: NIOSH—TWA 200 ppm, ST 300 ppm; OSHA—TWA 200 ppm; ACGIH—TWA 200 ppm, STEL 300 ppm

Reference values: RfD—0.6 mg/kg/day; RfC—5 mg/m³; MRL—not established

Hazard statements: H225—highly flammable liquid and vapor; H319—causes serious eye irritation; H336—may cause drowsiness or dizziness

Precautionary statements: P102—keep out of reach of children; P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking; P233—keep container tightly closed; P240—ground/bond container and receiving equipment; P241—use explosive-proof electrical/ventilating/lighting/ . . . /equipment; P242—use only non-sparking tools; P243—take precautionary measures against static discharge; P261—avoid breathing dust/fume/gas/mist/vapors/spray; P264—wash . . . thoroughly after handling; P271—use only outdoors or in a well-ventilated area; P280—wear protective gloves/protective clothing/eye protection/face protection; P405—store locked up; P501—dispose of contents/container to . . . ; P303+P361+P353—if on skin (or hair), remove/take off immediately all contaminated clothing; rinse skin with water/shower; P304+P340—if inhaled, remove victim to fresh air and keep at rest in a position comfortable for breathing; P305+P351+P338—if in eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P312—call a poison center or doctor/physician if you feel unwell; P337+P313—if eye irritation persists, get medical advice/attention; P370+P378—in case of fire; use . . . to extinguish; P403+P233—store in a well-ventilated place; keep container tightly closed; P403+P235—store in a well-ventilated place; keep cool

Risk phrases: R11—highly flammable; R36—irritating to eyes; R66—repeated exposure may cause skin dryness or cracking; R67—vapors may cause drowsiness and dizziness

Safety phrases: S2—keep out of the reach of children; S9—keep container in a well-ventilated place; S16—keep away from sources of ignition . . . no smoking

BACKGROUND AND USES

Methyl ethyl ketone (symbol MEK; 2-butanone, ethyl methyl ketone, methyl acetone; CASRN 78-93-3) is an organic solvent of relatively low toxicity, which is found in many applications. It is used in industrial and commercial products as a solvent for adhesives, paints, and cleaning agents and as a de-waxing solvent. A natural component of some foods, methyl ethyl ketone can be released into the environment by volcanoes and forest fires.

PHYSICAL AND CHEMICAL PROPERTIES

Methyl ethyl ketone is a colorless liquid with an odor that has been described as moderately sharp, fragrant, peppermint, or acetone like. It soluble in water up to 28% by weight and is miscible with many other organic solvents. The chemical has a molecular weight of 72.1, a boiling point of 175 °F, and a freezing point of –123 °F. The vapor pressure is 90.6 mm Hg at 25 °C and the specific gravity is 0.81. The lower explosive limit is 1.4% and the upper explosive limit is 11.4%. Methyl ethyl ketone may be incompatible with strong oxidizers, amines, ammonia, inorganic acids, caustics, isocyanates, and pyridines. When used industrially, methyl ethyl ketone must be handled with caution, as it is a Class IB flammable liquid NIOSH (2010).

MAMMALIAN TOXICOLOGY

Acute Effects

The acute effects of methyl ethyl ketone are similar to acetone. Dermal contact to methyl ethyl ketone can have irritant effects, such as contact urticaria (Varigos and Nurse, 1986). If methyl ethyl ketone comes in contact with the eyes, corneal damage and irritation can occur. When concentrations rise above 200 ppm, eye, nose, and throat irritation occurs. Continual exposure to elevated concentrations may result in central nervous system depression. Most health hazards associated with methyl ethyl ketone occur with inhalation exposure. Implicating methyl ethyl ketone exposure in occupational illness is confounded by the coexposures to other solvents and ketones, including acetone, toluene, and n-hexane. Decrease or change in neurologic function has been noted in most reports. Cases of polyneuropathy in separate shoe factories were suspected to be associated with methyl ethyl ketone, but the author could not conclude whether methyl ethyl ketone was the cause of the disease or acted as a potentiator for acetone, toluene, or n-hexane coexposures (Dyro, 1978; Vallat et al., 1981). A more recent study of volunteers working in a factory found no significant relationship to short duration methyl ethyl ketone exposures

of 200 ppm and neurological effects measured by specific motor tasks (Dick et al., 1988, 1989). A synergistic effect of methyl ethyl ketone was described by Altenkirch et al. (1977) in toxic polyneuropathies associated with individuals sniffing glue thinner as a substitute for illegal drugs. n-Hexane and methyl butyl ketone were reported to be the compounds mainly responsible for the neurological damage. An individual reportedly ingested a high dose of methyl ethyl ketone and was found unconscious with some respiratory and circulatory distress and a high degree of lactic acidosis (Kopelman and Kalfayan, 1983). Sodium bicarbonate was issued as treatment and the patient recovered completely. No residual effects were observed. A 2-year prospective study found that individuals working in a screen printing business had significantly impaired motor functions on dexterity tests, decreased visual memory, and impaired mood following acute exposure to a variety of chemicals, including methyl ethyl ketone (White et al., 1995).

Chronic Effects

Chronic illness associated with methyl ethyl ketone has not been well documented. A retrospective cohort mortality study by Wen (1985) found a decrease in overall cancer deaths and no significant site-specific cancer increase associated with methyl ethyl ketone exposure. A study of rats exposed for up to 7 weeks to extremely high concentrations of methyl ethyl ketone vapor did not show any neurology-related effects, although the animals did die of bronchopneumonia (Altenkirch et al., 1979). This study also showed a similar type of coexposure potentiation with n-hexane-induced neuropathies. Another study found that individuals chronically exposed to chemicals, including methyl ethyl ketone exhibited significantly poor performance on visual memory tasks and mood (White et al., 1995). The implication of methyl ethyl ketone as the causative agent of neurological decline was confounded by coexposures to other solvents during the study. Inhalation studies of pregnant rats did not reveal any significant fetotoxic or embryotoxic effects at exposure levels causing maternal toxicity (Deacon et al., 1981; Stoltenburg-Didinger et al., 1990). Shoe workers exposed to multiple organic substances, including methyl ethyl ketone experienced cytogenetic damage to buccal cells (Burgaz et al., 2002). A potential association may exist between cellular damage and methyl ethyl ketone exposure; however, this could not be determined by the noted study due to coexposures with other solvents.

Mechanism of Action(s)

The metabolism and distribution of methyl ethyl ketone has been studied in both humans and animals. The analysis of excreted urine and exhaled breath may yield small amounts of unchanged methyl ethyl ketone. It is also oxidized by

enzymes to 3-hydroxy-2-butanone and 2,3-butanediol and reduced to 2-butanol. Relatively little of these metabolites are detected in the urine or in expired air (Liira et al., 1990). According to a study by Liira et al. (1988), human volunteers exposed to 200 ppm of methyl ethyl ketone for 4 h excreted 3% of absorbed methyl ethyl ketone unchanged in exhaled breath and 2% excreted in the urine. Brown et al. (1987) examined the pharmacokinetics of methyl ethyl ketone in exposed volunteers and found a significant correlation between blood and breath levels. Assuming first order kinetics, the biological half-life for methyl ethyl ketone can be calculated to be approximately 49 min, which is much lower than that of acetone.

Chemical Pathology

Methyl ethyl ketone is known to cause irritation of eyes, skin, and respiratory system. When individuals were exposed to methyl ethyl ketone (200 ppm) along with methyl isobutyl ketone (100 ppm) for 4 h, odor sensations and irritant effects were reported (Dick et al., 1992). The polyneuropathies associated with methyl ethyl ketone are possibly a result of a potentiative effect of methyl ethyl ketone on the toxicity of other compounds. A study by Schmidt et al. (1984) showed more neurological changes in rats exposed to n-hexane and MEK than those exposed to n-hexane alone. Occupational exposure to methyl ethyl ketone is almost always concurrent with other solvents and compounds making it extremely difficult to determine which specific chemical may be responsible for pathological manifestations. The USEPA defines methyl ethyl ketone as a Group D (USEPA, 2000). This means that it is not classifiable as a human carcinogen based on human and animal data.

SOURCES OF EXPOSURE

Occupational

Methyl ethyl ketone is similar to other ketones in that it is widely used as an industrial solvent. It can be found in paints, paint removers, and adhesives. Methyl ethyl ketone is usually produced from a hydrogenation or selective oxidation reaction of sec-butyl alcohol. Major exposure routes include vapor inhalation and dermal contact. Ventilation and personal respiratory protection with organic cartridges are recommended to prevent inhalation exposure. Dermal contact can be prevented by using aprons, gloves, and goggles. Any skin that is exposed to methyl ethyl ketone should be cleansed immediately to limit the amount of the chemical that can be absorbed. Ingestion of methyl ethyl ketone is highly unlikely. The odor threshold for methyl ethyl ketone is low enough to alert workers of workplace concentrations far below those expected to be hazardous. Methyl ethyl ketone

does not typically remain in the body as it is metabolized and excreted in exhaled breath and urine.

Environmental

Much like other organic solvents, methyl ethyl ketone evaporates readily when exposed to the atmosphere. Individuals using the solvent should ensure that there is adequate ventilation to prevent chemical concentrations from building up. If ventilation is not available, personal respiratory protection may be necessary. Organic vapor cartridges must be attached to respirators to prevent inhalation exposure. Individuals using methyl ethyl ketone should avoid spilling the chemical as it could lead to negative environmental impact. The chemical can leach into groundwater and surrounding soil. Methyl ethyl ketone readily dissolves when mixed with water but can evaporate from both water and soil. Microorganisms present in both water and soil can breakdown the chemical and it is not likely to bioaccumulate in plants or animals (USEPA, 1994). Methyl ethyl ketone has the potential to contribute to the development of smog in urban and industrial areas when it reacts with organic substance in the atmosphere.

INDUSTRIAL HYGIENE

Methyl ethyl ketone is widely used in various occupational settings so exposure can easily occur. Workers likely to be exposed to high concentrations of methyl ethyl ketone vapors are advised to wear personal respirators with the appropriate filtering system. Proper ventilation may also be necessary to remove contaminated air from the work environment. Protective clothing, including aprons and gloves, can prevent dermal contact with the chemical. Irritation and injury may result if the chemical comes in contact with the eyes, therefore goggles should be worn. In a study by Vahdat et al. (1995) solid adsorbent tubes were found to be efficient and accurate for detecting atmospheric concentrations of methyl ethyl ketone. OSHA methods 16, 84, and 1004 as well as NIOSH method 2500 are validated sampling procedures for methyl ethyl ketone. Workplace allowable atmospheric concentrations of methyl ethyl ketone are similar for all guidelines. The ACGIH, NIOSH, and OSHA have all set their respective guideline values (TLV, REL, and PEL) at 200 ppm (590 mg/m^3), with a STEL for NIOSH and the ACGIH of 300 ppm (885 mg/m^3).

MEDICAL MANAGEMENT

Methyl ethyl ketone exposure can be monitored by examining contaminant levels in urine. Although the concentrations may be low, they may indicate that exposure has taken place. Ghittori et al. (1987) found a linear relationship between

exposure TWA concentrations and urinary concentrations in subjects exposed to a variety of solvents, including methyl ethyl ketone. Ong et al. (1991) examined three different methods for monitoring exposure to methyl ethyl ketone and found that urine was the most reliable exposure indicator when compared to blood and exhaled breath. Another study found that urine was a better indicator of methyl ethyl ketone exposure when compared to blood (Yoshikawa et al., 1995). It can also be detected in expired air by gas chromatography (Brown et al., 1987). Individuals exposed to methyl ethyl ketone may experience irritation of the eyes, skin, and nose, as well as headache dizziness, and vomiting. They should be removed from the contaminated environment and provided medical attention immediately.

METHYL ISOBUTYL KETONE

Target organ(s): Eye, skin, respiratory system, central nervous system, liver, kidneys

Occupational exposure limits: NIOSH—TWA 50 ppm, ST 75 ppm; OSHA—TWA 100 ppm; ACGIH—TWA 20 ppm, STEL 75 ppm

Reference values: RfD/MRL—not established; RfC—3 mg/m³

Hazard statements: H225—highly flammable liquid and vapor; H332—harmful if inhaled; H319—causes serious eye irritation; H335—may cause respiratory irritation.

Precautionary statements: P210—keep away from heat/sparks/open flames/. . . /hot surfaces . . . no smoking; P261—avoid breathing dust/fume/gas/mist/vapors/spray; P280—wear protective gloves/protective clothing/eye protection/face protection; P303+P361+P353—if on skin (or hair), remove/take off immediately all contaminated clothing; rinse with water/shower; P312—call a poison center or doctor/physician if you feel unwell; P403+P233—store in a well-ventilated place; keep container tightly closed.

Risk phrases: R11—highly flammable; R20—harmful by inhalation; R37—irritating to respiratory system; R66—repeated exposure may cause skin dryness or cracking.

Safety phrases: S2—keep out of the reach of children; S9—keep container in a well-ventilated place; S16—keep away from sources of ignition . . . no smoking; S29—do not empty into drains.

BACKGROUND AND USES

Methyl isobutyl ketone (symbol MIBK; hexone, isobutyl methyl ketone, 4-methyl-2-pentanone; CASRN 108-10-1) is an organic solvent similar in structure and use to methyl butyl ketone. In addition to its use as a solvent for paints, lacquers, and varnishes, methyl isobutyl ketone is used in extraction processes and as a denaturant for rubbing alcohol. Methyl isobutyl ketone is also used as a synthetic flavoring in some varieties of rum, candy, and cheese. Unlike methyl butyl ketone, methyl isobutyl ketone has not been found to occur naturally.

PHYSICAL AND CHEMICAL PROPERTIES

Methyl isobutyl ketone is a colorless liquid with a pleasant odor. The odor threshold can be as low as 0.10 ppm. It is 2% soluble in water by weight and with several other organic solvents. The chemical has a molecular weight of 100.2, a boiling point of 242°F, and a freezing point of -120°F. The vapor pressure is 19.9 mm Hg at 25°C and the specific gravity is 0.80. The lower explosive limit is 1.2% and the upper explosive limit is 8.0% at 200°F. Methyl isobutyl ketone may be incompatible with strong oxidizers and potassium tert-butoxide.

MAMMALIAN TOXICOLOGY

Acute Effects

Serious adverse health effects have not been associated with acute exposure to methyl isobutyl ketone. Respiratory tract and eye irritation have been known to result at high

concentrations. Unnecessary vapor inhalation has been associated with anesthetic effects. These exposure endpoints were demonstrated in a study by Iregren et al. (1993) in 12 volunteers. After 2-h exposures to low and high concentrations of methyl isobutyl ketone, there was no effect on heart rate or performance of a reaction time task. However, the volunteers did display central nervous system depression and airway irritation. One case report described a sensorimotor neuropathy after a brief, high intensity exposure to methyl ethyl ketone and methyl isobutyl ketone. A study of open-air VOCs from a plastic recycling plant described a potential association with mucocutaneous and respiratory symptoms in individuals living nearby (Yorifuji et al., 2012). A study in primates of response time and accuracy of task performance showed a general decrease in both as a result of methyl isobutyl ketone exposure (Geller et al., 1979).

As noted previously, the distinct odor of methyl isobutyl ketone can be detected at low concentrations. Workers detecting the chemical can remove themselves from an area before concentrations become dangerous. Olfactory perception threshold and adaptation were measured in subjects exposed to methyl isobutyl ketone for 7 h (Gagnon et al., 1994). The study reports a temporary loss of olfactory perception and adaptation to methyl isobutyl ketone, which may hinder workers' ability to detect methyl isobutyl ketone vapors at higher concentrations. A study conducted by Dalton et al. (2000) determined that the best predictor of methyl isobutyl ketone irritation at high concentrations is related to odor rather than threshold for sensory irritation (Dalton et al., 2000). Olfactory fatigue is often common when an individual is exposed to a chemical for an extended period of time. Individuals experiencing acute methyl isobutyl ketone exposure should remove themselves from the contaminated area and seek fresh air.

Chronic Effects

Methyl isobutyl ketone does not produce the neuropathies seen after chronic methyl butyl ketone exposures even though it is a structural isomer of methyl butyl ketone. Clinically, the worker appeared to have a similar ailment, but the etiology of the effect is not certain (Aubuchon et al., 1979). Multiple solvent exposures make it extremely difficult to determine if a specific solvent is responsible for negative health effects or if the solvents act in a synergistic manner to produce adverse health effects. Johnson (2004) conducted a study that described neuropathological changes in distal portions of tibial and ulnar nerves in rats exposed to high concentrations (1500 ppm) of methyl isobutyl ketone for 5 months. With proper controls in place, it is unlikely for exposure to occur at concentrations as high.

Some animal studies of methyl isobutyl ketone toxicity are available. Spenser and Schaumberg (1976) found no nervous system damage in a study comparing methyl butyl

ketone, methyl ethyl ketone, and methyl isobutyl ketone-associated effects. There have been some reports of methyl isobutyl ketone exposure acting as a potentiator of other solvent-induced neuropathies, such as n-hexane, and cholestasis-mediated hepatonecrogenesis caused by taurolicoic acid or manganese–bilirubin concentrations (Lapadula et al., 1991; Duguay and Plaa, 1993). A study of paint factory workers found that those exposed to a variety of organic solvents were 63.04% more likely to develop neuropsychological symptoms when compared to controls (El Hamid Hassan et al., 2013). According to Johnson (2004), several mammalian mutagenicity tests for methyl isobutyl ketone were negative and the chemical did not induce increases in embryotoxicity or fetal malformations. The same study indicated that kidney and liver changes were seen following exposure to the chemical. Additional research is needed to further determine chronic effects of methyl isobutyl ketone. Multiple exposures in the workplace are common, and care should be taken to prevent these potential health hazards.

Mechanism of Action(s)

Methyl isobutyl ketone metabolism has been characterized in some studies and the metabolites identified in animal studies. The two main metabolites of methyl isobutyl ketone metabolism are 4-methyl-2-pentanol (MPOL) and 4-hydroxy-4-methyl-2-pentanone (HMP) (DiVincenzo et al., 1976; Granvil et al., 1994). The carbonyl group of methyl isobutyl ketone is reduced to form MPOL, whereas the HMP metabolite is produced via an oxidation reaction. These biotransformations occur via alcohol dehydrogenase and P450-dependent monooxygenases (Vezina et al., 1990). Methyl isobutyl ketone induces cytochrome P450 expression and thereby increases the hepatotoxicity observed with carbon tetrachloride and chloroform. It has been suggested that methyl isobutyl ketone can cause adverse effects on the kidneys and the testes in males. The chemical was found to increase protein droplets, accumulation of α 2u-globulin, and renal cell proliferation, indicating that exposure to methyl isobutyl ketone may be associated with the development of nephropathy (Borghoff et al., 2009). Rats exposed to daily doses of methyl isobutyl ketone, 300 or 600 mg/kg/day, on their tails for 4 months developed changes in the testes and a reduction of spermatocytes, spermatids, and spermatozoa (Johnson, 2004).

Chemical Pathology

Tissue concentrations of methyl isobutyl ketone have been shown to increase in a dose-dependent manner; however, the observed concentrations of each metabolite depend on the route of exposure (Duguay and Plaa, 1995). MPOL is found in higher concentrations in rats after inhalation exposure in

relation to oral exposure. The transport and distribution of methyl isobutyl ketone in the body, which occur rapidly, may be dependent on the proteins of the red blood cells, such as hemoglobin (Lam et al., 1990). Methyl isobutyl ketone may play a role in the development of neurological impairment. One study explains that monoketones increase lipid fluidity in synaptic membranes which can disrupt the function of receptors and enzymes (USEPA, 2003). The loss of receptor and enzyme function may possibly be related to neuropathological findings. There has been consideration that methyl isobutyl ketone may lead to liver and renal impairment but a definitive association between exposure and pathological findings has not been established.

SOURCES OF EXPOSURE

Occupational

Methyl isobutyl ketone is used as a solvent in a variety of applications, including in paint, resins, varnishes, and lacquers. It has also been used as a synthetic flavoring in some food applications. Methyl isobutyl ketone is produced industrially via a hydrogenation reaction of mesityl oxide over nickel at a high temperature. It is also an oxidation product of methyl isobutyl carbinol. The major routes of exposure in the occupational setting are through inhalation and dermal contact. Ventilation and personal respiratory protection is recommended to prevent worker exposure to the chemical. Dermal contact can occur if the chemical reaches an individual's skin. Protective clothing, including aprons, gloves, and goggles, can prevent dermal exposure to methyl isobutyl ketone. Ingestion of methyl isobutyl ketone is highly unlikely. The chemical has a noticeable odor capable of alerting workers before concentrations rise to unacceptable levels. Workers exposed to the chemical should be removed from the contaminated work area and provided medical attention.

Environmental

Methyl isobutyl ketone is another solvent that may be released into the environment during manufacturing processes. It is also found in exhaust gas produced by internal combustion engines. Environmental inhalation of methyl isobutyl ketone can occur from these sources. Individuals using methyl isobutyl ketone should ensure that there is adequate ventilation to prevent vapor concentrations from building up. Personal respiratory protection with vapor cartridges may also be used to prevent exposure. Landfills and waterways may contain traces of methyl isobutyl ketone as a result of waste dumping. The chemical can leach into both the soil and water thereby negatively impacting the surrounding environment. Once in the soil or water, methyl isobutyl

ketone can volatize into the air. It has been estimated that the half-life of the chemical in a model river and a model lake are 9 h and 6 days, respectively (NCBI, 2014). Attempts should be made to avoid spilling the chemical and after use it should be disposed of in a proper manner.

INDUSTRIAL HYGIENE

The main routes of exposure to methyl isobutyl ketone are inhalation and dermal. The odor threshold of this compound is low enough to alert workers of possible overexposure. The sharp odor produced by methyl isobutyl ketone has been characterized to have an odor detection threshold of 0.410 mg/m³ (1 ppm) and is an irritant at 410.0 mg/m³ (Ruth, 1986). Proper ventilation and personal respirators equipped with proper vapor cartridges are recommended to control exposure. Like methyl butyl ketone, methyl isobutyl ketone is also flammable. All attempts should be made to ensure that the chemical does not come into contact with excessive heat, flames, or sparks. Explosive mixtures in air can be formed from vapors. Adequate clothing protection, barrier creams, and proper gloves can easily prevent dermal contact with methyl isobutyl ketone. The PEL set by OSHA for methyl isobutyl ketone air levels in the workplace is 100 ppm (410 mg/m³), which is the concentration identified as the threshold for irritant effects. The NIOSH (2010) recommended exposure limit is set at 50 ppm with a short-term exposure limit of 75 ppm. The ACGIH (2013) TLV has been set at 20 ppm (82 mg/m³), with a STEL of 75 ppm (300 mg/m³).

MEDICAL MANAGEMENT

Monitoring workers for plasma concentrations of methyl isobutyl ketone or its metabolites can be an effective way to evaluate worker exposure. Metabolites in the urine have not yet been characterized for this compound. It may be possible to detect methyl isobutyl ketone exposure by analyzing the urine for the unchanged chemical rather than its metabolites. A linear relationship has described for methyl isobutyl ketone in urine with environmental exposure. A hypothetical example would be that if an exposure occurred at 50 ppm, the mathematical equation predicts that the methyl isobutyl ketone concentration in urine should be 1.7 mg/l (Imbriani and Ghittori, 2005). If methyl isobutyl ketone contacts the skin, contaminated clothing should be removed and the skin should be rinsed thoroughly with soap and water to remove the chemical. If the chemical comes in contact with the eyes, they should be rinsed thoroughly with copious amounts of water. Medical attention should be sought if eye contact occurs. If methyl isobutyl ketone is inhaled, fresh air and medical attention is recommended. Proper controls in the workplace can prevent exposure to methyl isobutyl ketone.

OTHER KETONES

ISOPHORONE

Target organ(s): Eyes, skin, respiratory system, central nervous system, liver

Kidneys

Occupational exposure limits: NIOSH—TWA 4 ppm; OSHA—TWA 25 ppm

ACGIH—STEL ceiling 5 ppm

Reference values: RfD—0.2 mg/kg/day; RfC—0.012 mg/m³; MRL—0.2–3 mg/kg/day

Hazard statements: H351—suspected of causing cancer; H302—harmful if swallowed; H312—harmful in contact with skin; H319—causes serious eye irritation; H335—may cause respiratory irritation

Precautionary statements: P202—do not handle until all safety precautions have been read and understood; P271—use only outdoors or in a well-ventilated area; P281—use personal protective equipment as required; P308+P313—if exposed or concerned, get medical advice/attention; P403+P233—store in a well-ventilated place; keep container tightly closed

Risk phrases: R21/22—harmful in contact with skin and if swallowed; R36/37—irritating to eyes and respiratory system; R40—limited evidence of carcinogenic effect

Safety phrases: S13—keep away from food, drink, and animal feeding stuffs; S23—do not breath gas/fumes/vapors/spray; R36/37/39—wear suitable protective clothing, gloves, and eye/face protection; S46—if swallowed, seek medical advice immediately and show the container or label

Isophorone (CASRN 78-59-1), an alpha, beta-unsaturated ketone, is also an industrial solvent used in a variety of different applications. Most of the isophorone used in industry is used in vinyl coatings and inks. It is an insoluble, colorless to white liquid and has an odor similar to peppermint. Its characteristic odor is detectable at concentrations as low as 1.00 mg/m³ (0.2 ppm) (Ruth, 1986). Although not highly volatile, with a vapor pressure of 0.438 mm Hg at 25 °C, isophorone is primarily an irritant to the eyes and respiratory system at low concentrations. It may also depress the central nervous system at higher concentrations. Air concentrations of 10 ppm are tolerated for 15 min, but concentrations of 25 ppm produce irritation of the upper airways and eyes. The threshold for eye and nose irritation falls between 35 and 55 ppm. Fatigue and malaise have been associated with air levels of 5–8 ppm. Inhalation and dermal contact are the primary routes of worker exposure to isophorone. Adequate protection may include exhaust ventilation and respirators. The OSHA PEL for isophorone is 25 ppm (140 mg/m³) and the NIOSH (2010) REL is 4 ppm (23 mg/m³). The ACGIH (2013) has set a STEL for isophorone at 5 ppm (28 mg/m³) with a designation of A3, animal carcinogen.

Chronic effects of exposure in humans have not been reported. The liver, lungs, and kidneys are considered the target organs expected to be affected by isophorone exposure. Animal studies indicate a possible sex-linked carcinogenic effect in male rats, although the mechanism of action is not genotoxic (Bucher et al., 1986). Renal tubular cell adenomas and adenocarcinomas were produced in animal studies. The mechanisms by which these carcinogenic effects are produced cannot be extrapolated to humans. Glutathione levels in the reproductive system were also shown to decrease in male rats exposed to isophorone (Gandy et al., 1990).

BENZOPHENONE

Target organ(s): Eyes, skin, liver

Occupational exposure limits: NIOSH, OSHA, ACGIH—not Established; derived no effect level (DNEL); DNEL inhalation, systemic effects, long term: 0.7 mg/m³; DNEL dermal, systemic effects, long term: 0.1 mg/kg/bw/day

Reference Values: RfD, RfC, MRL—Not Established; DNEL inhalation, systemic effects, long term: 0.17 mg/m³; DNEL dermal, systemic effects, long term: 0.05 mg/m³

kg/bw/day; DNEL oral, systemic effects, long term: 0.05 mg/kg-bw/day

Hazard statements: H411—toxic to aquatic life with long lasting effects; H373—may cause damage to organs through prolonged or repeated exposures

Precautionary statements: P308+P313—if exposed or concerned, get medical advice/attention; P281—use personal protective equipment as required; P260—do not breath dust/fume/gas/mist/vapors/spray; P273—avoid release to the environment; P391—collect spillage; P501—dispose of contents/container to . . .

Risk phrases: R48/22—harmful: danger of serious damage to health by prolonged exposure if swallowed; R51/53—toxic to aquatic organisms, may cause long-term adverse effects in the aquatic environment

Safety phrases: S45—in case of accident or if you feel unwell, seek medical advice immediately (show label where possible); S36—wear suitable protective clothing; S23—do not breath gas/fumes/vapor/spray; S61—avoid release to the environment; refer to special instructions/safety data sheets

A derivative of benzene, benzophenone (CASRN 119-61-9) is found mostly in the cosmetics industry. It is used as a constituent in perfumes and sunscreens. It has a unique and characteristic rose-like odor. While found in products that require dermal application, some derivatives of this compound found in sunscreens have been the cause of sensitivity responses to certain sunscreens (English et al., 1987). Human and animal studies related to benzophenone have not been routinely investigated. Dutta et al. (1993) reported liver toxicity associated with benzophenone exposure in guinea pigs.

Alterations occurred that were similar to a chronic hepatitis, with areas of necrosis and regeneration. A study conducted in 2007 found an increased incidence in hepatocellular adenoma in both male and female mice (Rhodes et al., 2007).

ETHERS AND EPOXIDES

ERIN L. PULSTER, JACOB R. BOURGEOIS, AND RAYMOND D. HARBISON

ETHYL ETHER

Target organ(s): Eyes, skin, respiratory, central nervous system

Occupational exposure limits: OSHA PEL: 400 ppm (1200 mg/m³) TWA; ACGHI TLV: 400 ppm (1210 mg/m³) TWA, 500 ppm (1520 mg/m³) STEL; NIOSH IDLH: 1900 ppm [LEL]

Reference values: RfD: 2E-1 mg/kg/day, NOAEL: 500 mg/kg/day; LOAEL: 2000 mg/kg/day (USEPA)

Risk/safety phrases: Highly flammable and volatile. Can form explosive peroxides if exposed to air and light for long periods. Incompatible with strong oxidizers, halogens, sulfur, and sulfur compounds

BACKGROUND AND USES

Ethyl ether dates as far back as the thirteenth century when it was first discovered by mixing ethanol and sulfuric acid, historically known as oil of vitriol. During the 1800s, it was first used widely as an anesthetic until the mid-1950s when it was eventually replaced by less flammable anesthetics. Although ethyl ether has a wide range of uses in the chemical industry, it is more commonly used as a laboratory solvent because of its limited solubility in water and its inertness. It is widely used for reactions or extractions in the chemical, fragrance, and pharmaceutical industries. It is commonly used as a solvent for dissolving waxes, resins, gums, fats, oils, dyes, raw rubber, smokeless powder, and perfumes. In addition, it has also been used as an ignition enhancer in petroleum gasoline and diesel engines due to its relatively

high cetane number (>125) and low autoignition temperature (160 °C) (Miller Jothi et al., 2008; Bailey et al., 1997). Other applications of ethyl ether include as agricultural insecticides and fumigants, pharmaceutical solvents, paint removal and varnish, medicinal wound sealants, and the production of cellulose plastics.

PHYSICAL AND CHEMICAL PROPERTIES

Ethyl ether, more commonly known as diethyl ether (diethyl oxide, ether, ethyl oxide, solvent ether; CASRN 60-29-7) is a highly volatile and flammable colorless liquid (a gas above 94 °F) with a pungent, sweetish odor. It is extremely flammable with an autoignition temperature of 320 °F. The vapor pressure is 440 mmHg and has limited solubility in water (69 g/l at 68 °F). Additional chemical and physical properties are presented in Table 56.1.

MAMMALIAN TOXICOLOGY

Acute Effects

Typical effects from an acute ethyl ether inhalation exposure include respiratory and eye irritation, vomiting, dizziness, bradycardia, low body temperature, irregular respiration, salivation, drowsiness, muscle relaxation, paleness, acute excitement, loss of consciousness, and even death (Clayton and Clayton, 1982). Effects vary depending on the exposure concentration and duration. Mörch et al. (1956) determined that the concentrations of ethyl ether necessary for surgical anesthesia and respiratory arrest in mice were 6 and 18%. Induction as a human anesthetic is between 10 and 15%

TABLE 56.1 Ethyl Ether Chemical and Physical Properties

Characteristic	Properties
Chemical name	Ethyl ether
Synonyms	Diethyl ether; ethyl oxide; diethyl oxide; ether; 3-oxapentane; ethoxyethane; sulfuric ether; 1,1'-oxybisethane; anesthetic ether
CASRN	60-29-7
Molecular formula	C ₄ H ₁₀ O
Molecular weight	74.12 Da
Boiling point	94 °F (35 °C)
Freezing point	-177 °F (-116 °C)
Melting point	-177 °F (-116 °C)
Flash point	-49 °F (-45 °C)
Autoignition temperature	356 °F (180 °C)
Vapor pressure	440 mmHg at 68 °F (20 °C)
Specific gravity	0.71 at 68 °F (20 °C)
Density	713 kg/m ³
Ionization potential	9.53 eV
Solubility	Limited solubility in water; soluble in sulfuric acid, alcohol, acetone, benzene, and chloroform
Cetane number	>125

(100,000–150,000 parts per million (ppm); Patty et al., 1982). Surgical anesthetic maintenance is 5% (50,000 ppm). Maintenance levels above 10% could lead to fatalities (Flury and Klimmer, 1943). There have been very few reports of ethyl ether anesthesia as a contributing factor to death; however, in Philadelphia between 1957 and 1959, 645 reported deaths were associated with anesthesia (Campbell et al., 1961). Four of those cases were due to excessive ethyl ether and an additional six cases were a combination of ethyl ether and another anesthetic. Acute lethal concentrations (LC₅₀) in animals ranged from 6500 to 73,000 ppm for mice and rats, respectively (Schwetz and Becker, 1970).

Chronic Effects

Typical effects from chronic ethyl ether exposures are similar to those of acute exposures, including drowsiness, dizziness, excitation, headache, exhaustion, anorexia, and psychic disturbances. Chronic dermal exposure can result in dermatitis and dermal burns. Nasal irritation and dizziness are found to occur at concentrations of 200 ppm and over 2000 ppm, respectively. An increase in blood levels of liver enzymes and a decrease in liver weight relative to the body weight were noted in rats exposed to 2000 ppm of ethyl ether chronically over 30 weeks (Clayton and Clayton, 1982).

Mechanism of Action(s)

The use of ethyl ether as an anesthetic has a very slow induction and recovery period; however, an advantage of

ethyl ether as an anesthetic agent is its low hepato- and nephrotoxicity. Recovery side effects include headache, nausea, and vomiting. There are many theories on the mechanism of action of general anesthetics, such as ethyl ether, ranging from disrupting lipid membranes to highly selective and specific interactions upon central nervous system proteins (Weir, 2006).

Although ethyl ether has a direct myocardial depressant effect, during clinical anesthesia it increases the heart rate and cardiac output during the induction and emergence phases (Boniface et al., 1954). This effect observed in dogs concluded that the increase in heart rate can be explained by the sympathoadrenal activity. Krishna et al. (1975) observed a dose-dependent increase in the frequency of contractions in isolated rat atrial preparations. Furthermore, they were able to determine that these effects were not mediated by catecholamine release nor via direct stimulation of beta-adrenergic receptors or blocking of cholinergic receptors.

Inhaled ethyl ether is instantaneously absorbed into the bloodstream, from where it is rapidly passed into the brain (Patty et al., 1982). Historically it was believed that ether was not altered once it is absorbed by the body but later discoveries indicated that 8–10% of the absorbed ether is metabolized to ethanol and acetaldehyde (Haggard, 1924; Green and Cohen, 1971). The majority of inhaled ethyl ether is primarily eliminated via expiration (~87%) with nominal excretion via the urine (Haggard, 1924). Prolonged exposure to ether was shown to increase cytochrome P450 enzyme activity in rats (Liu et al., 1993), which are the enzymes also believed to be involved in the metabolism of ethyl ether in the human hepatic system (Chengelis and Neal, 1980; Kharasch and Thummel, 1993).

Chemical Pathology

Potential target organs for ethyl ether exposure include the eyes, skin, respiratory tract, and central nervous system, yet no specific chemical pathologies have been described.

SOURCES OF EXPOSURE

Occupational

Occupations that may result in worker exposures to ethyl ether are mainly from industries involved in the manufacturing or transportation of ethyl ether, in laboratories or industries where it is used as a solvent or an intermediate, and in hospitals where it is used as an anesthetic. Air concentrations starting at 200 ppm triggered nasal irritation and levels of 300 ppm were found to be unacceptable among industry workers (Nelson et al., 1943). Surgical nurses and doctors complained of exhaustion, headache,

irritability, appetite loss, and the inability to concentrate with prolonged exposures to ethyl ether (NIOSH, 1993). Results from a national study among over 49,000 exposed operating room personnel and over 23,000 unexposed individuals revealed that exposed female operating room personnel were subject to increased risks of spontaneous abortion, congenital abnormalities in their children, cancer, and hepatic and renal disease (American Society of Anesthesiologists, 1974).

Environmental

Although there are no published reports on environmental exposures to ethyl ether, the general public could be exposed to air concentrations of ethyl ether from its use as an additive in motor fuels, perfumes, and denatured alcohol.

INDUSTRIAL HYGIENE

The current permissible exposure limit (PEL) issued by Occupational Safety and Health (OSHA) for ethyl ether is 400 ppm (1200 mg/m^3) as the time-weighted average (TWA) for an 8-h workday. A recommended exposure limit (REL) has not yet been established by the National Institute for Occupational Safety and Health (NIOSH). Similarly to OSHA limits, the American Conference of Governmental Industrial Hygienists (ACGIH) issued a threshold limit value (TLV) of 400 ppm (1210 mg/m^3) as the TWA for an 8-h workday and a 40-h workweek. In addition, the ACGIH assigned a short-term exposure limit (STEL) of 500 ppm (1520 mg/m^3) for periods not exceeding 15 min and these concentrations should not be repeated more than four times a day and should be separated by intervals of at least 60 min (OSHA; ACGIH, 1994).

The OSHA recommends effective methods in controlling occupational exposures to ethyl ether, which include the implementation of process enclosures, local exhaust ventilation, general dilution ventilation, and personal protective equipment. Workers that may be subject to prolonged or repeated exposure to liquid ethyl ether should be required and provided with impervious clothing, gloves, and face shields or splash-proof safety goggles to prevent skin contact. If ethyl ether leaks or spills occur, remove all ignition sources, ventilate the spill or leak area, and follow cleanup procedures. Small quantities can be absorbed using spill pads or paper towels and placed in the hood to allow evaporation or placed in closed containers for later disposal. Large quantities can be collected and dissolved in an alcohol that has a greater molecular weight than butyl alcohol and atomized in a suitable combustion chamber.

MEDICAL MANAGEMENT

The OSHA recommends workers who handle or have had skin contact with ethyl ether should wash their hands, forearms, and affected areas thoroughly with soap and water. If irritation persists after washing, medical attention may be needed. Any clothing that becomes wet with ethyl ether should be removed immediately and placed in closed containers for storage until it can be discarded or cleaned properly. If the ethyl ether soaks through the clothing, the affected areas should be immediately flushed and washed thoroughly. Contaminated clothing should not be reworn until the ethyl ether is removed. The laundry personnel should be informed of the potential hazards of ethyl ether. If a person has inhaled large volumes of ethyl ether, the person should be moved to fresh air immediately. If an exposed worker is found unconscious, they should be moved to fresh air immediately and established emergency procedures should be followed. If a person has swallowed ethyl ether, prompt them to vomit and seek medical attention immediately.

HALOETHER

Target organ(s): Eyes, skin, and respiratory tract.
 BCME occupational exposure limits: ATSDR MRL: 0.0014 mg/m³ (0.0003 ppm) TWA
 Reference values: Human carcinogens

Risk/safety phrases: CMME and BCME are potent carcinogens. BCME is very volatile and may cause fire in presence of excessive heat. Hydrogen chloride and formaldehyde can react to form BCME. BCME hydrolyzes in water forming hydrogen chloride and formaldehyde. CMME is incompatible and will react with surface moisture forming hydrogen chloride. CMME can also contain 1–8% BCME. CMME can also decompose into hydrogen chloride and formaldehyde, which under certain temperatures and humidity can form BCME

BACKGROUND AND USES

Haloethers are compounds that contain an ether moiety and halogen atoms attached to the aryl or alkyl groups. Chloroethers are considered the most commercially significant haloethers and can be divided into alpha- and non-alpha chloroethers. One of the only commercially significant α -haloethers is chloromethyl methyl ether (CMME), which is primarily used as an alkylating agent and solvent for the manufacturing of water repellents, ion-exchange resins, and industrial polymers. It is also of toxicological importance. Bis-chloromethyl ether (BCME) is another α -haloether that is also known for its toxicity. Bis-chloromethyl ether was previously used to make polymers, resins, and textiles. However, it is only used in small quantities in fully enclosed systems to make other chemicals with highly restricted use and used commercially due to its carcinogenicity. A β -chloroether of commercial significance is bis(2-chloroethyl) ether (BCE), which has been used in the textile, petroleum, and paint and varnish industries. It is used as a dewaxing agent, wetting and cleaning agent, and a penetrant. It also serves as a good solvent and extraction solvent for tars, fats, waxes, oils, grease, and resins. In addition, BCE is a by-product of the process for making ethylene oxide. The focus of the discussion in this section will be on the two α -haloethers with the most toxicological relevance, CMME and BCME.

PHYSICAL AND CHEMICAL PROPERTIES

Haloethers have a wide range of physical and chemical properties; however, most are miscible in oils and soluble in organic solvents, such as benzene, carbon tetrachloride, and acetone. Chloromethyl methyl ether is a clear, colorless liquid that is highly flammable and has a strong noxious and irritating odor. Bis-chloromethyl ether is also a clear, colorless liquid at room temperature and has a strong unpleasant and suffocating odor. Additional chemical and physical properties for both are presented in Table 56.2.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute effects noted for both CMME and BCME have been dermal, mucous membrane, and respiratory tract irritation. Additional short-term effects reported from CMME exposure have been eye irritation, pulmonary edema, and pneumonia in humans. Acute inhalation studies using mice found BCME to be nonirritating to the upper respiratory tract at 10.6 ppm, yet concentrations of 40 ppm of CMME caused slight irritation (Leong et al., 1971). The LC₅₀ for the inhalation of CMME in rats and hamsters was 55 and 65 ppm, respectively, after 14 days (Drew et al., 1975). The 14-day LC₅₀ for BCME in

TABLE 56.2 Chemical and Physical Properties for Chloromethyl Methyl Ether and Bis-chloromethyl Ether

Characteristic	Chloromethyl Methyl Ether Properties	Bis-chloromethyl Ether Properties
Synonyms	CMME, MOM-chloride, chloro (methoxy)methane, methoxymethyl chloride, methyl chloromethyl ether	BCME, 1,1'-dichlorodimethyl ether, bis (2-chloromethyl) ether
CASRN	107-30-2	542-88-1
Molecular formula	C ₂ H ₅ ClO	C ₂ H ₄ Cl ₂ O
Molecular weight	80.5 Da	115 Da
Boiling point	138 °F (61 °C)	223 °F (106 °C)
Freezing point	-154 °F (-104 °C)	No data available
Melting point	-154 °F (-104 °C)	-43 °F (-42 °C)
Flash point	60 °F (15 °C)	100 °F (38 °C)
Vapor pressure	192 mmHg at 70 °F (21 °C)	33 mmHg at 72 °F (22 °C)
Specific gravity	1.06	1.32
Density	1.06	3.97 (vapor), 1.33 (liquid)
Solubility	Miscible in oils and soluble in organic solvents	

both species (7 ppm) was almost an order of magnitude lower than the LC₅₀ for CMME (Drew et al., 1975).

Chronic Effects

Chronic inhalation from CMME exposure may result in bronchitis. Chronic cough, impaired respiratory function, and bronchitis have all been reported from long-term inhalation of BCME. Increased incidences of respiratory cancers have been reported in experimentally exposed animals and in occupationally exposed workers to both of these α -haloethers. Rats chronically exposed to 1 ppm of CMME throughout their lifetime were found to have almost a doubling of bronchial hyperplasia compared to controls, yet mortality and weight gain were not significant (Laskin et al., 1975). In a lifetime observation study, mice and rats chronically exposed to 100 parts per billion (ppb) of BCME vapors for 6 months produced oncogenic responses (Leong et al., 1981). Over 86% of the rats exposed had nasal tumors, whereas pulmonary adenomas were more significant in mice exposed to the same concentrations. No carcinogenic responses were observed in either species at concentrations of 1 or 10 ppb of BCME over the 6-month exposure period. Mice chronically exposed to 1 ppm BCME and 2 ppm of CMME resulted in an increased incidence of pulmonary adenomas (Laskin et al., 1971). Based on animal studies, the Agency for Toxic Substances and Disease Registry (ATSDR) derived a minimal risk level (MRL) of 0.0003 ppm for human chronic inhalation exposure to BCME (ATSDR, 1989).

Mechanism of Action(s)

Specific modes of action for BCME and CMME have not been very well elucidated. Water can rapidly break down CMME into methanol, hydrochloric acid, and formaldehyde and BCME into formaldehyde and hydrochloric acid (Van Duuren, 1980). From the reviewed occupational exposures

and animals studies, BCME and CMME-containing BCME are confirmed potent carcinogens, primarily resulting in lung and nasal cancers. Oat cell (small cell) carcinomas account for a high proportion of the respiratory tumors reported. It has been suggested that BCME may be radiomimetic because of its property similarities with nitrogen mustard, which also had a predominant association with oat cell carcinomas and bronchogenetic cancers (Lemen et al., 1976).

Chloromethyl methyl ether hydrolyzes completely and irreversibly in water to form HCl, methanol, and formaldehyde (Van Duuren, 1980). The frequency of chromosomal aberrations was increased in peripheral lymphocytes of workers exposed to levels of BCME exceeding 0.4 mg (Sram et al., 1985). Chloromethyl methyl ether was also shown to inhibit DNA synthesis in human lymphocytes after being treated for 4 h (Perocco et al., 1983). It was also found to be weakly mutagenic in *Drosophila melanogaster* larvae (Filippova et al. 1967) and mutagenic in *Salmonella typhimurium* TA98 (in the absence of metabolic activation) (Norpoth et al. 1980), *Escherichia coli*, and *S. typhimurium* (Mukai and Hawryluk, 1973).

Chemical Pathology

Target organs of both BCME and CMME are the eyes, skin, and respiratory tract; however, no data are available on their chemical pathologies. Nevertheless, studies have typically exhibited a marked dose response and a histologic specificity for small cell tumors (Steenland et al., 1994; Ward, 1995).

SOURCES OF EXPOSURE

Occupational

Exposures to BCME and CMME are primarily through inhalation and dermal contact. An increased incidence of

lung cancer was observed in a group of 125 chemical manufacturing plant workers exposed to CMME (Figueroa et al., 1973). A 17-year follow-up of the cohort revealed a small epidemic of respiratory cancers, which included 14 cases of lung cancer and 2 cases of laryngeal cancer among 91 men (Weiss, 1982). Ninety-eight lung cancers were also observed (24.1 expected; SMR = 4.1) in a study group of over 3000 workers exposed to BCME worldwide (Steenland et al., 1994; Ward, 1995).

Environmental

Although it may be expected that CMME and BCME may be released into the environment via manufacturing and production processes, no data are available on their ambient levels of either in soil, water, or air.

INDUSTRIAL HYGIENE

The OSHA and the NIOSH have not set occupational limits for either CMME or BCME. However, any industry that may use CMME, BCME, or solid or liquid mixtures containing at least 0.1% by weight or volume of either compound are required by both OSHA and NIOSH to implement stringent controls (NIOSH, 1988a,b). A MRL for chronic inhalation of BCME in humans is 0.0003 ppm as the TWA for a normal 8-h workday and a 40-h workweek (ATSDR, 1989, 1999; NIOSH, 1988a,b). The ACGIH has designated CMME as a suspected human carcinogen without having sufficient evidence to assign a TLV.

The OSHA requires workers be provided and use full-body chemical protective clothing (CPC), including smocks, coveralls, or long-sleeved shirts and long pants. In addition, workers should be provided and required to wear respirators and remove CPCs prior to exiting regulated areas. Any products, residues, or container liners contaminated with BCME are considered acute hazardous waste under the Resource Conservation and Recovery Act (RCRA) and must be disposed of by transport to a RCRA waste storage and disposal facility where the preferred method of disposal is incineration. Areas that use either BCME or CMME should be restricted and controlled with only authorized personnel allowed to enter usage areas. Regulated areas should be posted with signs indicating that a potential human carcinogen is present and only authorized personnel with proper CPC are allowed access (NIOSH, 1988a,b). Indoor regulated areas should also operate under negative pressure. Other control methods include process enclosures, restricted access areas, local exhaust ventilation, personal protective equipment, good housekeeping and personal hygiene, and substitution of a less toxic substance where possible (NIOSH, 1988a,b).

MEDICAL MANAGEMENT

Eyes and skin that become exposed to CMME or BCME should be flushed for at least 15 min and washed thoroughly followed by immediate medical attention. Any industries where employees may be potentially exposed to hazardous chemicals are recommended to have a medical surveillance program. If workers are exposed to levels exceeding regulatory levels, this may be a requirement. Medical surveillance programs include baseline measurements and routine monitoring of air concentrations to determine worker TWA exposure during a workshift. Ceiling levels during peak expected airborne concentrations should also be measured and compared to regulatory levels. The medical surveillance program should also include a preplacement medical evaluation of workers to determine baseline health status. Periodic medical screening and biological monitoring (e.g., blood tests, X-rays, urinalysis) during employment as well as an exit or termination evaluation should also be performed regularly to identify any changes in health status.

ETHYLENE OXIDE

- Target organ(s): Eyes, skin, respiratory system, liver, central nervous system, blood, kidneys, reproductive system
- Occupational exposure limits: OSHA PEL: 1 ppm TWA, 5 ppm STEL; ACGHI TLV: 1 ppm (1.8 mg/m³) TWA; NIOSH REL: 0.1 ppm, 5 ppm STEL; NIOSH IDLH: 800 ppm; EEGL: 20 ppm for 1 h; 1 ppm for 24 h
- Reference values: MRL: 0.09 ppm in air (ATSDR, 1990)
- Risk/safety phrases: Classified as a Group 1 human carcinogen (IARC, 2012). Very toxic with carcinogenic, mutagenic, teratogenic, and reproductive hazards. Extremely flammable and potentially explosive in the presence of alkali metal hydroxides and highly active catalytic surfaces

BACKGROUND AND USES

Ethylene oxide was first reported in the mid-1800s by a French chemist, Charles-Adolphe Wurtz, who first synthesized it by treating 2-chloroethanol with potassium hydroxide. In 1931, another French chemist, Theodore Lefort, developed a method of direct oxidation of ethylene in the presence of silver catalyst, of which all industrial production uses this process (ATSDR, 1990). Ethylene oxide is mainly used as a chemical intermediate in the manufacturing process of textiles, detergents, polyurethane foam, automotive antifreeze, solvents, medicinals, adhesives, cosmetics, perfumes, pharmaceuticals, lubricants, plasticizers, and paint thinners. Ethylene oxides in the form of ethylene glycols (i.e., automotive antifreeze) account for the majority of the global consumption (75%). According to the Report on Carcinogens (2011), the U.S. production has increased from 4 billion pounds in 1973 to 7.6 billion pounds in 2002.

PHYSICAL AND CHEMICAL PROPERTIES

Ethylene oxide (CASRN 75-21-8), also called oxirane, is an extremely flammable and explosive, colorless gas (25 °C) with a sweet ether-like odor, more distinctive when air concentrations are in excess of 500 ppm. It is miscible in water and most organic solvents, such as ethanol, diethyl ether, acetone, benzene, alcohol, and carbon tetrachloride. Additional chemical and physical properties are presented in Table 56.3.

TABLE 56.3 Ethylene Oxide Chemical and Physical Properties

Characteristic	Properties
Chemical name	Ethylene oxide
Synonyms	Oxirane, epoxyethane, dimethylene oxide, oxacyclopropane, ethene oxide, ethyleneoxide, 1,2-epoxyethane
CASRN	75-21-8
Molecular formula	C ₂ H ₄ O
Molecular weight	44.05 Da
Boiling point	51 °F (11 °C)
Freezing point	-171 °F (-113 °C)
Melting point	-168 °F (-111 °C)
Flash point	-4 °F (-20 °C)
Autoignition temperature	804 °F (429 °C)
Vapor pressure	1.46 atm
Specific gravity	0.82 (liquid at 50 °F)
Density	0.882 g/ml
Solubility	Miscible in water

MAMMALIAN TOXICOLOGY

Acute Effects

Acute effects from short-term inhalation of ethylene oxide include nausea, headache, weakness, vomiting, drowsiness, incoordination, and irritation of the eyes and respiratory tract (NIOSH, 1988). Short-term skin exposures can result in blisters, edema, burns, frostbite, and severe dermatitis. Acute lethal concentrations (LC_{50}) of ethylene oxide in animals ranged from 800 to 4000 ppm in rats (Carpenter et al., 1949; Deichmann and Gerarde, 1969). Animal toxicity data concluded that concentrations of 2000 ppm for 60 min, 4000 ppm for 30 min, and 8000 ppm for 10 min are considered to cause injury or death (Clayton and Clayton, 1981). Nasal irritation was reported after 10 s of exposure to 12,500 ppm (Walker and Greeson, 1932).

Chronic Effects

Chronic exposures of ethylene oxide to the skin can cause dermatitis and can even result in burns and blisters. In severe cases, symptoms may include muscle weakness, loss of feeling or prickly sensation in the hands, feet, arms or legs, clumsiness, and paralysis. Hematological abnormalities were observed in 47 hospital workers chronically exposed to EtO levels ranging from <0.01 to 0.06 ppm (Shaham et al., 2000).

The IARC Monograph Volume 97 (IARC, 2008) concluded that there was *limited evidence* in humans for the carcinogenicity of ethylene oxide and was subsequently listed as a Group 2B probable human carcinogen. This conclusion has since changed, and it is now listed as a Group 1 human carcinogen (IARC, 2012). This decision was largely based on a combination of more recent studies with *limited evidence* in humans and *sufficient evidence* from animal experimental studies. These studies produced new data for an association of ethylene oxide with lymphatic and hematopoietic cancers and the genotoxicity of ethylene oxide (IARC, 2012).

Mechanism of Action(s)

Ethylene oxide is typically absorbed through the lungs and into the blood system. Once it is absorbed, it is either biotransformed or eliminated via respiration or excretion. It is rapidly cleared from tissues within 2–3 days. There are two pathways involved in the metabolism of ethylene oxide, hydrolysis to ethylene glycol and conjugation with glutathione. Evidence presented by Hengstler et al. (1994) strongly suggests that a metabolite of ethylene glycol (glycolaldehyde) leads to DNA–protein crosslinks and DNA strand breaks in human blood cells. Several studies using rats and mice have found that elimination predominantly takes place in the hepatic cytosol and is catalyzed by glutathione

S-transferase (GST) (Li et al., 2011; Brown et al., 1996). Although this is also considered the predominant elimination pathway in humans, it is also expected that epoxide hydrolase (EH)-catalyzed hydrolysis accounts for at least 1/4th of the overall ethylene oxide metabolism (Li et al., 2011).

Chemical Pathology

Potential target organs of ethylene oxide include the eyes, respiratory system, central nervous system, reproductive system, blood, and other organs (e.g., liver, kidneys). Most of the cohort studies conducted have not been able to illustrate a significant difference in cancer diagnoses among ethylene oxide-exposed workers in comparison to the general public. In contrast, the increase of genotoxic and mutagenic evidence has contributed to the recent change in classification to a Group 1 human carcinogen (IARC, 2012).

Possible mechanisms of neurotoxicity include the direct exposure of the peripheral nerves through cutaneous absorption and central involvement through inhalation and vascular dissemination (Brashear et al., 1996). Genotoxicity studies of ethylene oxide were reviewed in the IARC Monograph Volume 97 (2008) and revealed an elevated number of chromosomal aberrations and an increase in sister chromatid exchange in the blood of exposed workers. In addition, ethylene oxide is a direct alkylating agent, directly reacting with DNA and proteins and is believed to initiate genotoxicity and cancer (Swenberg et al., 2000). Several studies have reported DNA damage, DNA strand breaks, sister chromatid exchange, cell mutations, and gene mutations in both animal and human studies. It also induced specific locus mutation, micronucleus formation, unscheduled DNA synthesis, and dominant lethal mutations (IARC, 2008).

SOURCES OF EXPOSURE

Occupational

The majority of the occupational exposures are found in the chemical plants where ethylene oxide is produced and used as an intermediate in the manufacturing process of other products (i.e., detergents, polyurethane foam, automotive antifreeze, solvents, adhesives, etc.). The greatest potential for occupational exposures is considered to be during the loading or unloading of transport tanks, product sampling procedures, and equipment maintenance and repair (CDCP, 1981). However, NIOSH (1989) estimated that approximately 270,000 people were exposed to ethylene oxide in the United States, primarily in hospitals and during commercial sterilization.

A cohort study of over 18,000 exposed workers showed little evidence of excess cancer mortality, with the exception of a significant excess of bone cancer (six deaths) compared

to the general population (Steenland et al., 2004). This study has provided some evidence for the classification of ethylene oxide as a human carcinogen (IARC, 2012). In addition, this study found positive exposure-response trends for lymphoid tumors among males only and some evidence of a positive exposure-response for breast cancer mortality. Using exposure-response analysis, Stayner et al. (1993) reanalyzed Steenland's previous results (Steenland et al., 1991) and concluded that there was an increase in mortality from lymphatic and hematopoietic cancer in the groups with the highest cumulative ethylene oxide exposure (>8500 ppm/day). In another study evaluating hospital workers, cognitive impairment and personality dysfunction were observed more frequently in hospital workers chronically exposed to EtO, compared to a control group (Klees et al., 1990). Neurotoxicity and central nervous system toxicity were found among 12 nurses and operating technicians (Brashear et al., 1996). Levels measured in their surgical gowns 18 days post sterilization were 298 ppm; however, peak levels during exposure were not known. In addition, EtO was found to be associated, although a weak association, with breast cancer in a cohort study of over 7500 women occupationally exposed for at least 1 year for an average of 10.7 years (Steenland et al., 2003).

Environmental

The majority of ethylene oxide is released into the atmosphere with an estimated 23 tons from industries (WHO, 2003). California reported ethylene oxide levels in air ranging from <0.001 to 0.96 mg/m³ (Havlicek et al., 1992). Ethylene oxide is not only a synthesized product but it is also metabolically produced from ethylene by microorganisms internally and by the combustion of organic compounds. Furthermore, it is a component of cigarette smoke and is estimated to be present at levels of 7 µg/cigarette (IARC, 2004). In case of smoking, ethene via ethylene oxide (EtO) could be an initiator of approximately 15% of the smoking-related cancer cases (Törnqvist et al., 1986). Moreover, secondhand smoke potentially exposes almost everyone to ethene and ethylene oxide. A preliminary study evaluating fruit store workers exposed to 1 ppm ethene in the ambient air during work hours resulted in the same adduct level in hemoglobin as 0.3 ppm of ethylene oxide (Törnqvist et al., 1989). Hemoglobin adducts are currently used as effective biomarkers of exposure to potential carcinogens and other occupationally and environmentally relevant compounds.

INDUSTRIAL HYGIENE

The current PEL issued by the OSHA for ethylene epoxide is 1 ppm as the TWA for an 8-h workday. A REL established by the NIOSH is set at 0.1 ppm and a STEL of 5 ppm per day.

Similar to the OSHA limits, the ACGIH issued a TLV of 1 ppm as the TWA.

Engineering controls should be instituted to prevent and reduce employee exposures to ethylene oxide. Process enclosures, local exhaust ventilation, and personal protective equipment should be used during the synthesis and handling of ethylene oxide as well as when used as a sterilizing agent. In addition to engineering controls, personal protective clothing and equipment should be provided and used. Respirators may be needed depending on the airborne concentration of ethylene oxide. In the event of a leak or spill, all ignition sources should be removed immediately. Small quantities can be absorbed using paper towels and placed in a fume hood or appropriate container. For large quantities, vermiculite or dry sand may be needed.

MEDICAL MANAGEMENT

Eyes and skin that become exposed to ethylene oxide should be flushed and washed thoroughly followed by immediate medical attention. Any industry where employees may be potentially exposed to hazardous chemicals are recommended to have a medical surveillance program. If workers are exposed to levels exceeding regulatory levels, this may be a requirement. Medical surveillance programs include baseline measurements and routine monitoring of air concentrations to determine worker TWA exposure during a workshift. Ceiling levels during peak expected airborne concentrations should also be measured and compared to the regulatory levels. The medical surveillance program should also include a preplacement medical evaluation of workers to determine their baseline health status. Periodic medical screening and biological monitoring (e.g., blood tests, X-rays, urinalysis) during employment as well as an exit or termination evaluation should also be performed regularly to identify any changes in the health status.

DIOXANE

Target organ(s): Eyes, skin, respiratory system, central nervous system, liver, kidneys

Occupational exposure limits: OSHA PEL: 100 ppm (360 mg/m³) TWA; ACGIH TLV: 25 ppm (90 mg/m³) TWA; NIOSH REL: 1 ppm (3.6 mg/m³); NIOSH IDLH: 500 ppm

Reference values: RfD: 0.03 mg/kg/day; NOAEL: 9.6 mg/kg/day; LOAEL: 94 mg/kg/day

Risk/safety phrases: Classified as a Group 2B probable human carcinogen. Hydroscopic and will produce peroxides in the presence of moisture. Highly flammable

BACKGROUND AND USES

Dioxane is produced commercially by either 1. dehydration of ethylene glycol; 2. treatment of bis(2-chloroethyl) ether with alkali; 3. by dimerization of ethylene oxide; 4. or by heating and distilling diethylene glycol with dehydration catalysts (HSDB, 1995). It is primarily used as solvent in chemical processing, as well as a laboratory reagent, as a chemical intermediate, as a polymerization catalyst, and as an extraction medium. It has been used in several industries

TABLE 56.4 Dioxane Chemical and Physical Properties

Characteristic	Properties
Chemical name	Dioxane
Synonyms	Diethylene dioxide; diethylene ether, 1,4-dioxacyclohexane; diethylene oxide; dioxyethylene ether; glycol ethylene ether; p-dioxane; 1,4-dioxane
CASRN	123-91-1
Molecular formula	C ₄ H ₈ O ₂
Molecular weight	88.1
Boiling point	214 °F (101 °C)
Freezing point	53 °F (11.8 °C)
Melting point	53 °F (11.8 °C)
Flash point	54 °F (12 °C)
Vapor pressure	29 mmHg at 68 °F (20 °C)
Specific gravity	1.03
Density	1.03 g/ml
Ionization potential	9.13 eV
Solubility	Miscible in water, acetone, benzene, ether alcohols, and many common solvents

such as plastic, rubber, agriculture, and consumer. Commercial products that may contain dioxane include paint strippers, dyes, greases, varnishes, deodorants, shampoos, and cosmetics. Historically 90% of dioxane was used as a stabilizer for 1,1,1-trichloroethane (ATSDR, 2007). As of 2006, the estimated U.S. production plus imports of dioxane are estimated to be approximately 10 million pounds.

PHYSICAL AND CHEMICAL PROPERTIES

Dioxane (CASRN 123-91-1) is a cyclic ether that exists as a clear, colorless, flammable liquid at ambient temperatures (solid below 12 °C). It is a dimer of ethylene oxide and has a mild, pleasant ether-like odor. It is miscible in water, alcohols, and many other common solvents, such as acetone, ether, and benzene. Additional chemical and physical properties are presented in Table 56.4.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute exposures to dioxane are similar to those of other ethers, which include eye and respiratory irritation, headache, dizziness, drowsiness, nausea, loss of appetite, stomach pain, renal and hepatic damage, and difficulty in breathing. Additional symptoms reported have also included coma and death. The inhalation LC₅₀ of dioxane in rats was 46 and 65 mg/l for a 4-h and 2-h exposure period, respectively (Pilipiuk et al., 1977). This same study did not report any

induced skin damage as a result of a single and repeated dermal exposure; however, it was rapidly absorbed into the blood that led to acute poisoning and irritation of the eye.

Chronic Effects

Chronic low dose exposures to dioxane have resulted in liver and kidney damage and chronic dermal exposures have resulted in irritation of the eyes and respiratory system. Torkelson et al. (1974) exposed rats to 111 ppm of dioxane vapors for 2 years and did not find any evidence of carcinogenicity. An additional 2-year inhalation study found that nasal squamous cell carcinomas, hepatocellular adenomas, and peritoneal mesotheliomas statistically increased in rats chronically exposed to 1250 ppm (Kasai et al., 2009). Several long-term (>1 year) studies on exposing animals to dioxane in drinking water have reported cancer in several organs, including liver, kidney, gall bladder, and nasal cavity (DeRosa et al., 1996). Dioxane concentrations ranged from 444 to 1599 mg/kg/day.

Mechanism of Action(s)

An inhalation study in four male volunteers exposed to 50 ppm of dioxane determined that the majority (99.3%) of dioxane is eliminated by metabolism to β-hydroxyethoxyacetic acid (HEAA) with the remaining 0.7% being excreted through the urine (Young et al., 1977). Further studies suggest that the metabolism of dioxane is mediated by cytochrome P450 (Woo et al., 1978). The concentrations of HEAA were found to be 118% higher than the concentration of dioxane, suggesting rapid and extensive metabolism with a calculated metabolic clearance rate of 75 m/min. This same study concluded that repeated daily exposures to 50 ppm of dioxane would not cause adverse effects because accumulated concentrations would never exceed those attained at 50 ppm or less. β-Hydroxyethoxyacetic acid also accounted for >99% of the total urinary excretion of inhaled dioxane in rats (Young et al., 1978). Conversely, when dioxane is intravenously injected in rats, the metabolic clearance decreased indicating metabolic saturation at high doses (1000 mg/kg). Saturation was found to occur at doses >10 mg/kg/bw resulting in accumulation of 1,4-dioxane (HSDB, 1995).

Chemical Pathology

The chemical pathology has not been described in depth for dioxane. Radiolabeled dioxane in rats was found to be widely distributed relatively uniformly among different tissues, yet the extent of covalent bonding was significantly higher in the liver, spleen, and colon (Woo et al., 1977). In addition, an increase in the hepatocyte labeling index was noted with exposures of 1% (v/v) dioxane in drinking

water, suggesting a potential role of cell proliferation in the induction of hepatocellular carcinoma. Increased activity of microsomal enzymes also appears to be induced from repeated exposures of 1000 mg/kg/day in rats and 2000 mg/kg/day in mice (Dietz et al., 1982; Pawar and Mungikar, 1976).

SOURCES OF EXPOSURE

Occupational

Occupational exposures to dioxane may occur through inhalation or dermal contact. Occupations involving exposure include industries involved in the manufacturing and transportation, laboratories, and industries that use dioxane as a solvent, stabilizer, or as a paint and varnish stripper. Reports of occupational exposures are limited. However, eye and respiratory irritations were reported for occupational exposures to dioxane with concentrations ranging from 200 ppm for 15 min to 5500 ppm for 1 min (Silverman et al., 1946).

Environmental

Environmental exposures to dioxane may occur via the inhalation of contaminated air or ingestion of contaminated water. Dioxane can be released into the environment from the manufacturing process through the effluent or into the atmosphere. A study analyzing the effluents from nine different industries in Korea found levels ranging from 0.03 to 2.83 mg/l (Gurung et al., 2012). Average dioxane levels for outdoor air concentrations from across the United States during the 1980s were 0.107 parts per billion by volume (ppbv), which included urban, rural, suburban, and remote areas (Shah and Singh, 1988). This same study found average U.S. indoor concentrations at 1.029 ppbv for both workplace and residential environments. In Colorado, ground-water contaminated near a landfill site showed levels ranging from non-detectable to 79 µg/l (EPA, 1988). Cleanup levels vary from state to state ranging from 3 to 85 µg/l in drinking water or groundwater (EPA, 2009). The Environmental Protection Agency (EPA) regions 3 and 6 have calculated a screening level of 6.1 µg/l for dioxane in tap water.

INDUSTRIAL HYGIENE

The current PEL issued by the OSHA for dioxane is 100 ppm (360 mg/m³) as the TWA for an 8-h workday with a *skin* notation, indicating that the cutaneous route of exposure contributes to the overall exposure. The NIOSH considers dioxane as a potential occupational carcinogen and has established an exposure limit (REL) of 1 ppm (3.6 mg/m³) as a 30-min ceiling. The ACGIH issued a TLV of 25 ppm as

the TWA for a normal 8-h workday and a 40-h week and also includes a *skin* notation.

Engineering controls should be instituted where possible to prevent and reduce employee exposures to dioxane. Suggested engineering controls to be used during the synthesis and manufacturing of commercial products include process enclosures, local exhaust ventilation, and personal protective equipment. As with the other ethers, ignition sources should be removed immediately if there is a leak or spill. Small quantities can be absorbed using paper towels and placed in a fume hood or appropriate container. For large quantities, vermiculite or dry sand may be needed.

MEDICAL MANAGEMENT

Eyes and skin that become exposed to dioxane should be flushed with plenty of water and skin washed thoroughly with soap and water. Ingestion may require gastric lavage or use of activated charcoal. Severe dermal burns or blistering may need topical treatment. Dioxane-contaminated clothing should be removed and properly stored until the clothing can be properly laundered or disposed. Medical surveillance programs are recommended, which include worker medical screening, medical baseline and routine evaluations, and biological monitoring. Workplace measurements and monitoring should also be conducted to determine airborne concentrations.

ESTERS

RAYMOND D. HARBISON AND C. CLIFFORD CONAWAY

Esters are compounds that result from the reaction of an alcohol or phenol with acids or derivatives of acids. Almost all the aliphatic esters are prepared by the reaction between carboxylic acids and alcohols. The subclasses of esters presented in this chapter include the aliphatic esters, halogenated acid esters, alkyl esters of sulfuric acid, important phosphate esters, nitrate esters, and esters of phthalic acid. Some esters, such as aliphatics esters, may present human health hazards (USEPA, 2007), if exposure occurs via the respiratory or dermal routes.

Many organic esters are used extensively in the plastic industry, either as resins or as plasticizers, and as solvents for lacquers. The group of esters, including succinate, adipate, azelate, sebacate, citrate, and phthalate is generally used as plasticizers. Esters of inorganic acids, such as esters of sulfuric acid and phosphate esters, may have prominent corrosive or pharmacological properties. See Table 57.1 for some industrial uses of esters.

ALIPHATIC ESTERS

METHYL FORMATE

Occupational exposure limits: OSHA PEL 250 mg/m³; NIOSH recommended exposure limit (REL) 250 mg/m³; derived no effect level (DNEL); DNEL inhalation, systemic effects, long term: 120 mg/m³; DNEL inhalation, systemic effects, short term: 120 mg/m³; DNEL

inhalation, local effects, long term: 120 mg/m³; DNEL inhalation, local effects, short term: 120 mg/m³; DNEL dermal, systemic effects, long term: 17 mg/kg/bw/day; DNEL dermal, systemic effects, short term: 17 mg/kg/bw/day

Reference values: DNEL inhalation, systemic effects, long term: 20 mg/m³; DNEL inhalation, systemic effects, short term: 20 mg/m³; DNEL inhalation, local effects, long term: 20 mg/m³; DNEL inhalation, local effects, short term: 20 mg/m³; DNEL dermal, systemic effects, long term: 2.83 mg/kg/bw/day; DNEL dermal, systemic effects, short term: 2.83 mg/kg/bw/day; DNEL oral, systemic effects, long term: 2.83 mg/kg/bw/day; DNEL oral, systemic effects, short term: 2.83 mg/kg/bw/day

Hazard statements: H224—extremely flammable liquid and vapor; H332—harmful if inhaled; H302—harmful if swallowed; H319—causes serious eye irritation; H335—may cause respiratory irritation

Precautionary statements: P210—keep away from heat/sparks/ open flames/ . . . /hot surfaces . . . no smoking; P233—keep container tightly closed; P240—ground/bond container and receiving equipment; P241—use explosion-proof electrical/ventilating/lighting/ . . . /equipment; P242—use only non-sparking tools; P243—take precautionary measures against static discharge; P280—wear protective gloves/protective clothing/eye protection/face protection; P303 + P361 + P353—if in contact with skin (or hair), remove/take off immediately all contaminated clothing; rinse skin with water/shower; P370 + P378—in case of fire, use . . . for extinction; P403 + P235—store in well-ventilated place; keep cool; P501—dispose of contents/container to . . .

TABLE 57.1 Some Industrial and Commercial Uses of Esters

Areas of Use	Material Involved
Automotive and aircraft industry	Diphosphates, methyl acrylate phenolates, phosphates, succinates
Flavor and fragrance in food and cosmetics	Methyl and amyl salicylate, methyl anthranilate, benzyl and terpinyl acetate, ethyl butyrate
Lacquer and general solvents	Mainly ethyl and butyl acetates
Pharmaceuticals	p-Aminobenzoates, aspirin, methyl, and propyl p-hydroxybenzoates, diethyl malonates
Plastics and resins	Cellulose and vinyl acetate, phthalates, and polyesters
Plasticizers	Aliphatic carboxy esters, phthalates, and phosphates (Bisesi, 1994)

Risk phrases: R12—extremely flammable; R20/22—harmful by inhalation and if swallowed; R36/37—irritating to eyes and respiratory system

Safety phrases: S2—keep out of the reach of children; S9—keep container in a well-ventilated place; S16—keep away from sources of ignition . . . no smoking; S24—avoid contact with skin; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S33—take precautionary measures against static discharges

BACKGROUND AND USES

Methyl formate has a rather pleasant odor. It is an aromatic compound found in apples (Neubeller and Buchloh, 1986), and was identified as a volatile constituent in brewed, roasted, and dried coffee (Lovell et al., 1980); it has also been detected in the volatiles of chicken, beef, and pork flavor (Shahidi et al., 1986). Methyl formate is used primarily to manufacture formamide, dimethylformamide, and formic acid. It is also used as a solvent for quick-drying finishes such as lacquers and in organic synthesis. Other uses include use as a larvicide for tobacco and food crops, in the manufacture of certain pharmaceuticals, and as a blowing agent for foam insulation. It was formerly used as a refrigerant for house appliances.

PHYSICAL AND CHEMICAL PROPERTIES

Methyl formate (formic acid methyl ester; methyl methanoate; HCOOCH₃, CASRN 107-31-3, molecular weight 60.05) is a colorless, flammable liquid, with a melting point of -100 °C and a boiling point (bp) of 31.5 °C (O’Neil, 2001; NIOSH, 2010). The vapor density is 2.07 (air = 1). Its

solubility in water is 230 g/l at 25 °C (Riddick et al., 1985), but it reacts slowly with water to form formic acid and methyl alcohol (DOT, 1984). It is soluble in ether, chloroform, and is miscible with ethanol (Lide, 2000).

MAMMALIAN TOXICOLOGY

Acute Effects

Methyl formate is known as an irritant to mucous membranes and skin. May cause pneumonitis, but no known human cases have been reported (if exposure is respiratory). Potential symptoms of acute human overexposure to methyl formate are eye and nose irritation, chest tightness, dyspnea, visual disturbance, and central nervous system (CNS) depression (O’Neil, 2001). In experimental animals, high concentrations of inhaled methyl formate resulted in ocular and upper respiratory tract irritation, dyspnea, convulsions, coma, and death. The oral LD₅₀ in rats was 1500 mg/kg bw while the acute rat dermal LD₅₀ was >4000 mg/kg bw for 98% pure methyl formate (ECB, 2000). In animal studies, methyl formate caused narcosis and death at airborne concentrations of 5000 parts per million (ppm) to 10,000 ppm in 1–3 h. Inhalation of 1500–50,000 ppm by guinea pigs for 2–3 h caused ocular and upper respiratory tract irritation, retching, incoordination/CNS depression, and death; a concentration of 50,000 ppm was fatal within 20–30 min. Pulmonary irritation of lungs was observed after guinea pigs inhaled nonfatal concentrations, which resolved 4–6 days after exposure (ACGIH, 2001).

Young, healthy subjects exposed to 100 ppm (the American Conference of Governmental Industrial Hygienists’ [ACGIH] threshold limit value [TLV]) for 8 h reported increased subjective feelings of fatigue without significant measureable impairment of neurobehavioral performance (Sethre et al., 2000). Methyl formate was attributed to cause irritation of eyes and tearing in 10 of 15 women in a factory in which boiling methyl formate and other esters were employed (Grant, 1986). Occupational effects in workers exposed to methyl formate and other solvents (30% methyl formate, in addition to unspecified amounts of ethyl formate and ethyl and methyl acetate) consisted of visual disturbances, CNS depression, irritation of mucous membranes, and dyspnea (ACGIH, 2001).

Chronic Effects

No records for chronic exposure of methyl formate to laboratory animals were found. Methyl formate (98.4% pure) was negative in the Ames test using *Salmonella typhimurium* strains TA 1535, TA 100, TA 1537, and TA 98 at concentrations of 20–5000 µg/plate with and without metabolic activation (ECB, 2000). It is a known neurotoxicant, and in animal inhalation studies it has been demonstrated to cause CNS solvent syndrome, a disease of the nervous system, which causes confusion, headache,

dizziness, and/or stupor/coma. However, no known cases of CNS solvent syndrome in humans have been reported. Methyl formate may cause hemolytic anemia or met-hemoglobinemia (NCBI, 2014). A study of human volunteers experienced increased fatigue without any other neurobehavioral effects when exposed to 100 ppm for 8 h. There is no available data to indicate the carcinogenic effects, and is considered a pregnancy risk group C (NLM, 2011).

Mechanism of Action

In a mouse inhalation assay, sensory irritation of the upper airways and deep lung to 202–1168 ppm methyl formate was assessed. Sensory irritation, which developed slowly over the 30-min exposure period, was the only parameter observed. The possible role of esterase activity in the production of formic acid and methanol was evaluated by treatment of mice with the esterase inhibitor tri-*o*-cresol phosphate (TOCP). Tri-*o*-cresol phosphate pretreatment reduced the irritation response of methyl formate, suggesting that carboxylesterase-mediated hydrolysis plays a role in the irritation effect of methyl formate. The authors suggested that potential generation of formaldehyde was another source of irritation (Larsen and Nielsen, 2012). Cleavage of methyl formate produces methanol and formic acid, the latter is a critical metabolite responsible for metabolic acidosis.

Chemical Pathology

Application of 1 oz (28.35 g) of an insecticide ointment containing methyl formate to the scalp of a 19-month-old infant suffering from *Pediculosis capitis*, and subsequent covering with a rubber bathing cap, resulted in death 20–30 min later. Both methyl formate and methanol were found by micro-boiling point analysis of a 600 g extract of brain tissue. Further confirmation of the presence of formate was obtained by the detection of mercurous formate crystals (Snyder, 1992).

SOURCES OF EXPOSURE

Occupational

Occupational exposure may occur through inhalation and dermal contact at workplaces where methyl formate is produced or used. Workers may be exposed via, respiratory, dermal, oral, and/or eye contact (NIOSH, 2010). National Institute for Occupational Safety and Health (NIOSH) (1983) has estimated that 7738 workers, consisting of 1402 females, are potentially exposed to methyl formate in the United States.

Environmental

Methyl formate may enter the environment via release through various industrial waste streams. For example,

methyl formate has been released in waste water from urea-formaldehyde resin-manufacturing plants and in vent effluents during commercial production of methanol (Lovell et al., 1980). Methyl formate has been identified as a constituent of cigarette smoke and gasoline engine exhaust (Verschueren, 2001); the amount of methyl formate detected in exhaust gases from the combustion of various hydrocarbon fuels ranged from <0.1 to 0.7 ppm (Seizinger and Dimitriades, 1972). Its use as fumigant and larvicide results in direct release to the environment. Volatilization is probably an important fate process. The half-life of methyl formate in the atmosphere has been estimated to be about 71 days (Meylan and Howard, 1993). The half-life of hydrolysis of methyl formate in water has been estimated to be 5 and 12 days at pH values of 7 and 8, respectively (Mill et al., 1987). The potential for bioconcentration in aquatic organisms is estimated to be low (Franke et al., 1994). No data are available for ecotoxicity.

INDUSTRIAL HYGIENE

The permissible Occupational Safety and Health Administration (OSHA) exposure limit (permissible exposure limit [PEL]) for methyl formate in an 8-h time-weighted average (TWA) exposure is 100 ppm (250 mg/m³) (NIOSH, 2010). The 8-h TLV is 100 ppm, and the short-term exposure limit (STEL) for methyl formate is 150 ppm (ACGIH, 2008). The NIOSH REL (10-h TWA) is also 100 ppm (NIOSH, 2003). Methyl formate is a very dangerous fire hazard. The National Fire Protection Association (NFPA) hazard classification for methyl formate is Health: 2 (hazardous to health, but areas may be entered freely with self-contained breathing apparatus); Flammability: 4 (very flammable gas or very volatile flammable liquid.), making it a fire hazard; and Reactivity: 0 (material normally stable even under fire exposure conditions, not reactive with water; normal fire-fighting procedures may be used (NFPA, 2002). Immediately dangerous to life or health is 4500 ppm (NIOSH, 2003). Methyl formate is considered hazardous as per the Hazard Communication Standard 29 CFR 1910 1200.

MEDICAL MANAGEMENT

Persons exposed to high levels of methyl formate should be removed as soon as possible to fresh air. Immediate removal of contact lenses to prevent further eye irritation and contaminated clothing, and washing of the skin followed by inhalation of a mist of a 5% bicarbonate solution is recommended. If pulmonary edema develops, medical advice should be sought as quickly as possible. Oxygen should be administered if the patient exhibits signs of respiratory failure (Snyder, 1992). Seek medical treatment immediately. Monitor for shock and treat if necessary. Anticipate seizures,

and minimize all stimuli. For eye contamination, flush eyes immediately with water, then irrigate each eye continuously with normal saline if possible; do not use eye ointment. For ingestion, rinse mouth and administer 5 ml/kg up to 200 ml of water for dilution, if the patient can swallow, has a strong gag reflex, and does not drool. Alternatively, administer a 12.5% slurry of activated charcoal (25–100 ml) to minimize absorption from the alimentary tract (Bronstein and Currance, 1994). Do not induce vomiting (NCBI, 2014; NIOSH, 2010).

ETHYL FORMATE

Occupational exposure limits: 300 mg/m³ (OSHA PEL, NIOSH REL, ACGIH TLV)

Reference values: None

Risk phrases: R11—highly flammable; R20/22—harmful by inhalation and if swallowed; R36/37—irritating to the eyes and respiratory system

Safety phrases: S2—keep out of the reach of children; S9—keep container in a well-ventilated place; S16—keep away from sources of ignition . . . no smoking; S24—avoid contact with skin; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S33—take precautionary measures against static discharges

BACKGROUND AND USES

Ethyl formate (Ethyl ester, ethyl methanoate; HCOOCH₂CH₃; CASRN 109-94-4) is a volatile liquid with a fruity odor and slightly bitter taste (NIOSH, 1994). Ethyl formate is naturally found in some fruits, such as in apples and pears, in Florida orange juice, and in varieties of honey (Furia and Bellanca, 1975). Major industrial uses are in the lacquer industry, and as a solvent for cellulose acetate in the manufacture of artificial silk, safety glass, and celluloid for shoes, as well as in organic synthesis. It is also used as a solvent for various oils and greases (NLM, 2013). It is used as a flavoring agent in lemonade and in artificial rum and arrack, as a substitute for acetone, and in the synthesis of synthetic sex hormones (Budavari, 1996). It is also used as a larvicide or fungicide in agricultural fumigants and sprays for food crops, cereals, dried fruit, and tobacco (Bisesi, 1994).

PHYSICAL AND CHEMICAL PROPERTIES

Ethyl formate, molecular weight 74.09, is a colorless liquid. The bp is 54.5 °C at 760 mmHg, and melting point is –80.5 °C; its density is 0.9168 at 20 °C (Lide, 1990). The ester is slightly soluble in water (9 parts/100 at 18 °C) with gradual decomposition into formic acid and ethanol; it is miscible in ethanol, ether, and acetone (HSDB, 2013), as well as in benzene. The vapor density is 2.55 (air = 1) (Bisesi, 1994), and the vapor pressure is 245 mmHg at 25 °C (Daubert and Danner, 1989).

MAMMALIAN TOXICOLOGY

Acute Effects

It is considered moderately toxic at a lethal dose to humans at 0.5–5 mg/kg between 1 ounce and 1 pint for a 70 kg person (NCBI, 2014). Overexposure may cause irritation of the eyes, nose, throat, and skin (Budavari, 1996; Snyder, 1992). At 330 ppm in air, it causes slight eye irritation that subsides only after several hours (Grant, 1986); and strong persistent nasal irritation, probably due to its hydrolysis to formic acid and ethanol (ACGIH, 2008; Snyder, 1992). In persons with

impaired pulmonary function, especially those with obstructive airway disease, breathing ethyl formate might cause exacerbation of symptoms due to its irritant properties (NIOSH, 1981). The acute hazards of ethyl formate are regarded as considerably less than those of methyl formate. Nevertheless, exposure of mice, cats, and dogs to 10,000 ppm for 20 min produced eye irritation and dyspnea, and a 4-h exposure of 10,000 ppm to dogs was fatal after development of pulmonary edema (Bisesi, 1994). Concentrations of 1500 ppm are regarded as immediately dangerous to human life and health (NIOSH, 1997).

Chronic Effects

Potential effects of chronic exposure to ethyl formate have not been adequately reported. When tested by application to the skin of mice for a period of 10 weeks, no tumors were observed (Roe and Salaman, 1955). In another study using A/He mice, total doses of 2.4 or 12 g/kg ethyl formate injected intraperitoneally three times per week for 8 weeks resulted in no primary lung tumors (Snyder, 1992). Ethyl formate is not listed as a human carcinogen by International Agency for Research on Cancer (IARC), and no data were found regarding its genotoxicity. No data are available as per the mutagenic or teratogenic effects of ethyl formate (NCBI, 2014).

Mechanism of Action

Adverse effects of ethyl formate on the eyes and respiratory tract are probably due to rapid hydrolysis of the ester on contact with water, with subsequent formation of ethanol and formic acid. The irritating effects of ethyl formate appear to be less potent than that of methyl formate. The effects appear to be somewhat residual, rather than transient, as irritation of eyes and nose remained for 4 h after exposure to 10,500 ppm ethyl formate (Snyder, 1992). The anesthetic potency of ethyl formate is less than that of chlorinated hydrocarbons and ethyl ether, but it is more active than ethanol, acetone, and aliphatic hydrocarbons (ACGIH, 2008).

Chemical Pathology

The adverse effects of ethyl formate on the eyes, nasal passages, respiratory tract, skin, and other organs is more than likely due to its hydrolysis to formic acid, causing irritation and tissue damage.

SOURCES OF EXPOSURE

Occupational

It has been estimated that 8149 workers are exposed to ethyl formate in the United States (NOES, 1983). Occupational exposure is typically via inhalation and dermal contact.

Adequate personal protective clothing for skin protection and sufficient eye protection to prevent eye contact is required (NIOSH, 1997). Screening of employees for medical conditions that might place them at increased risk from ethyl formate, such as chronic respiratory disease, skin diseases, and liver and kidney disease is recommended (NIOSH, 1981).

Environmental

Release of ethyl formate to the environment will often occur from its transport, disposal, and use as a synthetic flavoring agent, as a fungicide and larvicide for tobacco, cereals, dried fruit and other crops, and manufacturing of other products. Ethyl formate is expected to degrade rapidly by chemical hydrolysis in soil and water. It will also readily volatilize, hence relatively high concentrations are released to the atmosphere, where it is attacked by photochemically produced hydroxyl radicals, with an estimated half-life of 11 days (Atkinson, 1989).

INDUSTRIAL HYGIENE

The PEL for ethyl formate is 100 ppm (300 mg/m³) (NIOSH, 2010). The 8-h TLV-TWA is 100 ppm; excursions in worker exposure levels may not exceed three times the TLV for more than 30 min during a work day (ACGIH, 2008). The NIOSH REL for a 10-h time-weighted exposure is also 100 ppm (300 mg/m³) (NIOSH, 2010). The NFPA hazard classification for ethyl formate is Health: 2 (hazardous to health, but areas may be entered freely with self-contained breathing apparatus). Flammability: 3 (easily ignited under fire exposure conditions; water may be ineffective in controlling or extinguishing fires). Reactivity: 0 (material normally stable even under fire exposure conditions, and do not react with water; normal fire-fighting procedures may be used) (NFPA, 1997).

MEDICAL MANAGEMENT

Target organs are eyes, respiratory, and CNS (NIH, 2011). Following inhalation exposure, the patient should be moved to fresh air. Monitor for respiratory distress, and if necessary, administer oxygen and assist with ventilation. Treat bronchospasm with an inhaled beta-2 agonist. Supportive care may be necessary for CNS depression. For eye exposure, irrigate exposed eyes with copious amounts of water at room temperature for 15 min or more. For dermal exposure, remove decontaminated clothing; treat dermal irritation or burns with standard topical therapy. For ingestion, do not induce emesis. Significant esophageal or gastrointestinal irritation and possibly burns may occur following ingestion of ethyl formate. Administration of 4–8 oz of water or milk

(children: not to exceed 4 oz) is advised in such instances. Administration of slurry of a 12.5% activated charcoal is also recommended (NLM, 2013).

METHYL ACETATE

Occupational exposure limits: ACGIH TLV 610 mg/m³; ACGIH STEL 757 mg/m³; DNEL inhalation, systemic effects, long term: 610 mg/m³; DNEL inhalation, local effects, long term: 305 mg/m³; DNEL dermal, systemic effects, long term: 88 mg/kg/bw/day

Reference values: DNEL inhalation, systemic effects, long term: 131 mg/m³; DNEL inhalation, local effects, long term: 152 mg/m³; DNEL dermal, systemic effects, long term: 44 mg/kg/bw/day; DNEL oral, systemic effects, long term: 44 mg/kg/bw/day

Hazard statements: H225—highly flammable liquid and vapor; H319—causes serious eye irritation; H336—may cause drowsiness or dizziness

Precautionary statements: P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking; P243—take precautionary measures against static discharge; P280—wear protective gloves/protective clothing/eye protection/face protection; P271—use only outdoors or in a well-ventilated area; P370 + P378—in case of fire: use . . . for extinction; additional text water spray, fire extinguishing powder, foam, or carbon dioxide; P304 + P340—if inhaled, remove victim to fresh air and keep at rest in a position comfortable for breathing; P312—call a poison center or doctor/physician if you feel unwell; P305 + P351 + P338—if in eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P337 + P313—if eye irritation persists, get medical advice/attention; P403 + P233—store in a well-ventilated place; keep container tightly closed

BACKGROUND AND USES

Methyl acetate (methyl ethanoate; CH₃COOCH₃; CASRN 79-20-9) occurs naturally in low concentrations in mint, fungus,

grapes, banana, coffee (Furia and Bellanca, 1975) and is a volatile constituent of nectarines (Takeoka et al., 1988). It is also present in some distilled alcoholic beverages (Shimoda et al., 1993). It is produced industrially via the carbonylation of methanol as a byproduct of acetic acid production or by esterification of acetic acid with methanol in the presence of strong acid such as sulfuric acid. Methyl acetate is mainly used as an effective solvent for the production of nitrocellulose, cellulose acetate, resins, greases, synthetic leathers, perfumes, and in organic synthesis (Budavari, 1996); it is also used as a solvent for glues, paints, and nail polish removers.

PHYSICAL AND CHEMICAL PROPERTIES

Methyl acetate is a colorless, volatile liquid, with a molecular weight of 74.08 (Budavari, 1996) and a fragrant, fruity odor and fleeting fruity taste (Furia, 1980). The water solubility of methyl acetate is 243.5 g/l at 20 °C (Stephan and Stephan, 1963). The vapor pressure is 216 mmHg at 25 °C (77 °F) (Budavari, 1996); the melting point is –98 °C and bp is 56.8 °C (Lide, 1995). The specific gravity is 0.9342 at 4 °C (Lide, 1995) and vapor density is 2.8 (air = 1) (ILO, 1983). Methyl acetate is soluble in benzene, acetone, and chloroform (Weast, 1988), and is miscible with alcohol and ether (Budavari, 1996).

MAMMALIAN TOXICOLOGY

Acute Effects

This ester causes irritation to the eyes, skin, nose, and throat; excess exposure causes headache, vertigo, drowsiness, palpitation, and even unconsciousness. Even so, the use of nail polish remover containing 50% w/w methyl acetate is regarded as safe by the Danish EPA (SCCNFP, 2003). Chest tightness, dyspnea, and blurred vision may occur after excess industrial exposure. Metabolic acidosis is a possible symptom of excess exposure, as methanol, which yields formic acid, is a major metabolite (Minns et al., 2013). Employees with chronic respiratory, skin, liver, or kidney disease may be at increased risk for symptoms (NIOSH, 1981). Cases of slight poisoning under industrial conditions have been reported, and one case of blindness had occurred, most likely the result of its biotransformation to methanol. No cases of lethal poisoning have occurred (ILO, 1983).

Chronic Effects

Repeated skin contact with liquid methyl acetate may cause dryness, cracking, and skin irritation. Methyl acetate is not listed in the most recent summary of industrial carcinogens published by the IARC (2012). Methyl acetate was not mutagenic in a robust Ames test (*Salmonella typhimurium*) (WHO, 1998). No additional information was found

regarding its potential mutagenic or genotoxic effects. No information was found regarding potential effects of methyl acetate on fetal development in animal studies. Hydrolysis products, such as methanol, may cause permanent damage to the retina (NLM, 2013).

Mechanism of Action

The primary action of methyl acetate in industry is its use as an effective solvent with a rather pleasant smell. In the presence of strong acid, it is converted to methanol and acetic acid, with subsequent toxicity. It reacts slowly with water to form acetic acid and methanol (NIOSH, 2010).

Chemical Pathology

In mammals, methyl acetate is metabolized to methanol and acetate. Methanol is then rapidly converted to formaldehyde by the action of alcohol dehydrogenase. In humans and other primates, formaldehyde is converted to formic acid, with a half-life of about 1.5 min, but formic acid is converted to carbon dioxide much more slowly, with half-life of approximately 20 h. For that reason formic acid builds up in tissues, and causes severe metabolic acidosis, which can lead to retinopathy similar to that of methanol poisoning. Other common clinical manifestations of methanol poisoning include CNS depression, weakness, headache, and vomiting (Fox and Boyes, 2008; SCCNFP, 2003).

SOURCES OF EXPOSURE

In addition to industrial exposure, methyl acetate is permitted as a minimal food additive, as a synthetic flavoring substance, and contaminant adhesives. Natural concentrations of methyl acetate in foods and alcoholic beverages are considered to be negligible. Contaminated drinking water is also a potential source of exposure (USEPA, 1975).

Occupational

National Institute for Occupational Safety and Health has estimated that 17,851 workers (4038 of these are female) are exposed to methyl acetate in the United States, 92% of which are exposed during the use of trade name compounds which contain methyl acetate (NOES, 1983). Most probable routes of occupational exposure are by inhalation and dermal contact. No cases of irritation or systemic injury have been reported for exposures at or below 200 ppm (ACGIH, 1991).

Environmental

The production of methyl acetate and its use as a solvent, synthetic flavoring additive, component of artificial leather,

as well as use in organic synthesis may result in its release to the environment. Methyl acetate is expected to have very high mobility in soil, and volatilization from soil surfaces is expected to be rapid (Buttery et al., 1969). If released into water, methyl acetate is expected to volatilize to the atmosphere rather rapidly (Lyman et al., 1982). Hydrolysis of methyl acetate is not expected to be significant except under highly basic conditions, that is, >pH 9 (Drossman et al., 1987). Laboratory experiments indicate that airborne methyl acetate is rapidly degraded by light at 250 nm (half-life ~24 h) or 360 nm (half-life <6 h) (Güsten et al., 1984).

INDUSTRIAL HYGIENE

The ACGIH TLV-TWA is 200 ppm (610 mg/m³), with a STEL of 250 ppm (757 mg/m³). Respiratory depression and metabolic acidosis are anticipated as early signs of excess exposure (ACGIH, 2001). Methyl acetate is a highly flammable liquid, and may form dangerous explosive mixtures with air (NFPA, 1997). The NFPA hazard classification for methyl acetate is Health: 1, Flammability: 3, and Reactivity: 0 (NFPA, 1997). The immediate dangerous to life or health level is above 3100 ppm (NIOSH, 2010; NLM, 2013).

MEDICAL MANAGEMENT

In general, gastrointestinal decontamination after oral ingestion is not very useful because methanol is rapidly absorbed and binds poorly to activated charcoal. Very shortly after large ingestions, insertion of a nasogastric tube to aspirate stomach contents may be helpful. Do not use emetics. Treat patients with either ethanol or fomepizole (4-methylpyrazole) to prevent its conversion to formate. This is indicated if plasma methanol concentrations are >20 mg/dL or there is a strong suspicion of methanol poisoning. Ethanol is given to maintain serum ethanol concentration of 100–150 ml/dL. Fomepizole is administered as a 15 mg/kg loading dose, followed by four bolus doses of 10 mg/kg every 12 h. Using fomepizole over ethanol is suggested, as fomepizole does not cause CNS depression or hypoglycemia and may decrease the need for dialysis (NIH, 2003). For inhalation exposure, move patient to fresh air, and monitor for respiratory distress. If cough or difficulty in breathing develops, evaluate for respiratory tract irritation, bronchitis, or pneumonitis. Administer oxygen and assist in ventilation as required. For eye exposure: decontaminate eyes with copious amounts of water at room temperature for at least 15 min. For dermal exposure, remove contaminated clothing and wash exposed area thoroughly with soap and water. If irritation or pain persists, consult a physician.

ETHYL ACETATE

Occupational exposure limits: 1400 mg/m³ (OSHA PEL, NIOSH REL, ACGIH TLV); DNEL inhalation, systemic effects, long term: 734 mg/m³; DNEL inhalation, systemic effects, short term: 1468 mg/m³; DNEL inhalation, local effects, long term: 734 mg/m³; DNEL inhalation, local effects, short term: 1468 mg/m³; DNEL dermal, systemic effects, long term: 63 mg/kg/bw/day

Reference values: DNEL inhalation, systemic effects, long term: 367 mg/m³; DNEL inhalation, systemic effects,

short term: 734 mg/m³; DNEL inhalation, local effects, long term: 367 mg/m³; DNEL inhalation, local effects, short term: 734 mg/m³; DNEL dermal, systemic effects, long term: 37 mg/kg/bw/day; DNEL oral, systemic effects, long term: 4.5 mg/kg/bw/day

Hazard statements: H225—highly flammable liquid and vapor; H319—causes serious eye irritation; H336—may cause drowsiness or dizziness

Precautionary statements: P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking; P233—keep container tightly closed; P240—ground/bond container and receiving equipment; P241—use explosion-proof electrical/ventilating/lighting/equipment; P242—use only non-sparking tools; P243—take precautionary measures against static discharge; P280—wear protective gloves/protective clothing/eye protection/face protection; P303 + P361 + P353—if in contact with skin (or hair): remove/take off immediately all contaminated clothing; rinse skin with water/shower; P370 + P378—in case of fire: use . . . for extinction; additional text water spray, foam, or carbon dioxide; P403 + P235—store in a well-ventilated place; keep cool; P501—dispose of contents/container to . . . ; P264—wash . . . thoroughly after handling; P305 + P351 + P338—if in eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P337 + P313—if eye irritation persists: get medical advice/attention; P261—avoid breathing dust/fume/gas/mist/vapors/spray; P271—use only outdoors or in a well-ventilated area; P304 + P340—if inhaled, remove victim to fresh air and keep at rest in a position comfortable for breathing; P312—call a poison center or doctor/physician if you feel unwell; P403 + P233—store in a well-ventilated place; keep container tightly closed; P405—store locked up

Risk phrases: R11—highly flammable; R36—irritating to eyes; R66—repeated exposures may cause skin dryness or cracking; R67—vapors may cause drowsiness and dizziness

Safety phrases: S2—keep out of the reach of children; S16—keep away from sources of ignition . . . no smoking; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S33—take precautionary measures against static discharges

BACKGROUND AND USES

Ethyl acetate (ethyl ethanoate; vinegar naphtha; CH₃COOC₂H₅; CASRN 141-78-6) is a colorless, clear liquid with an ether-like fruity odor and a wine-like burning taste. Commercial uses include as an artificial fruit essence, in perfumes, nail polish, and other manicure products. It is also used as a solvent for varnishes and lacquers, in the

manufacture of smokeless powder, photographic films and plates, and in artificial silk (Budavari, 1996). Ethyl acetate is found at 25–50 ppm in American-brewed lager beer (Reed, 1983). It is also a component of fresh grapefruit juice (Cadwallader and Xu, 1994). It has been identified as a volatile component of fried bacon, cheeses, kiwi fruit, wines, various cultivars of oranges, and of at least two apple species (NLM, 2013; Mattheis et al., 1991; Moshonas and Shaw, 1994).

PHYSICAL AND CHEMICAL PROPERTIES

At 25 °C, its solubility in water is 64 g/l. It is soluble in alcohol, ether, acetone, and benzene (Weast, 1988) and is miscible with chloroform. The bp for ethyl acetate is 77 °C; the specific gravity of ethyl acetate is 0.902 at 4 °C. Its vapor density is 3.04 (air = 1) (Budavari, 1996).

Acute Effects

Ethyl acetate is regarded as one of the least toxic of the volatile organic solvents, and its irritant effect is less strong than that of propyl acetate or butyl acetate (ILO, 1983). However, it reportedly causes mild eye, nasal, and throat irritation at 400 ppm (ACGIH, 2008), and some workers have complained of a strong odor at 200 ppm. A patch test with 10% ethyl acetate in petrolatum produced no irritation in a 48-h exposure in humans (Opdyke, 1979). However, prolonged exposure may cause skin irritation (NIOSH, 1981). Ocular exposure causes temporary dulling of the cornea, and, on repeated exposure, can cause conjunctival irritation and corneal clouding (Lewis, 1996). Symptoms of acute vapor intoxication include emotional lability, e.g., talkativeness, exhilaration, and boastfulness. In the event that acute exposure produces such effects, these symptoms may progress to flushing of face, impaired coordination, slurred speech, nausea, vomiting, and drowsiness. Ingestion can cause throat irritation and a narcotic effect. Acute exposure can produce more serious effects, such as nausea, vomiting, pulmonary changes, incontinence, shock, hypotension, hypothermia, and coma. Death may occur as a result of respiratory or circulatory failure (Gosselin et al., 1984).

Chronic Effects

No chronic systemic effects have been reported in humans (NIOSH, 1981). It is not listed as a carcinogen by IARC or EPA. Ethyl acetate was negative for mutagenicity in the Ames test (*Salmonella typhimurium*) assays (NTP, n.d.). No reproductive studies of ethyl acetate in animals or humans have been found.

Mechanism of Action

Ethyl acetate causes defatting of the skin, which may be a reason for skin irritation seen after prolonged exposure.

Metabolism of ethyl acetate produces acetic acid and ethanol, which may be partially exhaled. Ethanol is otherwise converted to acetaldehyde and then to acetic acid by aldehyde dehydrogenase. The biological half-life of ethyl acetate was found to be 5–10 min in mammals (The Chemical Society, 1977).

Chemical Pathology

Ethyl acetate is mildly toxic by ingestion, but high concentrations can cause congestion of the liver and kidneys. Chronic poisoning has been described to produce anemia, leukocytosis (transient increase in white blood cell count), cloudy swelling, and fatty degeneration of the viscera in animals (Lewis, 1996).

SOURCES OF EXPOSURE

Occupational

It has been estimated that 375,906 workers (87,691 of these are female) are exposed to ethyl acetate in the United States. Occupational exposure to ethyl acetate may occur primarily through inhalation and dermal contact where ethyl acetate is produced or used, or where adhesives, thinners, degreasers, paints, or inks containing ethyl acetate are used (NOES, 1983). Workers in auto paint shops are routinely exposed. Employees with chronic respiratory, skin, liver, or kidney disease may be at increased risk from the effects of ethyl acetate (NIOSH, 1981).

Environmental

Production and use of ethyl acetate as a flavor additive, solvent, manufacturing constituent or other uses may result in its release to the environment through various waste streams (Budavari, 1996). If released in air, ethyl acetate will exist solely as a vapor in the ambient atmosphere where it will be degraded; its estimated half-life is 9.4 days. If released in soil, ethyl acetate is expected to have high mobility, and to be volatilized rather rapidly from dry soil. If released into water, ethyl acetate is not expected to adsorb on the suspended solids and sediment. The bioconcentration factor (BCF) is estimated to be 3.2, which is low (NLM, 2013). Ethyl acetate is a natural product of fermentation, and natural sources of ethyl acetate include animal waste, plant volatiles, and microbes (Graedel, 1978).

INDUSTRIAL HYGIENE

The PEL, REL, and TLV for ethyl acetate are each 400 ppm (1400 mg/m³) (ACGIH, 2008 U. S. Department of Labor, 2013). It is considered immediately dangerous to life and health (IDLH) only when the lower exposure limit of

2000 ppm is reached (NIOSH, 1997). The NFPA hazard classification for ethyl acetate is Health: 1, Flammability: 3, and Reactivity: 0 (NFPA, 1997).

MEDICAL MANAGEMENT

Vapors have a more potent intoxicating effect at higher temperatures (Bisesi, 1994). Ethyl acetate is metabolized to acetic acid and ethanol. Because of its low toxicity and high rate of metabolism, people exposed to ethyl acetate rarely require treatment. However, the patient should be monitored for signs of CNS depression. If eyes are exposed, they should be flushed thoroughly with water. Exposed skin should be washed thoroughly with soap and water.

n-, sec-, AND tert-BUTYL ACETATE

Occupational exposure limits: *n*-butyl acetate (*n*-BA): 713 mg/m³ (OSHA PEL, NIOSH REL, ACGIH TLV); DNEL inhalation, systemic/local effects, long term: 480 mg/m³; DNEL inhalation, systemic/local effects, short term: 960 mg/m³; *sec*-butyl acetate (*sec*-BA): 950 mg/m³ (OSHA PEL, NIOSH REL, ACGIH TLV); *tert*-butyl acetate (*tert*-BA): 950 mg/m³ (OSHA PEL, NIOSH REL, ACGIH TLV); DNEL inhalation, systemic effects, long term: 159 mg/m³; DNEL inhalation, systemic effects, short term: 714 mg/m³; DNEL dermal, systemic effects, long term: 22.5 mg/kg/bw/day

References values: *n*-BA: DNEL inhalation, systemic/local effects, long term: 102.34 mg/m³; DNEL inhalation, systemic/local effects, short term: 859.7 mg/m³; *tert*-BA: DNEL inhalation, systemic effects, long term: 47.3 mg/

m³; DNEL inhalation, systemic effects, short term: 710 mg/m³; DNEL dermal, systemic effects, long term: 13.5 mg/kg/bw/day; DNEL oral, systemic effects, long term: 13.5 mg/kg/bw/day

Hazard statements: H225—highly flammable liquid and vapor (*tert*-BA); H226—flammable liquid and vapor (*n*-BA); H336—may cause drowsiness or dizziness (*n*-BA); additional text—vapor is heavier than air and can travel considerable distance to a source ignition and flashback (*n*-BA); vapors may form explosive mixture with air (*n*-BA); components of the product may be absorbed into the body by inhalation (*n*-BA)

P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking (*n*-BA; *tert*-BA); P233—keep container tightly closed (*n*-BA, *tert*-BA); P235—keep cool (*n*-BA); P243—take precautionary measures against static discharge (*tert*-BA); P261—avoid breathing dust/fume/gas/mist/vapors/spray (*n*-BA); P280—wear protective gloves/protective clothing/eye protection/face protection (*n*-BA, *tert*-BA); P303 + P361 + P353—if in contact with skin (or hair), remove/take off immediately all contaminated clothing; rinse skin with water/shower (*n*-BA); P304 + P340—if inhaled, remove victim to fresh air and keep at rest in a position comfortable for breathing (*n*-BA); P312—call a poison center or doctor/physician if you feel unwell (*n*-BA); P370 + P378—in case of fire, use . . . for extinction; additional text—dry chemicals, CO₂, water spray, or alcohol resistant foam (*tert*-BA); P501—dispose of contents/container to . . . (*tert*-BA); additional text—in accordance with local/regional/national/international regulations (*tert*-BA)

Risk phrases: R10—flammable (*n*-BA); R11—highly flammable (*sec*-BA, *tert*-BA); R66—repeated exposure may cause skin dryness or cracking (*n*-BA, *sec*-BA, *tert*-BA); R67—vapors may cause drowsiness and dizziness (*n*-BA)

Safety phrases: S2—keep out of the reach of children (*sec*-BA, *tert*-BA); S16—keep away from sources of ignition . . . no smoking (*sec*-BA, *tert*-BA); S23—do not breath gas/fumes/vapor/spray (appropriate wording to be specified by the manufacturer) (*tert*-BA); S25—avoid contact with eyes (*n*-BA, *sec*-BA); S29—do not empty into drains (*sec*-BA, *tert*-BA); S33—take precautionary measures against static discharges (*sec*-BA, *tert*-BA)

BACKGROUND AND USES

Butyl acetate (butyl ethanoate, C₆H₁₂O₂, molecular weight 116.16) is a clear, flammable ester of acetic acid that occurs in *n*-, *sec*-, and *tert*- forms (INCHEM, 2005). Butyl acetate

isomers have a fruity, banana-like odor (Furia, 1980). Isomers of butyl acetate are found in apples (Nicholas, 1973) and other fruits (Bisesi, 1994), as well as in a number of food products, such as cheese, coffee, beer, roasted nuts, vinegar (Maarse and Visscher, 1989). Butyl acetate is manufactured via esterification of the respective alcohol with acetic acid or acetic anhydride (Bisesi, 1994). *N*-butyl acetate is used as a solvent for nitrocellulose-based lacquers, inks, and adhesives. Other uses include manufacture of artificial leathers, photographic film, safety glass, and plastics (Budavari, 1996). Isomers of butyl acetate are also used as flavoring agents, in manicure products, and as larvicides (Bisesi, 1994). The *tert*-isomer has been used as a gasoline additive (Budavari, 1996). It may be used as a synthetic fruit flavoring in candy, ice cream, cheeses, and baked goods (Dikshith, 2013).

PHYSICAL AND CHEMICAL PROPERTIES

Butyl Acetate Isomers	CAS Number	Vapor Pressure kPa at 20 °C	Solubility in water, g/L at 20 °C, %
<i>n</i> -CH ₃ COO (CH ₂) ₃ CH ₃	123-86-4	1.2	7.0
<i>sec</i> -CH ₃ COOCH (CH ₃)CH ₂ CH ₃	105-46-4	1.33	0.8.0
<i>tert</i> -CH ₃ COOC (CH ₃) ₃	540-88-5	6.3 at 25 °C	Practically insoluble

(INCHEM, 2005)

At 20 °C, the density of the *n*-butyl isomer is 0.8825 g/cm³, and the density of the *sec*-isomer is 0.8758 g/cm³ (Bisesi, 1994). The *n*-butyl isomer is soluble in most hydrocarbons and acetone, and it is miscible with ethanol, ethyl ether, and chloroform (Haynes, 2010). It dissolves many plastics and resins (NIOSH, 1981). The bp for the *n*-butyl isomer is 126.1 °C (Haynes, 2010). The vapor pressure of the *n*-butyl isomer is 11.5 mmHg at 25 °C, and its vapor density is 4.0 (air = 1) (Verschueren, 2001).

MAMMALIAN TOXICOLOGY

Acute Effects

Butyl acetate isomers have a low toxicity to humans (Iregren et al., 1993); the odor threshold is 7–20 ppm. Nevertheless, *n*-butyl acetate has narcotic properties estimated to be 1.7 times that of ethyl acetate. Brief exposure to 3300 ppm caused marked irritation to the eyes and nose while mild irritation was reported at concentrations of 1400 ppm for 20 min or to 700 ppm for 4 h (NLM, 2013). Inhalation of high concentrations of *n*-butyl acetate can produce headache and drowsiness, eye inflammation and irritation, but it has not been reported to produce systemic ocular toxicity. Exposure can

also produce upper respiratory tract irritation and dryness of the skin. Skin contact in high concentrations can also cause a narcotic effect, but 4% *n*-butyl acetate in petrolatum was not irritating or a sensitizer on the skin of human volunteers (unpublished). In the rare case of an acute exposure at high concentrations, symptoms may include headache, nausea, vomiting, diarrhea, and gastrointestinal hemorrhage. Ataxia, confusion, delirium, coma, and disturbances in cardiac rhythm and cardiac failure may also occur after exposure to high air-borne concentrations of butyl acetate. Liver edema and fatty liver, as well as glycosuria and kidney damage have been observed after acute exposure in animal studies. Prolonged high inhalation exposures can cause death to animals, typically occurring from respiratory failure (NLM, 2013).

Chronic Effects

n-Butyl acetate is not regarded as a human teratogen on the basis of studies in rats and rabbits (Hackett et al., 1983). Yang et al. (2007) reported a no-observed-adverse effect level for *tert*-butyl acetate of 400 mg/kg/day for embryo–fetal development in rats. Reproductive toxicity for the *sec*-butyl isomer was found. The isomer *n*-butyl acetate was not found to be mutagenic in the Ames test (McGregor et al., 2005) and it did not induce chromosomal aberrations in Chinese hamster fibroblasts (Ishidate et al., 1984). Negative results were obtained for *n*-butyl acetate in a test for mitotic aneuploidy in *Saccharomyces cerevisiae* strain D61.M (Zimmermann et al., 1985). None of the isomers of butyl acetate (123-86-4, 105-46-4, or 540-88-5) are listed as human carcinogens by IARC (2012).

Mechanism of Action

In the body, *n*-butyl acetate and *sec*-butyl acetate undergo rather rapid hydrolysis to acetic acid and their respective alcohols. The acetic acid is then oxidized via the citric acid cycle to carbon dioxide and water. The major metabolites of butyl acetate excreted by mammals are (RS)-hydroxy(4-hydroxy-3-methoxy-phenyl)acetic acid or vanillylmandelic acid (Bisesi, 1994). In rats exposed to *tert*-butyl acetate by inhalation, the half-life of blood levels was about 45 min (Groth and Freundt, 1994).

Chemical Pathology

Butyl acetates are CNS depressants, and are irritating to the nose, throat, and eyes. Headache, nausea, and other non-specific symptoms such as fatigue may occur. No specific mechanistic information regarding the adverse effects of butyl acetate was found, however. Dermatitis may occur in sensitive individuals (NLM, 2013).

SOURCES OF EXPOSURE

Occupational

It has been estimated that 822,099 workers (143,606 of these are female) were potentially exposed to *n*-butyl acetate in the United States during the period 1981–1983 (NOES, 1983). Inhalation and dermal contact are the most important routes of exposure in the occupational setting. Spray painting and gluing may offer the highest exposure, but paint manufacturing, silk screen printing, installation of parquet floors, and the application of artificial finger nails by manicurists also offer substantial exposure to butyl acetate (NLM, 2013).

Environmental

The production and use of butyl acetate in the manufacturing of lacquer, artificial leather, photographic films, plastics and safety glass may result in its release to the environment through various waste streams (O’Neil, 2006). The vapor phase of *n*-butyl acetate is degraded by photochemically produced hydroxyl radicals, and the half-life for this reaction is estimated to be 3.8 days. If released to soil, *n*-butyl acetate is expected to have very high mobility, as volatilization is an important fate of *n*-butyl acetate at the soil surface. Volatilization from water surfaces is also expected to be an important fate process. The BCF is estimated to be 7 in fish, suggesting that the potential for bioconcentration in aquatic organisms is expected to be low (HSDB, 2013). In one study, the incidence of *n*-butyl acetate in finished waters using groundwater supplies in the United States was <5% (Dyksen and Hess, 1982).

INDUSTRIAL HYGIENE

The isomer *n*-butyl acetate has an odor threshold of 7–20 ppm. The PELs, RELs, and TLVs for *sec*- and *tert*-isomers are 200 ppm (950 mg/m³). However, *n*-butyl acetate has a slightly lower PEL, REL, and TLV of 150 ppm (713 mg/m³) (ACGIH, 2010). All isomers are considered IDLH when they reach their lower explosive limit at 1500–1700 ppm. The NFPA hazard classification for butyl acetate is Health: 2, Flammability: 3, and Instability: 0 (NFPA, 2010). Workplace air borne concentrations that are immediately dangerous to life or health are above 1700 ppm (USDOL, 2013).

MEDICAL MANAGEMENT

Treatment for these esters is seldom needed because of their low toxicity, but patients should be monitored for CNS depression. If ingested, butyl acetate may be diluted with 4–8 ounces of milk or water. In cases of inhalation, the patient should be moved to fresh air. Oxygen should be administered as required. If eyes are exposed, they should be

flushed thoroughly with water at room temperature. Dermal exposures should be treated with soap and water. Butyl acetate does not cause significant burns.

OTHER ALIPHATIC ESTERS

The American Chemical Council and its member companies are presently addressing the toxicological hazards associated with 45 high production volume aliphatic esters, including monoesters, diesters, glycol esters, esters of monoacids and sorbitan, and esters of monoacids and trihydroxy or polyhydroxy alcohols.

HALOGENATED ACID ESTERS

A small number of halogenated acid esters are potent lacrimating and vesicating agents and have the potential

capacity for producing pulmonary edema. Compounds in this category are important organic intermediates and include ethyl chloroformate, ethyl chloroacetate (CASRN 105-39-5), and related bromo- and iodo- compounds. These materials have been used as chemical warfare and riot control agents. There is no evidence that they produce chronic diseases, but fatalities have occurred from acute pulmonary edema. The highly hazardous character of these compounds appears to be related to the high reactivity of the halogen atoms.

ETHYL CHLOROFORMATE

Occupational exposure limits: None

Reference values: None

Hazard statements: H225—highly flammable liquid and vapor; H314—causes severe skin burns and eye damage; H301—toxic if swallowed; H330—fatal if inhaled

Precautionary statements: P210—keep away from heat/ sparks/open flames/ . . . /hot surfaces . . . no smoking; P233—keep the container tightly closed; P240—ground/bond container and receiving equipment; P241—use explosion-proof electrical/ventilating/lighting/ . . . /equipment; P242—use only non-sparking tools; P243—take precautionary measures against static discharge; P280—wear protective gloves/protective clothing/eye protection/ face protection; P284—wear respiratory protection; P271—use only outdoors or in a well-ventilated area; P260—do not breathe dust/fume/gas/mist/vapors/spray; P264—wash . . . thoroughly after handling; P270—do not eat, drink, or smoke when using this product; P310—immediately call a poison center or doctor/physician; P305 + P351 + P338—if in contact with eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P304 + P340—if inhaled, remove victim to fresh air and keep at rest in a position comfortable for breathing; P363—wash contaminated clothing before reuse; P321—specific treatment (see . . . on the label); P303 + P361 + P353—if in contact with skin (or hair), remove/take off immediately all contaminated clothing; rinse skin with water/shower; P370 + P378—in case of fire, use . . . for extinction; P403 + P235—store in a well-ventilated place; keep cool; P405—store locked up; P501—dispose of contents/container to . . .

Risk phrases: R11—highly flammable; R22—harmful if swallowed; R26—very toxic by inhalation; R34—causes burns

Safety phrases: S1/2—keep locked up and out of reach of children; S9—keep container in a well-ventilated place; S16—keep away from sources of ignition—no smoking;

S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S28—after contact with skin, wash immediately with plenty of . . . (to be specified by the manufacturer); S33—take precautionary measures against static discharges; S36/37/39—wear suitable protective clothing, gloves and eye/face protection; S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible)

BACKGROUND AND USES

Ethyl chloroformate (chloroformic acid ethyl ester; molecular weight 108.52, ClCOOC₂H₅ (CASRN 541-41-3) is used as a solvent in the photographic industry, and as a chemical intermediate in the production of various carbamates, and used in synthesis of dyes, drugs, veterinary medicines, herbicides, and insecticides. It is also used in the production of flotation agents for ores, as a stabilizer for PVC, and in the production of modified penicillins and heterocyclic compounds (Gerhardt, 1985).

PHYSICAL AND CHEMICAL PROPERTIES

Ethyl chloroformate is a colorless liquid that is corrosive and flammable. It is prepared from phosgene and ethanol. It has a sharp odor, like hydrochloric acid, and it decomposes in water. It is miscible with alcohol, benzene, chloroform, and ether. The bp is 95 °C, and the melting point is –80.6 °C (ICSC, 1025); the specific gravity is 1.1403 at 4 °C (Budavari, 1996). The vapor density is 3.7 (air = 1) (NFPA, 1997).

MAMMALIAN TOXICOLOGY

Acute Effects

Vapors of ethyl chloroformate are very strong irritants to the eyes, mucous membranes, and skin (Budavari, 1996). Irritation of the upper respiratory tract, with cough, dyspnea, pulmonary edema, lacrimation, nausea, vomiting, abdominal pain, weakness, and shock may occur. The toxic properties resemble those of the methyl homolog in the degree of corrosiveness, irritation, and lacrimary qualities (Bisesi, 1994). Onset of symptoms may be delayed, and pulmonary edema of late onset has been reported. Inhalation exposure to 190 ppm for 10 min has caused human fatalities, and exposure to 10 ppm has caused excessive lacrimation (NLM, 2003). Fatal occupational exposures have occurred. The oral LD₅₀ for the rat is <50 mg/kg and the intraperitoneal LD_{LO} for the mouse is 5 mg/kg (Sandmeyer and Kirwin, 1981). It reacts with water to produce heat, carbon dioxide, and hydrogen chloride gas (NLM, 2003).

Chronic Effects

No data were found on potential effects on pregnancy and fetal development. Ethyl chloroformate is not listed as a carcinogen by IARC (2012).

Mechanism of Action

Ethyl chloroformate is highly irritant and corrosive by ingestion, inhalation, or eye or skin contact. It is one of the agents used in biochemical carbobenzoxy group removal, without scission of the peptide bond. Analogously, a similar reaction may be responsible for the hepatic and renal effects seen upon exposure (Bisesi, 1994).

SOURCES OF EXPOSURE

Occupational

It has been statistically estimated that 2,247 workers in the USA are potentially exposed in the photographic industry and during its use as a chemical intermediate (NOES, 1983).

Environmental

The use of ethyl chloroformate in the photographic industry could result in release to the environment through evaporation or in various waste streams. In the ambient atmosphere, the estimated half-life of ethyl chloroformate is about 11 days (Meylan and Howard, 1993). Ethyl chloroformate hydrolyzes readily in water; the half-life is 31.5 min at 25 °C (Queen, 1967). Bioconcentration and adsorption on the sediment are not expected to be important fate processes, due to its rapid rate of hydrolysis. Hydrolysis will probably also dominate its fate in moist soils. This chemical has a relatively high vapor pressure of 22.4 mmHg at 25 °C (Daubert and Danner, 1991), which suggests that evaporation from dry soil surface will occur.

INDUSTRIAL HYGIENE

The ACGIH TLV and PEL or MAK values have not been established (ICSC, 1025). Reaction with water or moist air will release hydrogen chloride or other toxic, corrosive, or flammable gases. The NFPA hazard classification for ethyl chloroformate is Health: 4, Flammability: 3, Reactivity: 1; do not use water; use dry chemical, foam, carbon dioxide, or water spray (NFPA, 1997).

MEDICAL MANAGEMENT

If no respiratory compromise is evident, administer no more than 4–8 oz of water or milk to neutralize ingested acid. Vomiting should not be induced, but removal of acid from

stomach via gastric suction may be considered. Move patient to fresh air; monitor for respiratory distress, and evaluate possible respiratory tract irritation. Administer oxygen and assist ventilation as required. Irrigate exposed eyes with copious amounts of water at room temperature for at least 15 min. No specific protocol supportive care, respiratory care—may treat bronchospasm with beta 2 agonists and/or corticosteroids (NLM, 2003).

BACKGROUND AND USES

Ethyl chloroacetate (chloroacetic acid ethyl ester, molecular weight 122.55, ClCH₂COOC₂H₅, CASRN 105-39-5) is a highly flammable clear liquid with a pungent odor (Bisesi, 1994). Ethyl chloroacetate is utilized as a solvent and in organic synthesis; it is also used in vat dyestuffs and as a military poison (Lewis, 1997). In addition, it is a chemical intermediate in the synthesis of sodium fluoroacetate (rodenticide) and benzolin (herbicide) (SRI, 1999).

PHYSICAL AND CHEMICAL PROPERTIES

Ethyl chloroacetate has a vapor pressure of 10 mmHg at 38 °C (Lewis, 1997). It is insoluble in water, but miscible with alcohol, ether, and acetone (Lide, 1998); it is soluble in benzene (Lewis, 1997). The boiling point for ethyl chloroacetate is 143 °C while the melting point is –26 °C; its density is 1.1498 g/ml at 25 °C (Budavari, 1996). The flash point is slightly below 61 °F (Budavari, 1996). The vapor density is 4.3 (air = 1) (Bisesi, 1994). Ethyl chloroacetate readily decomposes in hot water and alkalis (Lewis, 1997).

MAMMALIAN TOXICOLOGY

Acute Effects

This chemical is easily vaporized, and it is a severe eye irritant and potent lacrimator. It is very harmful if inhaled or

swallowed; it may cause severe eye, skin, and respiratory tract irritation, with possible burns (Sax, 1979). Exposure to vapor causes immediate ocular burning, blepharospasm (involuntary blinking), lacrimation, rhinorrhea, coughing, sneezing, and pain, but usually no permanent tissue damage. These symptoms may be followed by chest tightness and coughing, sore throat, burning of tongue and mouth, salivation, and vomiting. Symptoms usually subside within 15–30 min, but chemical burns with keratitis, loss of corneal epithelium, and permanently reduced cornea sensation have been reported. One case of contact dermatitis has also been reported (Braun and van der Walle, 1987). Burning sensations of the skin, followed by erythema and bullous dermatitis may occur in 12 h to 3 days following exposure to tear gas (mace) containing ethyl chloroacetate and *o*-chlorobenzylidene malononitrile (CS). Pulmonary edema may occur 12–24 h postexposure. Erythema, vesicle eruptions, and denuded areas with weeping, tender erythematous base may develop 1 day after exposure to mace containing 1-chloroacetophenone (CN). Nausea is common, and vomiting may occur, especially if ethyl chloroacetate is swallowed. Tachycardia and mild hypertension may occur as a result of fear and pain. Agitation and syncope attributed to panic after exposure have also been reported. The acute rat oral LD₅₀ for ethyl chloroacetate is 180 mg/kg and the acute dermal LD₅₀ in rats is 161 mg/kg bw; the 4-h LC₅₀ for rats is 3.3 ml/m³ (Berufsgenossenschaft der Chemischen Industrie, 1992).

Chronic Effects

Chronic effects of exposure to ethyl chloroacetate have not been reported, as acute exposure is most commonly encountered. There is no evidence that ethyl chloroacetate represents a carcinogenicity risk. The literature does not provide evidence for tumorigenicity or genotoxicity using various in vivo and in vitro test systems and this supports the general conclusion that ethyl chloroacetate is not likely carcinogenic utilizing various laboratory testing methods. Adverse effects in developing animal fetuses were not found in the literature. Based on animal findings, there is no evidence that ethyl chloroacetate represents a carcinogenic risk (NLM, 2003).

Mechanism of Action

Ethyl chloroacetate is irritating and corrosive to all tissues; it can readily cause chemical burns.

Chemical Pathology

Reports of investigations regarding the chemical pathology of ethyl chloroacetate were not found; however, by hydrolysis to form ethanol and chloroacetic acid (NLM, 2003)

SOURCES OF EXPOSURE

Occupational

National Institute for Occupational Safety and Health has statistically estimated that 919 workers (306 of these are female) are potentially exposed to ethyl chloroacetate in the United States (NOES, 1983). Occupational exposure may occur through inhalation and dermal contact in workplaces where ethyl chloroacetate is produced or used.

Environmental

The production and use of ethyl chloroacetate may result in its release to the environment through various waste streams. If released in air, a vapor pressure of 4.87 mmHg at 25 °C indicates that it will exist as a vapor in the ambient atmosphere. Vapor phase ethyl chloroacetate will be degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals; the half-life for this reaction is estimated to be 13 days. If released to soil, ethyl chloroacetate is expected to have high mobility. Ethyl chloroacetate is subjected to hydrolysis, especially under acid or alkaline conditions. If released into water, it is not expected to adsorb rapidly on suspended solids and sediment, and volatilization from the surface of water is expected to be an important fate process. An estimated BCF of 3 for ethyl chloroacetate suggests that the potential for concentration in aquatic organisms is low (Bennett et al., 1984).

INDUSTRIAL HYGIENE

No published PEL or ACGIH exposure standards for ethyl chloroacetate were found. Ethyl chloroacetate is a flammable liquid. The NFPA hazard classification is Health: 3, Flammability: 2, Reactivity: 0 (NFPA, 1997). Sufficient personal protection should be worn when there is a possibility of exposure.

MEDICAL MANAGEMENT

After eye contact, immediately flush with plenty of water for at least 15 min and get medical aid immediately. In the instance of skin contact, flush skin with copious amounts of water for at least 15 min. Remove contaminated clothing and shoes, and get medical attention immediately. If swallowed, do not induce vomiting unless directed to do so by medical personnel. For inhalation exposure, remove to fresh air; give artificial respiration if not breathing. If breathing is difficult, give oxygen. Although permanent injury or death is not common, medical attention may be required for several days after acute exposure.

ETHYL 2-BROMOACETATE

Occupational exposure limits: None

Reference values: None

Hazard statements: None

Precautionary statements: None

Risk phrases: R26/27/28—very toxic by inhalation, when in contact with skin, and if swallowed

Safety phrases: S1/2—keep locked up and out of the reach of children; S7/9—keep container tightly closed and in a well-ventilated place; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible)

BACKGROUND AND USES

Ethyl 2-bromoacetate (2-bromoacetic acid, ethyl ester; BrCH₂COOC₂H₅, CASRN 105-36-2) is a flammable liquid that is easily vaporized (Lide, 1999). It has been employed as a tear gas (Grant, 1986). It is also utilized as a chemical intermediate or reactant in the synthesis of an analgesic (Rogers and May, 1974), other pharmaceuticals, and beta-keto acids. Ethyl 2-bromoacetate is also used as a warning agent for other poisonous, odorless gases (SRI Consulting, 1999). It is manufactured by esterification of bromoacetic acid with ethyl alcohol in the presence of sulfuric acid (Lewis, 1997).

PHYSICAL AND CHEMICAL PROPERTIES

Ethyl 2-bromoacetate, molecular weight 167, is colorless, and has a pungent odor. The specific gravity is 1.5032 at 20 °C (Lide, 1999), and the bp is 158 °C (316 °F). The melting point is –38 °C. It is insoluble in water, but is soluble in acetone and benzene (Lide, 1999; Lewis, 1997). Ethyl 2-bromoacetate is miscible with ethanol, ethyl ether, and with other oxygenated and aromatic solvents (Ashford, 1994; Lide, 1999). The vapor density is 5.8 (air = 1) (Lewis, 1997). It is partially decomposed by water (Lewis, 1997).

MAMMALIAN TOXICOLOGY

Acute Effects

Occupational exposure by inhalation or dermal contact may occur in workplaces where ethyl 2-bromoacetate is produced or utilized. Ethyl 2-bromoacetate is a potent irritant to eyes, skin, and all mucous membranes (Lewis, 1996); it is a more potent lacrimator than the chloroacetic acid ethyl ester. A concentration of 8 ppm in air is unbearable for more than a minute (Grant, 1986). High concentrations of vapor have caused keratitis, corneal edema with wrinkling of Descemet's membrane, loss of corneal epithelium, and/or reduced corneal sensation (HSDB, 2013). In most patients, their eyes return to normal. Nevertheless, direct eye contact with the liquid chemical has caused permanent corneal scarring and opacification (Grant, 1986). It is also toxic by inhalation, skin absorption, and ingestion. Upon inhalation, symptoms of chest tightness and coughing, sore throat, shortness of breath, burning of tongue and mouth, salivation, and vomiting may occur. Symptoms usually subside rapidly within 15–30 min of cessation of exposure in most individuals. Dermal contact causes skin irritation and possible bullous dermatitis on all significantly exposed body surfaces. Ethyl bromoacetate, like other esters, reacts with acids to form alcohols and acids (NLM, 2013).

Chronic Effects

Ethyl 2-bromoacetate is not listed as a carcinogen by the IARC (2012). One incomplete report suggests mutagenicity in Ames test or strain TA104 and in *E. coli* strain WP2uvrA/pKM101, both with S9 activation. No information on possible developmental toxicity or teratogenicity was found for animal models or humans. Based on animal findings, there is no evidence that ethyl 2-bromoacetate represents a carcinogenic risk (NLM, 2013).

Mechanism of Action

The biochemical mode of action of ethyl 2-bromoacetate has not been elucidated.

Chemical Pathology

Lesions of skin and eyes caused by acute exposure to ethyl 2-bromoacetate are described in Section 3.1.

SOURCES OF EXPOSURE

Occupational

National Institute for Occupational Safety and Health has statistically estimated that 851 workers (187 of these are female) are potentially exposed to ethyl 2-bromoacetate in the United States via inhalation or dermal contact at workplaces where this compound is produced or utilized (NLM 2013). Reaction with water will release heat, and toxic, corrosive or flammable gases.

Environmental

The production and use of ethyl 2-bromoacetate may result in its release to the environment via various waste streams. If released to air, an estimated vapor pressure of 3.37 mmHg at 25 °C indicates that this chemical will exist as a vapor in the ambient atmosphere. Vapor phase ethyl 2-bromoacetate will be degraded photochemically in air with a half-life estimated to be of 14 days (HSDB, 2013). If released into soil, it is expected to have very high mobility. Volatilization from moist soil surfaces and dry soil is expected to be an important fate process. If released into water, ethyl 2-bromoacetate is not expected to absorb by suspended solids and sediment in the water. An estimated BCF of 1 indicates that bioconcentration in aquatic organisms will be quite low.

INDUSTRIAL HYGIENE

No occupational exposure standards exist for ethyl 2-bromoacetate. Since it is highly toxic by ingestion, inhalation, and skin absorption, every effort should be made to provide sufficient worker protection from potential exposure,

especially via skin and eyes. Contact lenses should not be worn by individuals potentially exposed to ethyl 2-bromoacetate. Ethyl 2-bromoacetate is regarded as highly flammable, easily ignited by heat, sparks, or flames; vapors of ethyl 2-bromoacetate form potentially explosive mixtures with air. The NFPA hazard classification is Health: 3, Flammability: 2, Instability: 1, Special: none (NFPA, 1997).

MEDICAL MANAGEMENT

For inhalation exposure, move patient to fresh air. Monitor for respiratory distress; if cough or difficulty in breathing develops, evaluate for respiratory tract irritation, bronchitis, or pneumonitis. Laryngospasm may require endotracheal intubation and ventilation. Administer oxygen and assist ventilation as required. Treat bronchospasm with an inhaled beta-2 agonist and oral or parenteral corticosteroids. For exposure to skin, meticulously wash all exposed areas with copious amounts of soap and water. The patient's clothing may contain residual amounts of active chemical. Remove clothing and store in a sealed polyethylene bag to prevent degassing; wash all clothing with cold water. For eye exposure, irrigate exposed eyes with copious amounts of water at room temperature for 15 min or more. If irritation, pain, swelling, lacrimation, or photophobia persist, patient should be referred to a health care facility (HSDB, 2013).

ALKYL ESTERS OF SULFURIC ACID

DIMETHYL SULFATE

Occupational exposure limits: 1 ppm (OSHA PEL); 0.1 ppm (NIOSH REL); 0.1 ppm (ACGIH TLV with skin notation)

Reference values: None

Hazard statements: H301—toxic if swallowed; H314—causes severe skin burns and eye damage; H317—may cause an allergic skin reaction; H330—fatal if inhaled; H341—suspected of causing genetic defects; H350—may cause cancer

Precautionary statements: P202—do not handle until all safety precautions have been read and understood; P281—use personal protective equipment as required; P303 + P361 + P353—if on skin (or hair), remove/take off immediately all contaminated clothing; rinse skin with water/shower; P304 + P340—if inhaled, remove victim to fresh air and keep at rest in a position comfortable for breathing; P305 + P351 + P338—if in contact with eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P310—immediately call a poison center or doctor/physician

Risk phrases: R25—toxic if swallowed; R26—very toxic by inhalation; R34—causes burns; R43—may cause sensitisation by skin contact; R45—may cause cancer; R68—possible risk of irreversible effects

Safety phrases: S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible); S53—avoid exposure—obtain special instructions before use

BACKGROUND AND USES

Dimethyl sulfate (DMS; $(\text{CH}_3\text{O})_2\text{SO}_2$) sulfuric acid dimethyl ester; CASRN 77-78-1) is prepared by distillation of an oleum/methanol mixture; technical production using dimethyl ether and SO_3 has also been reported (NLM, 2013). It is currently used as a methylating agent in the manufacture of organic chemicals, including surfactants,

pesticides, water treatment chemicals, dyes, flavors, pharmaceuticals, rubber chemicals, and photographic films. It was formerly used as a chemical weapon (NTP, 2011).

PHYSICAL AND CHEMICAL PROPERTIES

Dimethyl sulfate has a molecular weight of 126.13 (O’Neil, 2006). It is essentially odorless (Langford, 2004). The specific gravity of this colorless, corrosive, oily liquid is 1.3322 g/cm³ (O’Neil, 2006); its vapor density is 4.35 (air = 1), and its vapor pressure is 0.54 mmHg at 20 °C. The bp is about 188 °C (O’Neil, 2006). Dimethyl sulfate is soluble in ether, dioxane, acetone, benzene, and other aromatic hydrocarbons. It is sparingly soluble in carbon disulfide and aliphatic hydrocarbons, and only slightly soluble in water (28 g/l at 18 °C) (O’Neil, 2006).

MAMMALIAN TOXICOLOGY

Acute Effects

Dimethyl sulfate is extremely hazardous. Major target organs are the eyes, respiratory system, skin, and CNS. Because of its deficient warning properties, unnoticed exposure to lethal quantities can occur, and appearance of symptoms may be delayed by 4–12 h. Symptoms of industrial poisoning uniformly found after each exposure began with headache, photophobia, and difficulty with breathing and swallowing. Other effects may also include painful coughing, erythema of eyes, lacrimation, blepharospasms (involuntary eye blinking), and chemosis. Corneal ulceration and severe inflammation of the eyes and eyelids with photophobia generally resolve satisfactorily although irreversible loss of vision has been reported. Even burns resulting from direct contact with the skin are delayed in their onset, in spite of immediate, thorough neutralization and irrigation of the exposed area (Littler and McConnell, 1955). Irritation of the mucous membranes of the mouth and respiratory tract may be severe, with pulmonary edema; there may also be hoarseness and oropharyngeal edema, which persists for several weeks. Systemic effects can include convulsions, delirium, coma, analgesia, pyrexia, pulmonary edema, delayed renal and hepatic failure, and cardiac damage. Edema of the tongue, lips, larynx, and lung may also occur later. Delayed effects may consist of respiratory, liver, and kidney damage; severe inflammation, and necrosis of the eyes, mouth, and respiratory tract; severe/fatal pulmonary damage; prostration; convulsions; delirium; paralysis; and coma (Dreisbach, 1987). Other systemic effects such as convulsions; delirium; coma; and renal, hepatic, and cardiac failure have been reported. Clinically, the usual manifestations include skin burns, corneal irritation with photophobia, lacrimation and blurring of vision, oropharyngeal edema with suffocation and hoarseness of the voice, nasal septal necrosis, cough, and dyspnea (Ellenhorn et al., 1997). Major causes of mortality in dimethyl sulfate intoxication

include respiratory failure following mucosal inflammation, edema of major airways, and noncardiogenic pulmonary edema.

Chronic Effects

Chronic symptoms include dysphonia, aphonia, dysphagia, chest pain, cyanosis, diarrhea, icterus, albuminuria, and hematuria. Symptoms of hepatic disease may include malaise, lethargy, nausea, vomiting, pruritus, anorexia, hepatic enlargement and tenderness. Other signs of hepatic disease may include upper right quadrant pain, anorexia, scleral icterus, hepatic enlargement and tenderness, dark urine, and light-colored, loose stools (Ellenhorn and Barceloux, 1988). Dimethyl sulfate is a confirmed animal carcinogen (NTP, 2011), and it is a suspected as a human carcinogen (A2) (NLM, 2013). Experimental inhalation studies confirm that DMS vapors at concentrations <8 ppm cause regional DNA methylation; under nose-only conditions N7-methylguanine and N3-methyladenine was found in the nasal mucosa of exposed rats (Mathison et al., 1995). Dimethyl sulfate was also carcinogenic to animals (sarcomas) at the injection site following subcutaneous injection. Furthermore, dimethyl sulfate administered to pregnant rats by intravenous injection caused tumors of the nervous system in the offspring (IARC, 1974). There is no data available for chronic, long-term effects of dimethyl sulfate in humans (USEPA, 2013).

Mechanism of Action

Dimethyl sulfate is a methylating agent that converts phenols, amines, and thiols to the corresponding methyl derivatives (IARC, 1999). Methylation of DNA in animal models is with little doubt a mechanism for its carcinogenic potency. Exposure to 0.2–20 mg/m³ dimethyl sulfate has caused chromosomal abnormalities in lymphocytes of exposed workers. Nevertheless, there is insufficient clinical or epidemiological evidence to indicate that dimethyl sulfate is a human carcinogen at this time (WHO, 1985).

Besides methylation of DNA, dimethyl sulfate is more than likely an active methyl donor with a number of endogenous nucleophiles, such as oxygen, carbon, sulfur, phosphorus, as well as with some metals.

Chemical Pathology

Severe eye and skin burns are relatively common.

SOURCES OF EXPOSURE

Occupational

Occupational exposure to dimethyl sulfate may occur through inhalation and dermal contact at workplaces where it is produced

or utilized. National Institute for Occupational Safety and Health has estimated that 10,481 workers (2455 of these are female) are potentially exposed to dimethyl sulfate in the United States (NOES, 1983). Dimethyl sulfate is highly toxic to humans, but the immediate symptoms of exposure may be non-existent or very mild making it particularly hazardous, especially to the respiratory tract. Some reports of exposure to fumes for only a few minutes have ultimately been fatal (NLM, 2003).

Environmental

The use of dimethyl sulfate as a methylating agent, stabilizer, and chemical intermediate may result in its release to the environment through various waste streams. If released to air, a vapor pressure of 0.667 mmHg at 25 °C indicates that dimethyl sulfate will exist solely as a vapor in the atmosphere, where it will be rapidly degraded by reaction with atmospheric water, or by the action of photochemically produced hydroxyl radicals with a half-life of 82 days. If released to soil, dimethyl sulfate is expected to be hydrolyzed in moist soils or to volatilize from dry soil. If released directly into water, dimethyl sulfate is anticipated to hydrolyze with a half-life of 1.15 h at pH 7, yielding methanol and sulfuric acid (NLM, 2013). Because of its rapid hydrolysis, binding to suspended solids and sediments in water or concentration in biota are not expected to be important fate processes.

INDUSTRIAL HYGIENE

Human exposures are possible during the manufacture, use, handling, or waste management of dimethyl sulfate. The OSHA PEL for DMS is presently 1 ppm (5 mg/m³), but the NIOSH REL is 0.1 ppm (1990) based upon its potential carcinogenicity. The ACGIH TLV has also been set at 0.1 ppm, with a skin notation (ACGIH, 2008). Dimethyl sulfate is classified as A2 (suspected human carcinogen) (NTP, 2011), and it is a confirmed animal carcinogen that can alkylate DNA (IARC, 1999; ACGIH, 2008). As a suspected carcinogen, dimethyl sulfate should be handled with extreme caution.

MEDICAL MANAGEMENT

After oral exposure, immediately dilute with 4–8 ounces (120–240 ml) of water or milk (not to exceed 4 ounces in a child). Emesis is not recommended due to corrosive nature of dimethyl sulfate. Ipecac is contraindicated. Gastric suction may be considered after recent ingestion, or administration of a 12.5% charcoal slurry. If cough or difficulty in breathing develops, evaluate for respiratory tract irritation and move to fresh air. Remove contaminated clothing and wash exposed skin area thoroughly with soap and water. For skin burns, administer humidified oxygen, and remove from exposure. Determine pulse and obtain a chest X-ray. Administer

inhaled beta-2 adrenergic agonists in patients with bronchospasm. Irrigate exposed eyes with copious amounts of water at room temperature for at least 15 min (NLM, 2013). Once exposed worker is deemed fit to return to work, management should strongly consider reassignment to prevent further exposure to DMS (Agabiklooei et al., 2010).

Safety phrases: S53—avoid exposure—obtain special instructions before use; S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible)

BACKGROUND AND USES

Diethyl sulfate (DES; sulfuric acid diethyl ester; CASRN 64-67-5 ($C_2H_5)_2SO_4$) is produced from ethanol and sulfuric acid, from ethylene and sulfuric acid, or from diethyl ether and fuming sulfuric acid (Budavari, 1996). It is used in the synthesis of ethyl derivatives of phenols, amines, and thiols, and as an accelerator in the sulfation of ethylene, and in some sulfonation processes. It is also used to manufacture dyes, pigments, carbonless paper, and textiles. Smaller quantities are

used in household products, cosmetics, agricultural chemicals, pharmaceuticals, and laboratory reagents (NTP, 2011).

PHYSICAL AND CHEMICAL PROPERTIES

Diethyl sulfate is a colorless, oily liquid with a faint peppermint-like odor, which darkens with age (Budavari, 1996). The molecular weight for diethyl sulfate is 154.2, and its density is 1.17 g/cm³ at 25 °C. The vapor pressure of DES is 1 mmHg at 47 °C, and its vapor density is 5.31 (air = 1). It is miscible with alcohol and ether (O’Neil, 2006). The bp is 210 °C, with some decomposition. The water solubility of DES is 7.0 g/l at 20 °C. At higher temperatures, DES rapidly decomposes into monoethyl sulfate and alcohol (NTP, 2011).

MAMMALIAN TOXICOLOGY

Acute Effects

Diethyl sulfate is highly toxic by inhalation, skin or eye contact, or ingestion. For rats, the lowest oral LD₅₀ found was 350 mg/kg, and the lowest toxic dose producing death in the rat by inhalation was 250 ppm for a 4-h exposure (Druckery et al., 1970).

Diethyl sulfate is extremely irritating to the skin, eyes, and mucous membranes. Toxicity is most common following inhalation of vapors or dermal exposure, and may be delayed to several hours. Effects of overexposure can include extreme eye pain, photophobia, lacrimation, blurred vision, corneal edema, and angioneurotic edema, followed by pharyngolaryngeal inflammation, dysphonia, aphonia, dysphagia, productive cough, and cyanosis. Delayed pulmonary edema may also occur. Prolonged inhalation of low concentrations produces nausea and vomiting (IARC, 1992). A human exposure of 97 ppm for 10 min may be fatal (Deichman and Gerade, 1969). Contact with the liquid can cause irritation with severe ocular and dermal chemical burns (NLM, 2013).

Chronic Effects

Diethyl sulfate has been shown to cause cancer in subcutaneous and oral administration studies in BD rats (Druckery et al., 1970). The World Health Organization classified vapors from DES as a Group 2A—probable human carcinogen (IARC, 1992). Ehling and Neuhauser-Klaus (1988) described mutations and chromosomal aberrations induced by DES in male mice. Other authors have also reported DNA damage, DNA repair, and mitotic induction in human cells, experimental animals, and bacterial studies; chromosome aberrations were also induced in humans and animals (NLM, 2013). In one reproductive toxicity study, a single dose of DES (85 mg/kg bw) was administered to three pregnant BD rats on day 15 of gestation. Malignant tumors of the nervous system were seen

in 2/30 of the offspring on days 285 and 541. The IARC has classified diethyl sulfate as a Group 2A, probable human carcinogen (IARC, 1992).

Mechanism of Action

Diethyl sulfate is an alkylating agent which induces DNA single-strand breaks, inhibits DNA repair, causes mutations, and attacks other chemical sites. Dominant lethal mutations, specific locus mutations, and aneuploid cells were reported in various animal studies (NLM, 2013).

Chemical Pathology

Diethyl sulfate is a mutagen. Ethylation of DNA at the N⁷ position of guanine is a major site for DNA damage *in vitro* (IARC, 1992).

SOURCES OF EXPOSURE

Occupational

National Institute for Occupational Safety and Health has estimated that 2261 workers (164 of these are female) are potentially exposed to diethyl sulfate in the United States (NOES, 1983). Occupational exposure may occur during the production of DES or during its use as an ethylating agent, as an accelerator in the sulfation of ethylene, and in other sulfonation reactions (NLM, 2013).

Environmental

The production and use of diethyl sulfate as an ethylating agent may result in its release to the environment through various waste streams. Diethyl sulfate is listed as a hazardous air pollutant, and is suspected to cause serious health problems. Nevertheless, it is expected to exist as a vapor, where it will be degraded by photochemically produced hydroxyl radicals with a half-life of about 9 days. In addition, it is expected to hydrolyze rapidly in the atmosphere in the presence of water vapor; the half-life for this reaction is <1 day (NLM, 2013). Based on the hydrolysis of DES in aqueous environments, it is not expected to volatilize from moist soil surfaces, and adsorption to soil is not expected to be an important process (Robertson and Sugamori, 1966). If released into water, DES is expected to hydrolyze rapidly with a half-life of 1.7 h at pH 7; the rate of hydrolysis increases under more acidic or more basic conditions (Weisenberger and Mayer, 1987). Volatilization from water surfaces, adsorption on suspended solids and sediments, biodegradation, and bioconcentration are not expected to be important because of the rapid rate of hydrolysis of DES.

INDUSTRIAL HYGIENE

No OSHA PEL or ACGIH TLV values have been established. Although there is inadequate evidence that DES is a human carcinogen, it has been labeled by the EPA as a probable carcinogen in humans (2A). There is sufficient evidence for the carcinogenicity of diethyl sulfate in experimental animals. Adequate personal protection measures must be utilized to minimize exposure at all times. Diethyl sulfate is combustible when exposed to heat or flame (Lewis, 1996). The NFPA hazard classification is Health: 3, Flammability: 1, and Instability: 1 (NFPA, 2002). Use dry chemical, foam, carbon dioxide, or water spray in extinguishing fires that are associated with diethyl sulfate. Runoff from fire control may be toxic. The Environmental Protection Agency has not established a reference concentration or reference dose.

MEDICAL MANAGEMENT

Treatment for DES poisoning is very similar to that for DMS (NLM, 2013); see Section 5. Maintain ventilation and oxygenation, and evaluate with frequent arterial blood gas or pulse oximetry monitoring. Decontaminate eyes with copious amounts of water. Remove clothing and wash exposed skin thoroughly with soap and water. For oral ingestion, immediately dilute with 4–8 oz of water or milk. Do not induce emesis due to the corrosive nature of DES and the potential for seizures (NLM, 2013).

PHOSPHATE ESTERS

Specific phosphate esters constitute a major category of organic insecticides, known as organophosphates (Costa, 2013).

These phosphate and phosphite esters, lacking significant insecticidal properties, are widely used as plasticizers and gasoline additives to control preignition. Included in this group are TOCP, triphenyl phosphate, butylated triphenyl phosphate, tri-2-ethylhexyl phosphate, and 2-ethylhexyl diphenyl phosphate. As plasticizers, these compounds offer an additional flame retardant property and are widely used in vinyl and cellulose formulations. Nonparalytic isomers have been used as plasticizers in the manufacture of vinyl plastics, as solvents in cellulosic molding compositions, as additives to extreme pressure lubricants, as inflammable fluids in hydraulic systems, and also as a lead scavenger in gasoline (Budavari, 1996).

The majority of reported cases of phosphate ester poisonings have been associated with ingestion of esters in contaminated food or drink, not occupational exposures. The most frequent occupational exposures to phosphate esters occur during manufacture, packaging, shipping, and storage, not at the point of product use. Increased absorption of phosphate esters has been noted with increased workplace temperatures. Phosphate esters tend to accumulate in fatty tissues, and hence have a long biological half-life (LeBel and Williams, 1986). Bisesi (1994) provides a more thorough discussion of the phosphate esters and their hazards.

TRI-*o*-CRESYL PHOSPHATE

Occupational exposure limits: 0.1 mg/m³ (OSHA PEL, NIOSH REL); 0.1 mg/m³ (ACGIH TLV with skin notation)

Reference values: None

Hazard statements: None

Precautionary statements: None

Risk phrases: R39/23/24/25—toxic: danger of very serious irreversible effects through inhalation, in contact with skin and if swallowed; R51/53—toxic to aquatic organisms, may cause long-term adverse effects in the aquatic environment

Safety Phrases: S1/2—keep locked up and out of the reach of children; S20/21—when the product is in use do not eat, drink, or smoke; S28—after contact with skin, wash immediately with plenty of . . . (to be specified by the manufacturer); S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible); S61—avoid release to the environment; refer to special instructions/safety data sheets

BACKGROUND AND USES

Tri-*o*-cresyl phosphate (TOCP, tri-*o*-tolyl phosphate, CASRN 78-30-8), is by far the most toxic of the three isomers of the tri-tolyl phosphates (ILO, 1983). Historically, flaccid paralysis was reported because of the ingestion of TOCP-contaminated Jamaican ginger alcoholic extract (“Jake”) liquor during the prohibition era, causing 10,000–15,000 cases, from which recovery was slow or which resulted in permanent disability (Kidd and Langworthy, 1933). Similar cases of paralytic disease have occurred after accidental ingestion of this ester in contaminated cooking oil, accidental contamination of drinking water, and in adulterated illegal alcoholic beverages. Workers engaged in manufacturing and other occupational uses of TOCP have also been affected (NLM, 2013).

Tri-*o*-cresyl phosphate has been used as a plasticizer in lacquers and varnishes, gasoline additive, fire retardant, extreme pressure additive, and to sterilize certain surgical instruments (Bisesi, 1994).

PHYSICAL AND CHEMICAL PROPERTIES

Tri-*o*-cresyl phosphate is a colorless to pale-yellow, practically odorless liquid, molecular weight 368.37. Its density is 1.1955 at 20 °C, and it is a solid below the 25.6 °C melting point. It is sparingly soluble in water, but is slightly soluble in ethanol and very soluble in ethyl ether (Budavari, 1996). The vapor pressure of TOCP is 0.00002 mm Hg at room temperature, but is 10 mm Hg at 265 °C (Bisesi, 1994). The relative vapor density of TOCP is 12.7 (air = 1) (Kuney and Mulligan, 1995). It decomposes slightly upon boiling (bp 410 °C) (Budavari, 1996).

MAMMALIAN TOXICOLOGY

Acute Effects

Symptoms of acute human poisoning include sudden diarrhea, nausea or vomiting, dizziness, tremors of tongue and eyelids, sweating, lacrimation or salivation, respiratory distress, convulsions, and coma that may occur during or shortly after ingestion; these symptoms are seldom prolonged for more than 48 h. Fatalities are quite rare, and occur principally in those who have ingested large quantities over a short period of time. This is followed by an asymptomatic latent period, or with a feverish feeling in spite of normal body temperature, and brief episodes of diarrhea, conjunctivitis, rhinitis, pharyngitis, and laryngitis accompanied by dysphagia (NLM, 2013). Inhalation and skin contact are typical industrial routes of exposure (Bisesi, 1994). Vapors may irritate the eyes, but only at high temperatures.

Chronic Effects

Typically, after a period of 10–40 days, an unusual polyneuritis with flaccid paralysis abruptly appears caused by destruction of anterior horn cells of corticospinal tracts and is accompanied by axonal degeneration. Loss of pain, temperature, and vibration sense may accompany the dysfunction in the motor system. Paralysis, characterized by numbness or tingling in hands and feet, with cramp-like pains that may occur in calves, is followed by weakness, sensory loss of pain, temperature, and vibration sensations. Optic neuritis, with headache, vertigo, loss of appetite, and paresthesia has also been reported (Grant, 1974). The minimum paralytic dose is not known, but has been estimated to be 10–30 mg/kg for an adult human (Bisesi, 1994). Other species, e.g., hens,

rats, rabbits, cats, guinea pigs, and cattle, have demonstrated similar neuromuscular symptoms (NLM, 2013). There has been no evidence that TOCP causes effects on pregnancy or fetal development in rats (FMC, 1978). Tri-*o*-cresyl phosphate is not classifiable as a human carcinogen (ACGIH, 2008). It was not mutagenic in the Ames test (Haworth et al., 1983). There are no other genetic studies available for TOCP (EPA, 2013).

Mechanism of Action

A decrease in blood cholinesterase, identical to that caused by organophosphate insecticides, occurs only rarely (NLM, 2013). Tri-*o*-cresyl phosphate has also been reported to cause cholesterol lipidosis in adrenocortical and ovarian interstitial cells (Latendresse et al., 1994). This may affect cholesterol and steroid hormone metabolism (Latendresse et al., 1995). Of the three isomers of tri-cresyl phosphate, TOCP is by far the most toxic, and it alone gives rise to polyneuritis (ILO, 1983).

Chemical Pathology

Six human cases were characterized by the involvement of anterior horn cells; fatty degeneration of white substance cord; tigrolysis/disappearance of chromophil substance of nerve cells with displacement of nucleolus to periphery; and demyelination with marked fragmentation and fatty degeneration of the myelin sheath (Sandmeyer and Kirwin, 1981). In hens, TOCP-induced delayed neurotoxicity and increased calcium ion and calmodulin-dependent kinase II phosphorylation of cytoskeletal proteins in the brain, spinal cord, and sciatic nerve (Abou-Donia et al., 1988). The effects on 2',3'-cyclic-nucleotide-3'-phosphohydrolase and calmodulin kinase II phosphorylation activity in the spinal cord and sciatic nerve were strongly associated with organophosphate-induced delayed neurotoxicity in chickens (Lapadula et al., 1991). Evidence in rats showed that histopathologic testicular damage may also occur after exposure to TOCP; effects on Leydig cells and Sertoli cells of the testis were seen (Chapin et al., 1990, 1991).

SOURCES OF EXPOSURE

Occupational

National Institute for Occupational Safety and Health has estimated that 20 workers (20 of these are female) are potentially exposed to TOCP in the United States (NOES, 1983). Intoxication is a rare occurrence, since production of TOCP is completely enclosed (ILO, 1983). The most frequent occupational exposures to phosphate esters occur during manufacture, packaging, shipping, and storage, not

at the point of product use (NLM, 2013). Persons with cardiorenal or nervous system disorders should be specially protected from industrial exposure to TOCP (ILO, 1983).

Environmental

Industrial usage of TOCP may result in its release to the environment through various waste streams. If released into the atmosphere, it will exist in both the vapor and particulate phases (USEPA, 2013). Vapor phase TOCP is degraded in the atmosphere by reaction with photochemically produced hydroxyl radicals with an estimated half-life of about 1.2 days. Air-borne particulate TOCP may be physically removed by both wet and dry deposition. Significant volatilization from dry soil, moist soil, or the surface of streams or lakes is not expected to occur, however, based on the very low vapor pressure. Tri-*o*-cresyl phosphate is expected to biodegrade in both soil and water; the half-life for TOCP in water is about 12 days at 14 °C. Tri-*o*-cresyl phosphate in water is expected to absorb strongly to suspended solids and sediments. Its estimated BCF is very high (3.6×10^4), but available data indicate that bioconcentration may not be an important process.

The general population may be exposed to TOCP via ingestion of contaminated drinking water (NOES, 1983). Several instances of low level TOCP contamination of drinking water or surface water have been reported (NLM, 2013).

INDUSTRIAL HYGIENE

National Institute for Occupational Safety and Health and OSHA have set the REL and PEL for TOCP at 0.1 mg/m³; this standard was vacated in 1989, but is still enforced in some states (NIOSH, 1997). The 8-h TWA is also 0.1 mg/m³, with a skin notation (ACGIH, 2008). Tri-*o*-cresyl phosphate is considered IDLH at levels of 40 mg/m³ and above (NIOSH, 1997). Individuals in workplace environments where exposure to TOCP is possible should wear safety glasses, gas mask, long-sleeve coveralls with tight collars and cuffs, gloves, and boots (International Technical Information Institute, 1988). The NFPA Hazard Classification for TOCP is Health: 2, Flammability: 1, Reactivity: 0, (NFPA, 1997).

MEDICAL MANAGEMENT

For oral exposure, do not induce emesis. If life-threatening amounts of TOCP have been ingested, administration of slurry of 12.5% activated charcoal followed by gastric lavage is suggested. Control any seizures. In the event of skin contact with tri-cresyl phosphates, contaminated clothing

should be rapidly removed, and affected body areas copiously irrigated with water. Move patient to fresh air and monitor for respiratory distress. If cough or difficulty in breathing develops, evaluate for respiratory tract irritation. Further treatment is symptomatic and supportive (NLM, 2013). For those that develop significant paralysis, about 3/4th of all cases recover to the point of not requiring further treatment after 1–2 years; only about 5% remain incapacitated (Gosselin et al., 1984). If signs and symptoms of cholinesterase poisoning persist, hospitalization needs to be considered (NLM, 2013).

TRIPHENYL PHOSPHATE

Occupational exposure limits: 3 mg/m³ (OSHA PEL, ACGIH TLV); 0.1 mg/m³ (NIOSH REL); DNEL inhalation, systemic effects, long term: 0.55 mg/m³; DNEL dermal, systemic effects, long term: 5.55 mg/kg/bw/day

Reference values: DNEL inhalation, systemic effects, long term: 0.14 mg/m³; DNEL dermal, systemic effects, long term: 2.77 mg/kg/bw/day; DNEL oral, systemic effects, long term: 0.04 mg/kg/bw/day

Hazard statements: H400—very toxic to the aquatic life; H411—toxic to the aquatic life with long-lasting effects

Precautionary statements: None

Risk phrases: R50/53—very toxic to the aquatic organisms, may cause long-term adverse effects in the aquatic environment

Safety phrases: S61—avoid release to the environment; refer to special instructions/safety data sheets

BACKGROUND AND USES

Triphenyl phosphate (TPP, CASRN 115-86-6, C₁₈H₁₅O₄P) is prepared by reacting phosphorus pentoxide and phenol (Budavari, 2001), or by reacting phosphorus oxychloride and phenol (Snyder, 1990). One primary use is as a flame retardant in phenolic- and phenylene oxide-based resins for the manufacture of electrical and automobile components, for auto upholstery, and as a nonflammable plasticizer in cellulose acetate for photographic films. It has also been used to impregnate roofing paper. Triphenyl phosphate occurs as a plasticizer in various lacquers and varnishes (O’Neil, 2006), and as a component of lubricating oil and hydraulic fluids (ACGIH, 2012).

PHYSICAL AND CHEMICAL PROPERTIES

The molecular weight for triphenyl phosphate is 326.28; it is a colorless, crystalline powder with a slight, phenol-like odor (O’Neil, 2006). Its density is 1.2055 g/cm³ at 50 °C and its melting point is 50.5 °C (Haynes, 2010). Triphenyl phosphate is practically insoluble in water at 1.9 × 10⁻⁷ mg/l at 24 °C (Yalkowsky et al., 2010). It is very soluble in carbon tetrachloride (Haynes, 2010) and is soluble in most lacquers, solvents, thinners, and oils, as well as in alcohol, benzene, ether, chloroform, and acetone (Lewis, 1996). The vapor density is 1.19 (air = 1.0) (Bingham et al., 2001). The boiling point is 245 °C (O’Neil, 2006). It begins to decompose at about 600 °C in inert gas, and in a large excess of air, complete combustion to carbon dioxide occurs in the range 800–900 °C (Lhomme et al., 1984). Hydrolysis of TPP occurs very slowly in acidic or neutral solutions, but occurs rapidly in alkaline solutions (Barnard et al., 1966)

MAMMALIAN TOXICOLOGY

Acute Effects

In spite of rather widespread human exposure to triphenyl phosphate, there are minimal reports of human health effects. Triphenyl phosphate does not possess a strong potential for irritation of the skin, and the irritation potential on the mucous membranes of the eyes is very low (EHC111, 1991). Exposure to high concentrations of TPP has been shown to inhibit

cholinesterase *in vitro* and *in vivo*, but TPP is not considered a potent anticholinesterase agent (Bingham et al., 2001). The oral LD₅₀ for rats is 3500 mg/kg (Hierholzer et al., 1957).

Chronic Effects

Animal experiments with 99.99% pure triphenyl phosphate did not demonstrate neurotoxicity (Wills et al., 1979). While a statistically significant reduction in red blood cell cholinesterase has been reported in some workers in a TPP-manufacturing plant exposed to 3.5 mg/m³ TPP for an average of 7.4 years, there was no evidence of neurological disease (Sutton et al., 1960). Triphenyl phosphate is not classifiable as a human carcinogen (ACGIH, 2012). Triphenyl phosphate was not active in *Salmonella* (Ames test) mutagenicity studies with and without metabolic activation (Zeiger et al., 1987). Earlier results for mutagenicity in the Ames test and in *Saccharomyces cerevisiae* (strain D4) were also negative (Monsanto, 1979). In a developmental/reproductive study in Sprague-Dawley rats, in which daily intake of TPP from 4 weeks post weaning through mating and gestation was up to 690 mg/kg bw TPP, no toxic effects were seen in the dams or offspring; TPP was thus not a teratogen at the dose levels tested (Welsh et al., 1987).

Mechanism of Action

Statistically significant depression of human erythrocyte cholinesterase was associated with chronic exposure of 32 workers to TPP, but depression of plasma cholinesterase or effects on neurological parameters were not affected (Sutton et al., 1960). In a separate study, in which 39 workers were exposed to 30% TPP and 70% different isopropyl TPPs, statistically significant depressions in serum IgM and borderline significant depressions in erythrocyte cholinesterase and depressions in red blood cell cholinesterase were reported in some workers, but plasma cholinesterase activity and other parameters were not significantly affected (Emmett et al., 1985).

Chemical Pathology

Minimal human chemical pathology has been reported for TPP.

SOURCES OF EXPOSURE

Occupational

National Institute for Occupational Safety and Health has estimated that 91,754 workers (22,800 were female) are potentially exposed to triphenyl phosphate in the United States (NOES, 1983). Exposure is primarily via inhalation and dermal contact in workplaces where it is produced or utilized,

and also by inadvertent ingestion of contaminated food and drinking water. Workers may be exposed to low levels of triphenyl phosphate by inhalation of vapors during injection molding, by dermal contact, or by ingestion of food contaminated by diffusion from packaging (Daft, 1982; Kalman, 1986). The toxicity of TPP is low. With the exception of dermatitis, no reported cases of human poisoning from triphenyl phosphate exposure have been reported. Nevertheless, persons with preexisting neuromuscular disorders may be at increased risk of neurotoxic effects (NIOSH, 1981).

Environmental

Combustion of plastics and volatilization from plastics is a potential source of atmospheric contamination. Entry of high amounts of TPP into the aquatic environment is thought to occur principally via hydraulic fluid leakage. With the exception of relatively high concentrations of TPP in sediments collected near heavily industrialized areas, environmental concentrations of TPP near sites of production or industrial use are generally <100–400 ng/l. The degradation pathway for TPP is reported to involve stepwise enzymatic hydrolysis to orthophosphate and phenolic moieties (EHC111, 1991). Fish, algae, and phytoplankton are subject to toxicity in the aquatic environment. Triphenyl phosphate is regarded as a severe marine pollutant, with a TWA of 3 mg/m³ of water (USDOL, 2012).

INDUSTRIAL HYGIENE

National Institute for Occupational Safety and Health has set the REL for triphenyl phosphate at 0.1 mg/m³ (13.35 mg/m³ = 1 ppm). The OSHA PEL is 3 mg/m³ (NIOSH, 1994). The TWA-TLV is also 3 mg/m³ (ACGIH, 2008) in order to minimize possible eye and skin irritation and allergic contact dermatitis (Camarasa and Serra-Baldrich, 1992). The OSHA 8-h PEL for triphenyl phosphate is 3 mg/m³ (29CFR 1910.100). The 8 h TWA and TLV is also 3 mg/m³ (ACGIH, 2012), with a recommended excursion limit of 3× the TLV for 30 min. Under no circumstances can exposure exceed 5× the TLV–TWA (ACGIH, 2012). The IDLH value is 1000 mg/m³. The NFPA hazard classification is Health: 1, Flammability: 1, and Instability: 0; it is regarded as noncombustible (flash point: 428 °F) (NFPA, 2010). To fight a fire of burning triphenyl phosphate, use carbon dioxide or dry chemical. Toxic gases and vapors such as phosphoric acid fumes and carbon monoxide may be released in such a fire.

MEDICAL MANAGEMENT

No cases of human systemic poisoning from TPP exposure have been reported. Skin sensitization has been reported

rarely. Triphenyl phosphate is not regarded as an irritant, and is poorly absorbed through intact skin (Camarasa and Serra-Baldrich, 1992).

NITRATE ESTERS

GLYCERYL TRINITRATE

Occupational exposure limits: 0.2 ppm (OSHA PEL); 0.01 ppm (NIOSH REL); 0.05 ppm (ACGIH TLV); DNEL dermal, systemic effects, long term: 0.5 mg/kg bw/day; DNEL dermal, systemic effects, short term: 2.5 mg/kg/bw/day

BACKGROUND AND USES

Glyceryl trinitrate (GTN; nitroglycerin; CASRN 55-63-0) is a representative compound from the organic nitrate ester family. Introduced in 1879, it has been used as a therapeutic agent in the treatment of angina pectoris. In the later part of the nineteenth century, the explosive property of nitroglycerin was discovered, and it then became the active component of dynamite. Glyceryl trinitrate, ethylene glycol dinitrate, and other nitrate esters are commonly used in military and mining explosives. In preparing dynamite, these nitrate esters are absorbed in a dope of oxidizing salts and various inert fillers.

PHYSICAL AND CHEMICAL PROPERTIES

Glyceryl trinitrate is a colorless to pale-yellow, viscous liquid or solid (below 13.3 °C [56 °F]). It begins to decompose at 50–60 °C (122–140 °F). Both GTN and ethylene glycol

trinitrate are volatile and can pass directly through the skin (Hogstedt and Stah, 1980). Because of their volatility, explosive makers, dynamite packagers, miners, and workers handling cordite (a smokeless powder composed of GTN, guncotton, mineral jelly, and acetone) can be exposed to these organic nitrate esters.

MAMMALIAN TOXICOLOGY

Acute Effects

The headache characteristic of exposure to GTN and ethylene glycol trinitrate typically begins as a feeling of warmth or fullness in the head, and develops into a throbbing sensation that progresses from the forehead to the back of the neck. The throbbing headache has been attributed to dilation of intracerebral blood vessels and can be minimized or prevented by pretreatment with an oral vasopressor similar to amphetamine sulfate. The occurrence of headache associated with vasodilator therapy is the most common side effect of the nitrates, appearing in patients after treatment, but tolerance is developed with continued treatment. Development of cross tolerance is a characteristic produced from prolonged use of nitrate esters. It has been demonstrated that the effect of sublingual GTN on blood pressure and heart rate is diminished, during treatment with pentaerythrityl trinitrate and isosorbide dinitrate (Thadani et al., 1980). Increased tolerance to organic nitrate esters is usually attributed to increased biodegradation or elimination of active components and biotransformation by vascular smooth muscle and other target tissues. This controversial topic does not appear to be an important clinical problem for patients being treated properly with GTN (Abrams, 1983).

Many reports have documented characteristic withdrawal symptoms in munitions workers handling nitrate esters. These consist of typical severe headaches in exposed individuals who are absent from the nitrate-laden environment for 2–3 days. To avoid the headaches, employees rubbed GTN into their skin or wore impregnated headbands on weekends or holidays. In addition, more serious sequelae to nitrate withdrawal have been reported. It is well known that GTN-dependent individuals may experience symptoms of angina pectoris leading to cardiovascular collapse, usually within 48–72 h after withdrawal from exposure (Hogstedt and Andersson, 1979; Hogstedt, 1980). Some experts have recommended that nitrates should not be withdrawn abruptly (Abrams, 1980). The adverse effects that do exist are mainly attributed to the vasodilatory effects. Such side effects include headaches, postural hypotension, impaired coronary and cerebral perfusion, dizziness, syncope, flushing, palpitation, and, less frequently, nausea, vomiting, or abdominal distress. The interval between exposure and the onset of symptoms and

the duration of the nitrate effect vary with individual compounds. Glyceryl trinitrate typically produces a prompt response of brief duration, whereas other compounds are slower in producing effects.

Chronic Effects

Contact dermatitis is the long-recognized chronic effect produced by dermal exposure to GTN. Ischemic heart disease has been noted to be linked to GTN exposure in munitions workers although no chronic effect was shown for cardiovascular disease risk (Stayner et al., 1992). Glyceryl trinitrate is not classified as a human carcinogen (USEPA, 2013).

Mechanism of Action

The principal biological properties of these esters are their ability to oxidize heme to the ferric state to produce methemoglobinemia and relaxation of various smooth muscles. Most nitrates produce the Heinz bodies commonly associated with methemoglobinemia. Red blood cells containing Heinz bodies have relatively short life spans and appear to be preferentially sequestered by the spleen. There is variability in the ability of nitrate esters to produce methemoglobin. Ethylene glycol dinitrate is more potent than GTN. The basic hemodynamic effect of the nitrates is vasodilation of both venous and arterial vessels in different degrees. This relaxant effect of organic nitrate esters on vascular smooth muscles is responsible for their clinical therapeutic use in the treatment of stable angina pectoris, coronary spasm, silent myocardial ischemia, myocardial infarction, and congestive heart failure.

Nitrate esters have also been used to treat esophageal spasm and spasms in hepatic ducts and the urinary tract and to lower the intraocular pressure in glaucoma (Ahlner, 1991). The two major potential complications associated with the vasodilating nitrate esters are systemic hypotension and intensification of hypoxemia, which can be fatal (Rubin, 1983).

Contact dermatitis has been reported to be an irritant and allergenic. Kanerva et al. (1991) demonstrated an allergic mechanism on patch testing to GTN, ethylene glycol dinitrate, and dinitrotoluene. In most cases, however, the mechanism appeared to be that of an irritation (de la Fuente et al., 1994).

Chemical Pathology

Unable to determine carcinogenic or mutagenic effects in humans, however, glyceryl trinitrate has been associated with mutagenic effects in the species of *Salmonella typhimurium*. It is speculated that glyceryl trinitrate releases nitric oxide via metabolic reduction (Maragos et al., 1993).

SOURCES OF EXPOSURE

Occupational

Exposures are due to use of nitroglycerin or in the production of explosives.

Environmental

Environmental exposures are due to the use of glyceryl trinitrate in the form of propellants, explosives, and pharmaceuticals. Degraded in the environment by photochemically produced hydroxyl radicals with a half-life of 15 days in the air and biodegradable in water is 13 days. Half-life in soil may be up to 37–96 days under alkaline conditions (USEPA, 2013).

INDUSTRIAL HYGIENE

Hygienic protection from nitrate esters should focus on eliminating skin contact. Clean gloves that are resistant to nitrate esters are necessary, and the hygienic routines should be stringent. Glove changes as often as hourly may be required for some work assignments. Effective measures to prevent skin absorption include easy access to washrooms for cleanup after spills or before breaks, meals, or toilet use. Although skin contact is more common, some industrial applications expose workers to nitroglycerin via inhalation. These workers should wear respirators with a recommended prefilter to an organic vapor cartridge to protect them from adsorbed aerosol particles (Cohen, 1993). The PEL for GTN and ethylene glycol dinitrate is 0.2 ppm, but NIOSH (1994) recommends a TWA of 0.01 ppm for either of these compounds. The ACGIH has set a ceiling TLV of 0.05 ppm (1995).

MEDICAL MANAGEMENT

Exposures occur via dermal, oral, or respiratory routes. If inhalation exposure occurs, remove victim from area to fresh air. Provide respiratory support as necessary. If contact with eyes, wash with water or normal saline. Victims that experience an oral exposure may consider activated charcoal;

deliver as a slurry 24 ml water/30 g charcoal. Call regional poison center for exact dosage. Gastric lavage may be considered for life-threatening situations. Protect airway when appropriate. Dermal exposures are to be treated by removing contaminated clothing and wash exposed areas with soap and water (USEPA, 2013). Due to the vasodilation effects of glyceryl trinitrate, there can be a drop of blood pressure, discontinue use of medication, put patient flat and seek medical care immediately. There may be a need to consider using a vasoconstrictor like methoxamine or phenylephrine. If methemoglobinemia is present, consider using intravenous methylene blue (NLM, 2015).

BACKGROUND AND USES

Phthalic acid esters (also known as phthalate) are used in enormous quantities, mainly as plasticizers in PVC. Workers in the PVC-processing industry are exposed to phthalates through inhalation in varying concentrations, depending on different job categories. Phthalates are found in brominated flame retardants. Patients in the intensive care units and neonates may be exposed to high levels of phthalates due to exposure to medical devices such as catheters and nasogastric tubes (Talsness et al., 2009). The general population may be exposed to phthalates, for example, bisphenol A, by food packaging and food containers possibly due to leaching effects when heated (Talsness et al., 2009). Phthalates are

PHTHALATES

DIETHYL PHTHALATE

Occupational exposure limits: 5 mg/m³ (NIOSH REL); DNEL inhalation, systemic/local effects, long term: 10.56 mg/m³; DNEL inhalation, systemic/local effects, short term: 52.8 mg/m³; DNEL dermal, systemic effects,

used in the production of perfumes, nail varnish, hairsprays, and other cosmetics (Bang et al., 2011).

Diethyl phthalate (CASRN 84-66-2) is a colorless oily liquid with a slight aromatic odor. It has been measured both in indoor and outdoor air (NLM, 2014; Schields and Weschler, 1987). Another survey of 39 public water wells identified diethyl phthalate at a maximum concentration of 4.6 µg/l (USEPA, 2010). National Institute for Occupational Safety and Health has specified 5 mg/m³ as the TWA for diethyl phthalate. Bisphenol A has a “safe dosing” level of 50 µg/kg (NLM, 2011). It causes irritation of the eyes, nose, and skin; nausea; and dizziness. In rats, may cause spasticity in the lungs (Bang et al., 2011). Hepatitis has been attributed to chronic exposure to phthalates (Neilson et al., 1985). Phthalates do bioaccumulate in humans but are metabolized (Bang et al., 2011). Generally, phthalates are rapidly metabolized via oxidation and their metabolites are excreted in the urine and feces (Bang et al., 2011).

Currently, phthalates, such as dioxins and bisphenol A, are labeled as endocrine-disrupting chemicals that interfere with endogenous hormones and may act as anti-androgens (Craig et al., 2011). Some phthalates, such as polybrominated diphenyl ethers (PBDE) and tetrabromo benzoic acid (TBBA), have been suggested to alter thyroid hormone activities (Talsness et al., 2009). Phthalates are being investigated for their possible role in obesity, diabetes, hormonal cancers, such as breast cancer. Bisphenol A is currently being investigated for its role in diabetes, type 2 (Talsness et al., 2009). Bisphenol A may stimulate insulin secretion as well as decrease adiponectin, which is a critical regulatory cytokine. Children may be at increased risk of the effects of phthalates (Talsness et al., 2009). There are ongoing studies investigating the role of bisphenol A and its effect on socio-sexual behavior (Dessi-Fulgheri et al., 2002).

MISCELLANEOUS ESTERS

In spring 1992, an epidemic outbreak of papular and follicular rashes caused by a new line of cosmetics occurred throughout Switzerland. Data obtained from epidemiological and clinical studies have suggested that vitamin E linoleate (a mixture of tocopheryl esters, mainly tocopheryl linoleate), used in the cosmetics and other dermatological preparations, was the cause of papular and follicular contact dermatitis (Perrenoud et al., 1994). In most cases, itchy patches were found to be symmetrically distributed and located on the trunk and extremities. Sometimes, secondary extension of these patches to the face had also been observed with pronounced erythema and edema in the ears. Oxidized vitamin E derivatives may act *in vivo* as haptens or as irritants, possibly with synergistic effects.

In addition, other esters of varying chemical classes are also responsible for contact allergic dermatitis. This group includes corticosteroids (His a et al., 1993; Lepoittevin et al., 1995), nicotinic acid esters (Audicana et al., 1990), alkyl gallates as antioxidants (Hausen and Beyer, 1992), sodium lauryl sulfate as a surfactant (Rhein et al., 1990), ester of polyethylene glycol 600, and C21 dicarboxylic acid as a component of cutting fluid (Niklasson et al., 1993) and rosin (colophony) esters (Gäfvert et al., 1994).

CHLORINATED HYDROCARBONS

MICHAEL H. LUMPKIN

Chlorinated hydrocarbons are hydrocarbons containing one or more chlorine atoms within their chemical structure. Chlorine is one of the most common halogens found in halogenated hydrocarbons used in industrial settings.

While some chlorinated hydrocarbons are found in nature (i.e., combustion reactions), most are manufactured for industrial use in material synthesis, as chemical intermediates, or are produced as secondary products of industrial chemistry. Many chlorinated hydrocarbons are long-lived in the environment, may accumulate in various organisms, and may cause toxicity at sufficiently high exposures, including central nervous system (CNS) narcosis, reproductive effects, and cancer.

ALLYL CHLORIDE

First aid: Oral: Avoid emesis, administer charcoal slurry.

Inhalation: Move the person to fresh air, evaluate for respiratory tract irritation, bronchitis, or pneumonitis if cough or difficulty in breathing develops. Treat bronchospasm with β_2 agonists and corticosteroids. Eye: Irrigate with water for 15 min. Dermal: Remove the contaminated clothing and wash the skin with soap and water.

Target organ(s): Eyes, skin, respiratory system, liver, kidneys

Occupational exposure limits: OSHA PEL = 1 ppm (3 mg/m³) 8-h TWA; ACGIH TLV = 1 ppm 8-h TWA; NIOSH REL = 1 ppm 10-h TWA, IDLH = 250 ppm

Reference values: EPA RfC: 0.0003 ppm (0.001 mg/m³)

Risk/Safety phrases: 11-26-50; (1/2)-16-29-33-45-61
Note D

BACKGROUND AND USES

Allyl chloride (3-chloropropene; 1-chloro-2-propene; CASRN 107-05-1) is a chemical intermediate used in the synthesis of allyl compounds found in varnish, resins, polymers, pesticides, and pharmaceuticals (O'Neil, 2001).

PHYSICAL AND CHEMICAL PROPERTIES

Allyl chloride (molecular weight = 76.53 g/mol) is a colorless, brown, yellow, or purple liquid with a pungent, unpleasant odor. It has a vapor pressure of 368 mmHg at 25 °C and is miscible in alcohol, ether, chloroform, and has a water solubility of 3370 mg/l at 25 °C. It may dissolve some plastics, coatings, and rubber (O'Neil, 2001).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Allyl chloride released to the environment via manufacturing waste streams exists in the atmosphere as a vapor and is degraded by photochemical hydroxyl radicals. It has high mobility in soil and evaporates from dry (due to vapor pressure) or moist (due to Henry's law constant of 1.1×10^{-2} atm-m³/mol) soil. Allyl chloride volatilizes significantly from surface water and is not likely to bind to sediments of suspended solids. Bioaccumulation in aquatic

organism is low, with a bioconcentration factor (BCF) of <0.14–<1.3 (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

In aquatic organisms, allyl chloride resulted in the following LC₅₀ values: 59.3 mg/l/24 h in *Lepomis macrochirus* (Bluegill), 0.34 mg/l/48 h in *Xenopus laevis* (African clawed frog), and 250 mg/l/24 h in *Daphnia magna* (Waterflea).

Chronic Effects

No chronic toxicity data are available for allyl chloride.

MAMMALIAN TOXICOLOGY

Acute Effects

No data for the acute effects of allyl chloride were available.

Chronic Effects

A study of more than 1000 workers exposed to allyl chloride and epichlorohydrin found no increase in mortality for malignant neoplasms, circulatory diseases, or heart disease (Olsen et al., 1994). In one study of occupational exposure to allyl chloride in China, workers reported weakness, numbness, and paresthesia in the extremities (He et al., 1985).

Electroneuromyographic measurements at one facility with high exposure (2.6–6650 mg/m³) showed a neuropathy prevalence of 53%. At another facility with lower exposure (0.2–25 mg/m³), 48% of workers were classified as having mild neuropathy.

Chemical Pathology

Distal peripheral nerve degeneration was reported in rabbits injected with 100 mg/kg three times a week for 7.5–11.5 weeks (Fengsheg et al., 1980).

Mode of Action(s)

The mode of action for allyl chloride is unknown.

SOURCES OF EXPOSURE

Occupational

Exposure to allyl chloride may occur from inhalation or to a much lesser extent from dermal absorption.

Environmental

Inhalation of allyl chloride may result from fugitive emissions from chemical manufacturing sites utilizing allyl chloride in product synthesis.

INDUSTRIAL HYGIENE

Neoprene or rubber gloves, gas-tight goggles or full-face shield, and complete skin coverings should be used when handling allyl chloride. Respirator should be used for ambient air levels of 1 parts per million (ppm) for up to 30 min; supplied-air respirators should be used for longer or higher exposure concentrations. The Occupational Safety and Health Administration (OSHA) has set the permissible exposure limit (PEL) for allyl chloride at 1 ppm (3 mg/m³) as an 8-h time-weighted average (TWA). The National Institute for Occupational Safety and Health (NIOSH) set a recommended exposure limit (REL) of 1 ppm as a 10-h TWA and an Immediately Dangerous to Life and Health (IDLH) level of 250 ppm. The American Conference of Governmental Industrial Hygienists (ACGIH) set a threshold limit value (TLV) of 1 ppm as an 8-h TWA.

RISK ASSESSMENTS

Environmental Protection Agency (EPA) Reference concentration (RfC): 0.001 mg/m³, C—possible human carcinogen.

International Agency for Research on Cancer (IARC) Group 3: not classifiable as to its carcinogenicity to humans.

CARBON TETRACHLORIDE

First aid: Rinse eyes with water. Clean the skin with soap and water. If swallowed, administer gastric lavage and oxygen and artificial respiration (if necessary).

Target organ(s): CNS, eyes, lungs, liver, kidneys, skin

Occupational exposure limits: OSHA: 10 ppm (PEL); NIOSH: 2 ppm (REL), 300 ppm (IDLH); ACGIH: 5 ppm (TLV)

Reference values: ATSDR: Intermediate and chronic inhalation MRLs: 0.03 ppm

EPA: RfC: 0.1 mg/m³, RfD: 0.004 mg/kg/day

Risk/safety phrases: 23/24/25-40-48/23-52/53-59; (1/2-23-36/37-45-59-61

BACKGROUND AND USES

Carbon tetrachloride (tetrachloromethane; CASRN 56-23-5) is used in organic chemical synthesis, in metal recovery, and catalyst regeneration. Historically, it was used in refrigeration and semiconductor production and as a solvent for processing fats, rubber, and various oils. It was formerly widely used as a fumigant, metal degreaser, dry-cleaning solvent, and in fire extinguishers but has been replaced by other organochlorine solvents of lower toxicity for most industrial uses. Because of its ozone-depleting properties, carbon tetrachloride was scheduled for phase out as per the Montreal Protocol; its industrial use has been diminishing since the 1980s.

PHYSICAL AND CHEMICAL PROPERTIES

Carbon tetrachloride (molecular weight = 153.82 g/mol) is a clear, colorless liquid with a distinctive, sweet ether-like odor. It has a high vapor pressure of 91 mmHg at 20 °C. It has a water solubility of 1160 mg/l and is miscible with various organic solvents. It is mildly reactive with lead and copper and can be reduced to chloroform in the presence of zinc and an acid.

ENVIRONMENTAL FATE AND BIOACCUMULATION

In the atmosphere, carbon tetrachloride exists solely as a gas. It is persistent in the atmosphere and degraded by photochemically produced hydroxyl radicals. It can be degraded by high energy irradiation in the troposphere, where it may last for 30–50 years and has been implicated in the breakdown

and depletion of ozone. Carbon tetrachloride is mobile in soil and is cleared either by volatilization or by aerobic or methanogenic microbial degradation. It volatilizes quickly from surface waters, is not expected to bind to sediments or suspended particulates, and is not expected to bioaccumulate (BCF = 3.2–7.4) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

No mortality was seen in water fleas (*Daphnia magna*) exposed to 7.7 mg/l carbon tetrachloride for 2 days, but LC₅₀ values of 350–770 mg/l were reported. In bullfrog (*Rana catesbeiana*) embryos exposed for 4 days, no mortality was seen at 0.026 mg/l, but 100% mortality occurred at 66 mg/l. In 28-day exposures of fathead minnows, 0 and 80% reduction in hatch rates were seen at 18 and 73 g/ml, respectively.

Chronic Effects

No chronic-duration studies were identified.

MAMMALIAN TOXICOLOGY

Acute Effects

In humans, acute carbon tetrachloride exposure results in liver, kidney, gastrointestinal (GI), and CNS depressant effects. Acute CNS effects include dizziness, blurred vision, headache, giddiness, and fatigue Stewart et al. (1963). Death occurred in one alcoholic male following a 15-min inhalation of 250 ppm (Stevens and Forster, 1953; Norwood et al., 1950). Gastrointestinal effects were also seen at 250 ppm, including nausea, vomiting, and abdominal cramps (Norwood et al., 1950). Cases of polyneuritis have been associated with acute dermal exposure (Farrell and Senseman, 1944). No CNS effects were observed in humans exposed to 50 ppm for up to 3 h (Stewart et al., 1961). Single oral ingestions of 90–180 mg/kg resulted in nausea, fatty degeneration of the liver, and swelling of renal tubules (Docherty and Nicholls, 1923; Ruprah et al., 1985). Death was reported in cases involving ingestion of as little as 40 mg/kg (Lamson et al., 1928).

In rats, an LC₅₀ of 9500 ppm for 8 h was identified (Svirbely et al., 1947). Dogs exhibited CNS depression after 2–10 h inhalation of 15,000 ppm (von Oettingen et al., 1949). Liver changes in rats occurred after a 7-h exposure to 100 ppm (Adams et al., 1952). Oral doses as low as 5 mg/kg in rats results in slight liver vacuolation (Smialowicz et al., 1991). Litter resorption in rats was seen after 25 mg/kg/day ingestion for 9 days (Narotsky et al., 1997).

Chronic Effects

In mice and rats, chronic lifetime inhalation of 25 ppm carbon tetrachloride resulted in frank liver and kidney damage. Liver and kidney tumors also developed in mice and rats chronically inhaling 25 ppm carbon tetrachloride (Nagano et al., 1998). Chronic oral ingestion of 47 mg/kg/day in rats resulted in fatty liver degeneration and cirrhosis and development of liver tumors (ATSDR, 2005).

Chemical Pathology

Gastrointestinal effects in humans arise from GI irritation. The effects of carbon tetrachloride on the liver include cirrhosis, fibrosis, fatty degeneration, and centrilobular necrosis. Liver tumors in rodents include hepatocellular adenoma and carcinoma. In the kidney, oliguria, nephrosis, ketone bodies, protein casts, occult blood, and urobilinogen occurred. Adrenal pheochromocytomas were reported in mouse kidney.

Mode of Action(s)

CNS effects from carbon tetrachloride exposure arise from generalized CNS depression. Liver and kidney toxicity result from activation of the parent chemical by liver (primarily) and kidney (secondarily) cytochrome P-450-dependent monooxygenase to highly reactive free radicals (Azri et al., 1992). These reactive species may form adducts with DNA or other cellular macromolecules and/or initiate oxidative insult to membrane lipids, leading to a cascade of glutathione depletion, release of phagosomal contents, necrosis and cell death, cytokine recruitment (Holden, 2000), and cellular regeneration and proliferation. Non-gentoxic loss of proliferative control at high carbon tetrachloride exposure may lead to exacerbation of genetic mutations and resultant tumor initiation and progression in liver and kidneys.

SOURCES OF EXPOSURE

Occupational

Workers in chemical manufacturing plants using carbon tetrachloride may be exposed to vapors or liquids from accidental spill or contact with process waste streams. Workers performing remediation tasks at hazardous waste sites may be exposed to carbon tetrachloride vapors.

Environmental

With the phase out of carbon tetrachloride in refrigerant systems, aerosol propellants, dry cleaning facilities, and metal cleaning products, environmental exposures are likely to result from contact with older remaining carbon tetrachloride-containing products.

INDUSTRIAL HYGIENE

Rubber or polyvinyl gloves, goggles, and skin coverings should be used when handling carbon tetrachloride. The NIOSH recommends that a self-contained breathing apparatus be used if carbon tetrachloride concentration is above the REL of 2 ppm. OSHA has set a PEL at 10 ppm. NIOSH set an IDLH level of 300 ppm. ACGIH set a TLV of 5 ppm and a short-term exposure limit (STEL) of 10 ppm.

RISK ASSESSMENTS

Agency for Toxic Substances and Disease Registry (ATSDR): Intermediate and chronic inhalation minimal risk levels (MRLs): 0.03 ppm

EPA: RfC: 0.1 mg/m³, RfD: 0.004 mg/kg/day, Likely to be carcinogenic to humans

IARC: Group 2B (not classifiable as to carcinogenicity in humans).

CHLOROFORM

First aid: Oral: Start gastric lavage and administer activated charcoal if ingestion was recent. Inhalation: Move the person to fresh air, evaluate for respiratory tract irritation, bronchitis, or pneumonitis if cough or difficulty breathing develops. Treat bronchospasm with β_2 agonists and corticosteroids. Eye: Irrigate with water for 15 min. Dermal: Remove the contaminated clothing and wash the skin with soap and water.

Target organ(s): Liver, kidneys, heart, eyes, skin, CNS

Reference values: ATSDR acute, intermediate, and chronic inhalation MRLs = 0.1, 0.05, and 0.02 ppm; EPA RfD = 0.01 mg/kg

Risk/safety phrases: 22-38-40-48/20/22; (2)-36/37

BACKGROUND AND USES

Chloroform (trichloromethane, CAS# 67-66-3) is used primarily in the production of hydrochlorofluorocarbon-22 (HCFC-22) and secondarily in the production of fluoropolymers like polytetrafluoroethylene (PTFE). It has been used historically as an organic solvent, insecticidal fumigant, and as an anesthetic.

PHYSICAL AND CHEMICAL PROPERTIES

At ambient temperature and pressure, chloroform (molecular weight = 119.38 g/mol) exists as a clear, colorless liquid with a non-irritant ethereal odor and a sweet taste. It is very volatile, with a vapor pressure of 197 mmHg at 25 °C. It may dissolve some plastics and rubber. It is highly water soluble and is miscible in volatile organic compounds (VOCs) and alcohols.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Chloroform may find its way into the environment as part of the waste stream for hydrochlorofluorocarbon (HCFC) and fluoropolymer production, as well as a drinking water disinfection by-product. It exists exclusively as a vapor in the atmosphere and can be photochemically (but not photo-lytically) degraded with a half-life of about 150 days. It is highly mobile in soil and evaporates from both soil and surface water. Chloroform binds to sediment and suspended solids. It is not expected to bioaccumulate (BCF = 2.9–10.4) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

Chloroform is lethal in *Xenopus* frog embryos at 36 mg/l. The LC₅₀ for zebrafish was >100 mg/l. The LC₅₀ in Japanese Medaka was 215 mg/l. An EC₅₀ of 602 mg/l for reduced reproduction was reported for *D. magna* (EPA, 2013).

Chronic Effects

Not chronic ecotoxicological effects were reported for chloroform.

MAMMALIAN TOXICOLOGY

Acute Effects

Occupational exposure to chloroform resulted in symptoms of general lassitude, dry mouth and thirst, gastrointestinal discomfort, and urinary frequency (Challen et al., 1958; Phoon et al., 1983). When used as a general anesthesia, inhalation of 40,000 ppm resulted in respiratory failure and death (Whitaker and Jones, 1965). Nausea and vomiting also occurred during occupational exposures or following anesthesia. Cardiac arrhythmias and hypotension have been reported after ingestion of chloroform or when it was used as an anesthetic (Schroeder, 1965; Smith et al., 1973). Pulmonary obstruction has been reported in cases of very

high inhalation or oral exposures (Schroeder, 1965). Mice exposed to 10 ppm or more for 7 days developed liver toxicity (Larson et al., 1994c). Rodent studies have also indicated renal toxicity following acute exposures.

Chronic Effects

Vomiting and chloroform-induced hepatitis was seen in workers exposed to 14 ppm in the workplace for 6 months (Phoon et al., 1983). Fatty liver, hepatitis, hepatomegaly, jaundice, and increased serum enzymes indicative of liver toxicity occurred in chronically exposed workers (Bornski et al., 1967). Lung toxicity has been reported in rodents exposed to ≥ 50 ppm.

Chronic renal toxicity has been reported in rodents, particularly mice. Both mice and rats exhibited developmental effects in offspring following inhalation exposures (Bornski et al., 1967). Both liver and kidney cancer were seen in rodents during chronic oral drinking water studies (IARC, 1987).

Chemical Pathology

Chloroform exposure in rodents leads to hepatocellular vacuolation, fatty liver, and centrilobular necrosis (Larson et al., 1994c; Culliford and Hewitt, 1957; Kylin et al., 1963). High inhalation levels may lead to interstitial pneumonitis in rodent lungs, resulting in pulmonary surfactant disruption. Rodent kidneys exhibited nephrosis, renal necrosis and regeneration, fatty degeneration, chronic inflammation, and formation of hyaline casts.

Mode of Action(s)

Chloroform depletes hepatic glutathione (Docks and Krishna, 1976). Both liver and kidney toxicity appears to be mediated by oxidative metabolism *in situ* to phosgene, resulting in cytotoxicity and cellular proliferation (Hook and Smith, 1985). Administration of chloroform in a corn oil vehicle via gavage reportedly enhanced cell proliferation, whereas administration of chloroform via drinking water inhibited cell proliferation (Pereira, 1994). Reports have also suggested that the corn oil vehicle may interact with chloroform to increase toxicity (Jorgenson et al., 1985). Gastrointestinal effects seen at low exposure levels are likely due to neurological effects rather than direct mucosal irritation.

SOURCES OF EXPOSURE

Occupational

Occupational exposure may occur from dermal contact or inhalation at sites of HCFC or fluoropolymer manufacturing.

Environmental

The highest expected environmental exposure is from ingestion of water disinfected by chlorination. Other exposure routes include inhalation of ambient air and dermal contact with this compound or other products containing chloroform (Sheperd et al., 1996).

INDUSTRIAL HYGIENE

Gloves, goggles, and skin coverings should be used when handling chloroform. Appropriate cartridge respirators should be used if exposure concentration is > 2 ppm. OSHA has set the PEL (ceiling limit) for chloroform at 50 ppm (240 mg/m³). The NIOSH set a 60-min STEL level of 2 ppm and states that chloroform may be a potential occupational carcinogen. ACGIH set a TLV at 10 ppm as an 8-h TWA.

RISK ASSESSMENTS

ATSDR: Acute, intermediate, and chronic inhalation MRLs: 0.1, 0.05, and 0.02 ppm

EPA: RfD: 0.01 mg/kg, likely to be a human carcinogen

IARC: Group 2B, possibly carcinogenic to humans.

EPICHLOROHYDRIN

First aid: Oral: Start gastric lavage and administer activated charcoal if ingestion was recent. Inhalation: Move the person to fresh air, evaluate for respiratory tract irritation, bronchitis, or pneumonitis if cough or difficulty in breathing develops. Treat bronchospasm with β_2 agonists and corticosteroids. Eye: Irrigate with water for 15 min. Dermal: Remove the contaminated clothing and wash the skin with soap and water.

Target organ(s): Eyes, skin, respiratory system, kidneys, liver, reproductive system

Occupational exposure limits: OSHA PEL: 5 ppm 8 h TWA; NIOSH: lowest feasible concentration; ACGIH TLV: 0.5 ppm 8-h TWA with skin notation

Reference values: EPA RfC—0.001 mg/m³

Risk/safety phrases: (2-)36/37; 53-45 Note E

BACKGROUND AND USES

Epichlorohydrin (CASRN 106-89-8) is mainly used in the production of epoxy resins. It was also used as a solvent for paints, varnishes, lacquers, cellulose esters and ethers, and gums. Epichlorohydrin was historically used as an insecticide fumigant.

PHYSICAL AND CHEMICAL PROPERTIES

Epichlorohydrin (molecular weight = 92.53 g/mol) is a colorless liquid with a sweet or garlic-like pungent odor. It is a volatile compound with a vapor pressure of 16.4 mmHg at 25 °C. It is soluble in water (6.6×10^4 mg/l at 25 °C) and miscible with most organic solvents.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Epichlorohydrin may be found in the environment as a result of release in waste streams of resin, paint and lacquer, cellulose ester/ether, and gum production. The high vapor pressure of epichlorohydrin maintains it as a gas in the atmosphere, where it is degraded by photochemically produced hydroxyl radicals (half-life = 36 days). Epichlorohydrin is highly mobile in soil, evaporates quickly from dry soil, and is extensively hydrolyzed in moist soil and water. It is not expected to be adsorbed to sediments and suspended particles and is not expected to bioaccumulate in aquatic organisms (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

D. magna exhibited a 2-h LC₅₀ of 29 mg/l epichlorohydrin. The LC₅₀ for zebrafish was 30.5 mg/l, while no mortality was seen in rainbow trout at 19 mg/l (EPA, 2013).

Chronic Effects

No chronic ecotoxicological data were available for epichlorohydrin.

MAMMALIAN TOXICOLOGY

Acute Effects

Epichlorohydrin has been reported to cause irritation and allergic contact dermatitis (van Joost et al., 1990; Jolanki et al., 1994). The inhalation LC₅₀ in rats is 360 ppm for 6 h (Laskin et al., 1980). Inhalation of ≥ 25 ppm epichlorohydrin by male rats resulted in reduced reproduction (Slott et al., 1990; John et al., 1983).

Oral exposures in animals also caused reproductive and developmental effects. Developmental effects were reported in mice and rats receiving ≥ 120 mg/kg/day but were only seen in conjunction with frank maternal toxicity (Marks et al., 1982). Rats exhibited impaired sperm metabolism following 12 mg/kg/day, with total reproductive impairment seen at

50 mg/kg/day (Wester et al., 1985). Shin et al. (2010) reported increased sperm histopathology and reduced reproduction in male rats receiving 30 mg/kg/day.

Chronic Effects

A case control study of epoxy resin line workers indicated that workers involved in the production of anthraquinone dyes had an increased association with the central nervous system neoplasms (CNSNs) (Barbone et al., 1994). Cases of CNSN were histologically similar and found in workers with longer duration exposures. Barbone et al. (1992) studied the relationship between lung cancer and epichlorohydrin production, noting an increased, but not statistically significant risk in lung cancer. A study of workers with potential epichlorohydrin exposure in one facility showed no increase in malignant neoplasms, lung cancer, circulatory diseases, or heart disease (Olsen et al., 1994). Further, Tsai et al. (1990) did not report any significant difference in heart disease or malignant neoplasm mortality in a cohort of workers from the two facilities.

Inhalation studies have demonstrated that epichlorohydrin is an animal carcinogen (Laskin et al., 1980). In that study, short-term exposure to high concentrations of epichlorohydrin was a more potent inducer of neoplastic lesions than chronic, long-term exposures to 10 ppm or less. An inhalation study of epichlorohydrin in rats and rabbits reported no teratogenic effects (John et al., 1983). Chronic oral exposure in animals resulted in the development of stomach tumors. Lifetime exposure of 2–10 mg/kg/day in rats resulted in stomach tumors (Wester et al., 1985).

Chemical Pathology

Rats inhaling 100 ppm epichlorohydrin exhibited reduced sperm velocity (Slott et al., 1990). Gonadal histopathology was seen in rats exposed orally to ≥10 mg/kg/day (Shin et al., 2010).

In rats, forestomach squamous carcinomas resulted from lifetime exposure (Konishi et al., 1980; Wester et al., 1985). Dose-related increases in incidences of forestomach hyperplasia and hyperkeratosis were reported in rats (Daniel et al., 1996). Girolamo et al. (2006) suggested that epichlorohydrin causes tissue proliferation at the point of contact in chick embryos.

SOURCES OF EXPOSURE

Occupational

Workers involved in the production of epoxy resins, paints, laquers, varnish, and cellulose gums may be exposed to epichlorohydrin via inhalation or dermal contact.

Environmental

The general population may be exposed to epichlorohydrin via contact with epichlorohydrin-containing products.

INDUSTRIAL HYGIENE

Gloves (preferably butyl rubber), goggles/face shield, and skin coverings should be used when handling epichlorohydrin. Respirators should be used if exposure concentration is >0.5 ppm. OSHA has set the PEL for epichlorohydrin at 5 ppm as an 8-h TWA. NIOSH did not set a REL but recommends that occupational exposures be limited to the lowest feasible concentration. ACGIH set a TLV for epichlorohydrin at 0.5 ppm with a skin notation.

RISK ASSESSMENTS

EPA: RfC: 0.001 mg/m³, B2 probable human carcinogen

IARC: Group 3, not classifiable as to human carcinogenicity

ETHYLENE DICHLORIDE

First aid: Oral: Dilute with 4–8 oz of water or milk; administer activated charcoal if ingestion was recent. Inhalation: Take the person out to fresh air, evaluate for respiratory tract irritation, bronchitis, or pneumonitis if cough or difficulty in breathing develops. Treat bronchospasm with β 2 agonists and corticosteroids. Eye: Irrigate with water for 15 min. Dermal: Remove the contaminated clothing and wash the skin with soap and water.

Target organ(s): Eyes, skin, kidneys, liver, CNS, cardiovascular system

Occupational exposure limits: OSHA PEL: 50 ppm 8-h TWA; NIOSH: 1 ppm 10-h TWA; ACGIH TLV: 10 ppm 8-h TWA.

Risk/safety phrases: 45-11-22-36/37/38; 53-45 Note E

BACKGROUND AND USES

Ethylene dichloride (1,2-dichloroethane, CASRN 107-06-2) is used in the synthesis of vinyl chloride and other organic compounds. It is also used as a solvent for nail lacquers, as a degreaser and metal cleaner, in adhesives, in pharmaceutical production, and in tobacco and spice extraction. Ethylene dichloride was historically used as an insecticide fumigant.

PHYSICAL AND CHEMICAL PROPERTIES

Ethylene dichloride (molecular weight = 98.96 g/mol) is a clear and colorless, oily liquid with a sweet odor and taste. It is a volatile compound with a vapor pressure of 78.9 mmHg at 25 °C. It is relatively insoluble in water (8.6×10^3 mg/l at 25 °C) but soluble in various organic solvents and is miscible with alcohol, chloroform, and ether (NLM, 2013).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Ethylene dichloride may be found in the environment as a result of the release in industrial waste streams. It exists in the atmosphere as a gas due to high vapor pressure, where it is degraded by photochemically produced hydroxyl radicals (half-life = 63 days). Ethylene dichloride is highly mobile in the soil and evaporates quickly from dry soil and surface waters. It is not expected to be adsorbed to sediments and suspended particles and is not expected to bioaccumulate in aquatic organisms (BCF = 2).

ECOTOXICOLOGY

Acute Effects

The 2-h LC₅₀ for *D. magna* was 220 mg/l. Similarly, the 4-h LC₅₀ for zebrafish was 254 mg/l. The LC₅₀ for Japanese medaka was 840 mg/l (EPA, 2013).

Chronic Effects

Reduced reproduction was observed in *D. Magna* after a 28-day exposure to 21 mg/l (EPA, 2013).

MAMMALIAN TOXICOLOGY

Acute Effects

Acute intoxication with ethylene dichloride may cause headache, dizziness, nausea, vomiting, weakness, trembling, and

epigastric cramps (Siegel, 1947; Liu et al., 2010). In severe cases, collapse, coma, and death may follow as a result of respiratory and circulatory failure. Hepatic and renal injuries have been noted in fatal cases, including fatty liver injury.

Acute inhalation of ≥ 200 ppm ethylene dichloride in rats resulted in CNS depression. Pregnant rats and rabbits exposed to ≤ 300 ppm produced no embryotoxic or teratogenic effects (Schlachter et al., 1979). Resistance to bacterial infection was reported in mice exposed to a single 5 ppm exposure (Sherwood et al., 1987).

Oral gavage doses of 136 mg/kg ethylene dichloride in rats resulted in pulmonary injury (Salovsky et al., 2002).

Chronic Effects

Hazardous material workers exposed to high levels of ethylene dichloride exhibited possible CNS effects in vision, memory, and behavior (Bowler et al., 2003). Maltoni et al. (1980) exposed rats and mice to ethylene dichloride via inhalation in a long-term carcinogenicity study and reported no exposure-related increase in mortality or tumors. However, Nagano et al. (2006) reported significant increased incidences of benign and malignant lung, mammary gland, and liver tumors in rats and mice inhaling ≥ 10 ppm for life.

Oral drinking water exposures in mice of 8000 ppm for 13 weeks resulted in significant renal cell regeneration (Morgan, 1991).

Chemical Pathology

Edema, congestion, and inflammatory changes were seen in rats receiving 136 mg/kg/day (Salovsky et al., 2002). DNA single-strand breaks were seen in rats following oral, but not inhalation, exposures (Storer et al., 1984). Olfactory epithelial degeneration and necrosis were seen in rats inhaling ≥ 200 ppm for 4 h (Hotchkiss et al., 2010). Adenomas and adenocarcinomas developed in the liver, mammary glands, and bronchoalveolar regions of rats and mice inhaling ≥ 10 ppm over a lifetime (Nagano et al., 2006).

Mode of Action(s)

General CNS depression is the likely mode of action for CNS effects seen at high exposures, although indicators of oxidative stress have been associated with changes in glutamate and GABA expression (Wang et al., 2012). The appearance of fatty liver injury, following acute high level ethylene dichloride exposure, was a result of inhibited lipoglycoprotein secretion by hepatocytes (Cottalasso et al., 1994). The exact mechanism of action of ethylene dichloride carcinogenicity is unclear. Cheng et al. (2000) suggest genotoxic effects in workers as evidenced by

increased sister chromatid exchanges. CYP- and GST-mediated chromosomal aberrations, DNA adducts, and gene point mutations were reported in rodents (Gwinn et al., 2011). Markers of lipid peroxidation were seen in rat lungs following oral gavage (Salovsky et al., 2002).

SOURCES OF EXPOSURE

Occupational

Workers involved in the production of epoxy resins, paints, laquers, varnish, and cellulose gums may be exposed to ethylene dichloride via inhalation or dermal contact.

Environmental

The general population may be exposed to ethylene dichloride via food and drinking water and from contact with ethylene dichloride-containing products.

INDUSTRIAL HYGIENE

Gloves, eye protection, and skin coverings should be used when handling ethylene dichloride. Respirators should be used if exposure concentration is > 1 ppm. OSHA has set the PEL for ethylene dichloride at 50 ppm as an 8-h TWA. NIOSH set a REL of 1 ppm as a 10-h TWA. ACGIH set a TLV for ethylene dichloride at 10 ppm as an 8-h TWA.

RISK ASSESSMENTS

EPA: B2, probable human carcinogen

METHYL CHLORIDE

First aid: Move the person to fresh air. If seizure occurs, administer benzodiazepine IV, followed by phenobarbital

or propofol if seizures reoccur. Eye: Irrigate with water for 15 min.

Target organ(s): CNS, liver, kidneys, reproductive system
Occupational exposure limits: OSHA PEL: 100 ppm 8-h TWA; NIOSH: 1 ppm 10-h TWA; ACGIH TLV: 50 ppm 8-h TWA, 100 ppm STEL.

Reference values: EPA: RfC: 9×10^{-2} mg/m³

Risk/safety phrases: Not available

BACKGROUND AND USES

Methyl chloride (chloromethane CASRN 74-87-3) is used in the synthesis and solvent extraction of various organic compounds. It is also used in the production of plastic and polystyrene foams and processing of timber wood products, and historically, it was used as an insecticide, anesthetic, and aerosol propellant.

PHYSICAL AND CHEMICAL PROPERTIES

Methyl chloride (molecular weight = 50.49 g/mol) is a colorless gas possessing a sweet odor and taste. It is a highly volatile compound with a vapor pressure of 4300 mmHg at 25 °C. It reacts with plastics, rubber, aluminum, zinc, and magnesium. It is relatively insoluble in water (5.3×10^3 mg/l at 25 °C) but soluble in acetone and ethanol and miscible with chloroform, acetone, and ethyl ether.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Methyl chloride found in the environment may result due to the release from chemical synthesis waste streams. It exists in the atmosphere solely as a gas due to its high vapor pressure, where it is slowly degraded by photochemically produced hydroxyl radicals (half-life = 310 days). Methyl chloride is highly mobile in soil and tends to evaporate quickly from dry soil and surface waters. It may be biodegraded under anaerobic conditions. It is not expected to be adsorbed to sediments and suspended particles and is not expected to bioaccumulate in aquatic organisms (BCF = 3) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

The 4-h LC₅₀ for methyl chloride in bluegill fish was 550 mg/l (EPA, 2013).

Chronic Effects

No chronic ecotoxicological data were identified for methyl chloride.

MAMMALIAN TOXICOLOGY

Acute Effects

Methyl chloride has been shown to affect the CNS, liver, kidney, and male reproductive tissues. Inhalation of methyl chloride in humans has resulted in headache, giddiness, drowsiness, ataxia, convulsion, and coma (Repko, 1981).

Inhalation of methyl chloride in laboratory rodents has resulted in decreased reproduction and specific developmental effects. Mouse dams inhaling 500 ppm during gestation gave birth to pups exhibiting structural heart defects. This effect was not seen at 100 ppm (Wolkowski-Tyl et al., 1983a, 1983b).

Chronic Effects

Chronic intoxication, primarily with neurological symptoms, has been reported in methyl chloride and foam plastic workers (Scharnweber et al., 1974). Cases of long-standing neuropsychiatric alterations have also been described with depression, irritability, change of personality, insomnia, and disturbances of vision.

Inhalation of ≥ 450 ppm methyl chloride in male mice for 10 weeks resulted in a reduced number of litters at mating (Hamm et al., 1985; Chellman et al., 1986, 1987; Working et al., 1985a,b). Heart malformations were seen in mouse pups born to dams inhaling 500 ppm methyl chloride (Wolkowski-Tyl et al., 1983a). In mice, continuous inhalation of ≥ 100 ppm methyl chloride for ≥ 11 days resulted in brain lesions (Landry et al., 1985; Jiang et al., 1985).

Chemical Pathology

Heart malformations in mouse pups born to dams inhaling 500 ppm methyl chloride included reduction/absence of the atrioventricular valve, papillary muscle, and chordae tendinae in the bucuspid or tricuspid valve (Wolkowski-Tyl et al., 1983a, 1983b).

In mice, continuous inhalation of 100 ppm methyl chloride for 11 days resulted in cerebral granular cell layer degeneration (Landry et al., 1985). This effect was not seen if the exposure was intermittent rather than continuous. Further, focal and diffuse malacia was observed in these brain tissues following inhalation of 1500 ppm for 2 weeks in rats (Jiang et al., 1985).

Mode of Action(s)

Increased preimplantation fetal losses in rats are likely caused by failure to fertilize, resulting from testicular or epididymal epithelium cytotoxicity, rather than sperm cell genotoxicity (Working et al., 1985a, 1985b; Working and Bus, 1986), although high inhalation doses may result in dominant lethal genotoxicity mediated by epididymal inflammation (Chellman et al., 1987). Some testicular and epididymal lesions reported in rats inhaling methyl chloride may result from centrally disrupted testosterone levels, rather than impaired Leydig cell or gonadotrope function (Chapin et al., 1984). *In vitro* assays on bacterial and human cells suggested that methyl chloride is a weak direct acting mutagen (Fostel et al., 1985).

SOURCES OF EXPOSURE

Occupational

Workers involved in the chemical production involving methyl chloride may be exposed primarily via inhalation, with some possible dermal contact.

Environmental

The general population may be exposed to methyl chloride via drinking water and inhalation of ambient air containing methyl chloride.

INDUSTRIAL HYGIENE

Eye protection and skin covering should be used to protect from freezing temperatures associated with liquid methyl chloride releases. Respirators should be used for exposures of up to 5000 ppm. OSHA has set the PEL for methyl chloride at 100 ppm as an 8-h TWA. NIOSH set a REL of 1 ppm as a 10-h TWA. ACGIH set a TLV for methyl chloride at 50 ppm as an 8-h TWA.

RISK ASSESSMENTS

EPA: RfC: 9×10^{-2} mg/m³, D, not classifiable as to human carcinogenicity

IARC: Group 3, not classifiable as to its human carcinogenicity.

METHYL CHLOROFORM

First aid: *Oral*: Do not induce vomiting; use gastric lavage only if the ingested amount was large and consumed within the past 30 min. *Inhalation*: Move the person to fresh air. *Dermal*: Wash the exposed skin with soap and water. *Eye*: Irrigate with water for 15 min.

Target organ(s): Eyes, skin, CNS, cardiovascular system, liver

Occupational exposure limits: OSHA PEL: 350 ppm 8-h TWA; NIOSH: 350 ppm 15-min ceiling; ACGIH TLV: 350 ppm 8-h TWA

Reference values: None identified.

Risk/safety phrases: 20–59; (2-)24/25-59-61 Note F

BACKGROUND AND USES

Methyl chloroform (1,1,1-trichloroethane, CASRN 71-55-6) was used historically in degreasing processes and metal cleaning and as a solvent. It was also found in adhesives and household cleaners. It is used in the chemical synthesis as a chemical intermediate in vinylidene chloride productions. It was used as a food and grain fumigant and propellant for pressurized aerosol spray products. Classified in the Montreal Protocol of 1987 as an ozone-depleting chemical, it was to be phased out of production and use by treaty members by 2010.

PHYSICAL AND CHEMICAL PROPERTIES

Methyl chloroform (molecular weight = 133.42 g/mol) is a colorless liquid having a sweet odor. It is a volatile compound with a vapor pressure of 124 mmHg at 25 °C. It is relatively insoluble in water (1.3×10^3 mg/l at 25 °C) but soluble in many common organic solvents.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Methyl chloroform found in the environment may result from the release in electronics manufacturing and metal cleaning waste streams, as well as from the disposal of household products, in which it is an ingredient. It exists in the

atmosphere solely as a gas due to its high vapor pressure, where it is slowly degraded by photochemically produced hydroxyl radicals (half-life = 4.7 years). Because of its persistence in the atmosphere, it tends to diffuse into the stratosphere, where it may contribute to the catalytic degradation of ozone. Methyl chloroform is highly mobile in soil and evaporates quickly from dry soil and surface waters. It may get biodegraded slowly in the soil. It is not expected to be adsorbed to sediments and suspended particles and is not expected to bioaccumulate in aquatic organisms (BCF = 3) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

The 2- and 17-h LC₅₀ for methyl chloroform was 11.2 and 5.4 mg/l, respectively. The 2-h LC₅₀ in zebrafish and Japanese medaka were 79 and 1 g/l, respectively (EPA, 2013).

Chronic Effects

No chronic ecotoxicological data were identified for methyl chloroform.

MAMMALIAN TOXICOLOGY

Acute Effects

An exposure to high air concentrations of methyl chloroform lead to narcosis with CNS depression and even fatal respiratory depression (Stewart, 1971). Experimental (Reinhardt et al., 1971; Aviado and Belej, 1974) and clinical observations suggest that abusive recreational exposure levels may increase the risk of cardiac arrhythmias. No adverse cardiovascular or neurological effects were seen in volunteers inhaling 200 ppm methyl chloroform while exercising (Laine et al., 1996). Slight sedation was indicated by electroencephalography (EEG) in volunteers inhaling 200 ppm (Muttray et al., 2000). Human data do not indicate carcinogenicity of methyl chloroform in occupational or environmental exposures.

Inhalation of ≥ 1000 ppm methyl chloroform for 30 min in mice resulted in reduced locomotor activity, muscle tone, and operant behavior (Bowen and Balster, 1996; Warren et al., 1998). Delayed neurological development occurred in pups of mice and rats exposed to ≥ 6000 ppm during gestation (Jones et al., 1996; Coleman et al., 1999). In dogs, increased pulmonary arterial pressure and cardiac workload

was reported following inhalation exposure (Aoki et al., 1997).

Chronic Effects

Kelafant et al. (1994) reported deficits in memory, balance, and rhythm in a small group of workers exposed to methyl chloroform. Cases of liver disease and sensory neuropathy were reported in individual adults (House et al., 1994; Cohen and Frank, 1994). Tolerance or sensitization to neurological effects was shown in mice inhaling high doses of methyl chloroform (Bowen and Balster, 2006). Although one research group reported significant increases in tumor development in mice and rats when tumor types were grouped for statistical analysis (Ohnishi et al., 2013), studies performed by the NTP were not suggestive of mutagenic or carcinogenic potential in rodents (NTP, 2008).

Chemical Pathology

Postmortem examination following methyl chloroform-induced worker fatalities showed pulmonary, hepatic, and renal congestion and edema (Stahl et al., 1969; Hatfield and Maykoski, 1970; Winek et al., 1997).

Mode of Action(s)

Acute methyl chloroform inhalation depresses CNS function similar to other VOCs. Okuda et al. (2001) suggest that peripheral neuropathy may be mediated by the inactivation of Ca²⁺ channels in the neuron.

SOURCES OF EXPOSURE

Occupational

Workers involved in chemical production involving methyl chloroform may be exposed primarily via inhalation with some possible dermal contact. Tay et al. (1995) showed that end-of-shift blood and alveolar air levels of methyl chloroform, but not urine levels, correlated well with measured exposures.

Environmental

The general population may be exposed to methyl chloroform via drinking water and inhalation of ambient air containing methyl chloroform.

INDUSTRIAL HYGIENE

Eye protection and skin coverings should be used to protect from freezing temperatures associated with liquid

methyl chloroform releases. Air-purifying respirators should be used for exposures of up to 700 ppm. OSHA has set the PEL for methyl chloroform at 350 ppm as an 8-h TWA. NIOSH set a REL of 350 ppm as a 15-min ceiling value. ACGIH set a TLV for methyl chloroform at 350 ppm as an 8-h TWA.

RISK ASSESSMENTS

No risk assessments for methyl chloroform were identified.

METHYLENE CHLORIDE

First aid: *Oral:* Do not administer activated charcoal. *Inhalation:* Move the person to fresh air; monitor for CNS symptoms and carboxyhemoglobin levels; administer 100% oxygen for possible CO poisoning. *Dermal:* Remove the contaminated clothing and wash the exposed skin with soap and water. *Eye:* Irrigate with water for 15 min.

Target organ(s): Eyes, skin, cardiovascular system, CNS
Occupational exposure limits: OSHA PEL: 25 ppm 8-h TWA; NIOSH: lowest concentration feasible; ACGIH TLV: 50 ppm 8-h TWA.

Reference values: ATSDR: Acute, intermediate, and chronic inhalation MRLs: 0.6, 0.3, and 0.3 ppm; Acute and chronic oral MRL: 0.2 and 0.06 mg/kg/day

EPA: RfC: 0.6 mg/m³; RfD: 6×10^{-3} mg/kg/day

Risk/safety phrases: 40; (2)-23-24/25-36/37

BACKGROUND AND USES

Methylene chloride (dichloromethane, CASRN 75-09-2) is used in degreasing and metal cleaning and paint stripping and removal. It is also used in caffeine extraction of coffee and the manufacture of polycarbonate plastics. It has been used historically as a pesticide fumigant and refrigerant.

PHYSICAL AND CHEMICAL PROPERTIES

Methylene chloride (molecular weight = 84.93 g/mol) is a colorless liquid having a sweet odor. It is a volatile compound with a vapor pressure of 124 mmHg at 25 °C. It is soluble in water (1.3×10^4 mg/l at 25 °C) but insoluble in carbon tetrachloride. It is miscible with ethanol, dimethylformamide, and ethyl ether.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Methylene chloride found in the environment may be emitted from release sites involving degreasing and metal cleaning operations. It exists in the atmosphere as a vapor, where it is degraded by photochemically produced hydroxyl radicals (half-life = 119 days). Methylene chloride is highly mobile in soil and evaporates quickly from dry soil and surface waters although some biodegradation in soil and water is possible. It is not expected to be adsorbed to sediments and suspended particles and is not expected to bioaccumulate in aquatic organisms (BCF = 2) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

The 2-h EC₅₀ (immobility) and 1-h LC₅₀ for *D. magna* was 1.3 and 2.5 g/l, respectively. The 4-h LC₅₀s in zebrafish and bluegill were 254 and 220 mg/l (EPA, 2013), respectively.

Chronic Effects

No chronic ecotoxicological data were identified for methylene chloride.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute inhalation effects in humans include eye and throat irritation, nasal discharge, cough, fatigue, and light-headedness (Shusterman et al., 1990). Deaths have been reported from methylene chloride exposure at small furniture stripping facilities (Novak and Hain, 1990). Exposure of volunteers to 500 ppm produced decreased manual performance and attention lapses (Winneke and Fodor, 1976). Sensory and psychomotor function may be impaired at ≥ 300 ppm. Effects of methylene chloride on the nervous system are reversible.

CNS depression occurred in guinea pigs inhaling 5000 ppm, with sleep cycle disturbances being reported at 1000 ppm (Winneke, 1981). Mice exhibited reduced learning capabilities following inhalation exposures (Alexeef and Kilgore, 1983). No reproductive, embryotoxicity or fetotoxicity was reported in rats exposed to methylene chloride (Schwetz et al., 1975; Hardin and Manson, 1980; Nitschke et al., 1988a).

Chronic Effects

Epidemiological studies have provided no statistically significant association between chronic methylene chloride exposure and cancer, death, or chronic illness in humans. These data include cohorts of photography workers (Hearne et al., 1990), airline mechanics (Lash et al., 1991), cellulose fiber workers (Lanes et al., 1993), synthetic fiber workers (Soden, 1993), and U.S. Air Force employees (Radican et al., 2008).

In inhalation studies, increases in incidences of fatty lung and mammary gland tumors were reported in rats and liver tumors in mice and rats exposed to ≥ 500 ppm for 2 years (Nitschke et al., 1988b; Mennear et al., 1988).

Liver effects were seen in drinking water studies involving rodents. Serota et al. (1986) reported fatty liver changes in mice following lifetime exposure at ≥ 50 mg/kg/day. Malignant mammary gland tumors occurred in mice at 500 mg/kg/day (Maltoni et al., 1988).

Chemical Pathology

Increased carboxyhemoglobin levels occur as a result of metabolism to carbon monoxide. Exposure of volunteers to 1000 ppm methylene chloride for 2 h resulted in higher carboxyhemoglobin levels than permitted in the workplace from exposure to carbon monoxide (Stewart et al., 1972).

Mode of Action(s)

Acute cardiovascular and CNS effects following high inhalation exposure to methylene chloride arise due to

solvent-like CNS depression and oxidative metabolism of carbon monoxide, resulting in carboxyhemoglobin. The liver is the primary site for methylene chloride metabolism although it may also be metabolized by the kidneys and lung. Methylene chloride is metabolized via the cytochrome P-450 monooxygenase pathway to carbon monoxide and via the glutathione s-transferase pathway (GSTT1) (Kubic and Anders, 1975; El-Masri et al., 1999) to formaldehyde and a glutathione conjugate. Thus, oxidative metabolism is a detoxification pathway (Jonsson and Johanson, 2001). The methylene chloride-glutathione conjugate (S-chloromethylglutathione) is known to induce single-strand breaks in DNA in some assays (Graves et al., 1994), while DNA adducts were reported in human lung cell lines having an absence of GSH metabolism (Evans and Caldwell, 2010).

SOURCES OF EXPOSURE

Occupational

Workers involved in metal cleaning and degreasing or chemical production involving methylene chloride may be exposed via inhalation and dermal contact.

Environmental

The general population may be exposed to methylene chloride via drinking water and inhalation or dermal contact with paint strippers containing methylene chloride.

INDUSTRIAL HYGIENE

Eye protection, gloves (not PVC or rubber), and skin coverings should be used to protect from freezing temperatures associated with liquid methylene chloride releases. Avoid close-circuit air-rebreathing respirators that employ carbon dioxide absorption media, as neurotoxic compounds may be formed. OSHA has set the PEL for methylene chloride at 25 ppm as an 8-h TWA. NIOSH did not set a REL but recommends exposure to lowest concentration feasible. ACGIH set a TLV for methylene chloride at 50 ppm as an 8-h TWA.

RISK ASSESSMENTS

ATSDR: Acute, intermediate, and chronic inhalation MRLs: 0.6, 0.3, and 0.3 ppm, respectively; Acute and chronic oral MRL: 0.2 and 0.06 mg/kg/day, respectively. EPA: RfC: 0.6 mg/m³; RfD: 6×10^{-3} mg/kg/day; likely to be carcinogenic to humans. IARC: group 2B: Possibly carcinogenic to humans.

PHOSGENE

First aid: *Inhalation:* Move the person to fresh air. Check for bronchitis, pneumonitis, or severe respiratory tract irritation if cough or breathing difficulty develops or persists. Experimental medical interventions include intratracheal bolus dose of N-acetylcystiene and aminophylline (Sciuto and Hurt, 2004). *Dermal:* Remove the contaminated clothing and wash the exposed skin with soap and water. *Eye:* Irrigate with water for 15 min.

Target organ(s): Eyes, skin, respiratory system

Occupational exposure limits: OSHA PEL: 0.1 ppm 8-h TWA; NIOSH: 0.1 ppm 10-h TWA; ACGIH TLV: 0.1 ppm 8-h TWA

Reference values: EPA: 10 min AEGL 1. NR, AEGL 2. 0.6 ppm, AEGL 3 3.6 ppm;

RfC: 3×10^{-4} mg/m³

Risk/safety phrases: 26–34; (1/2-)9-26-36/37/39-45

BACKGROUND AND USES

Phosgene (dichloromethane, CASRN 75-44-5) is used as an intermediate in the chemical synthesis of polycarbonates, aniline dyes, isocyanates, carbamate pesticides, perfumes, and pharmaceuticals. It is used in some metal ore separations and has been used historically as a pesticide fumigant and chemical warfare agent.

PHYSICAL AND CHEMICAL PROPERTIES

Phosgene (molecular weight = 98.92 g/mol) is a colorless gas at ambient temperature with an odor of musty hay at very low concentrations. It is a highly volatile compound with a vapor pressure of 1420 mmHg at 25 °C. It is slightly soluble in water but soluble in most hydrocarbon solvents.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Phosgene found in the environment may result due to the release at sites of chemical synthesis of a variety of products. It is also an atmospheric degradation product of a number of chlorinated hydrocarbons. It exists in the atmosphere as a gas, where it is degraded over a half-life of 44 days. Phosgene is highly mobile in soil and evaporates quickly from dry soil and surface waters. It is not expected to be adsorbed to sediments and suspended particles and is not expected to bioaccumulate due to its very high rate of hydrolysis; a 1% phosgene solution is completely hydrolyzed in 20 s at 0 °C (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

No acute ecotoxicological data were identified for phosgene (EPA, 2013a).

Chronic Effects

No chronic ecotoxicological data were identified for phosgene.

MAMMALIAN TOXICOLOGY

Acute Effects

Inhalation of high concentrations (>3 ppm) of phosgene results in shallow respiration, with decreases in respiratory

tidal volume and vital capacity occurring (an initial protective phase). This reflexive reaction tends to diminish if exposure ceases. In the second phase, clinical signs and symptoms are typically absent for several hours. The terminal phase involves the development of pulmonary edema (Schneider and Diller, 1989; Diller, 1985). Edema severity increases as gas exchange decreases and fluid rises up the respiratory tract. Cardiac failure mediated by pulmonary congestion may occur at sufficiently high exposures.

Chronic Effects

Occupational epidemiology studies of uranium processing workers chronically exposed to low levels of phosgene did not provide an indication of chronic pulmonary toxicity (Polednak, 1980; Polednak and Hollis, 1985).

Chemical Pathology

Acute histopathology includes edematous swelling of the lung tissues, with infiltration of blood plasma into the pulmonary interstitium and alveoli (Duniho et al., 2002). Alveolar glutathione levels are depleted (Sciuto, 1998). Subsequent damage to the alveolar type I cells and necrosis results (Schneider and Diller, 1989; Diller, 1985; Brown et al., 2002). Rapid respiration may result in the appearance of a frothy fluid.

Mode of Action(s)

Phosgene gas is highly reactive, causing oxidative-like tissue damage. Acrylation of macromolecules and hydrolysis of phosgene to HCl are the main modes of action for acute tissue damage. Chronic exposure may lead to the onset of pulmonary fibrosis. Development of interstitial and intra-alveolar fibrosis may be accompanied by increased lung hydroxyproline content and prolyl hydroxylase and galactosylhydroxy-lysyl glucotransferase activity (Kodavanti et al. (1997); Hatch et al., 2001; Borak and Diller, 2001).

SOURCES OF EXPOSURE

Occupational

Chemical workers producing phosgene or using it for the synthesis of other compounds may be exposed via inhalation and dermal contact. Combat personnel may be exposed via inhalation of phosgene dispersed as a chemical warfare agent.

Environmental

The general population is unlikely to be exposed to phosgene, except in the event of deployment of phosgene munitions against the public.

INDUSTRIAL HYGIENE

Complete eye and skin protection is required, as phosgene may cause severe irritation and/or burns of the exposed skin. Phosgene-specific respirator canisters or supplied-air or self-contained air respirators must be used. Specialized safety training is required to work in areas of phosgene exposure. OSHA has set the PEL for phosgene at 0.1 ppm as an 8-h TWA. NIOSH set a REL of 0.1 ppm as a 10-h TWA, and set an IDLH of 2 ppm. ACGIH set a TLV for phosgene at 0.1 ppm as an 8-h TWA.

RISK ASSESSMENTS

EPA: 10 min AEGLs 1: NR, AEGL 2: 0.6 ppm, AEGL 3: 3.6 ppm, RfC: 3×10^{-4} mg/m³, Inadequate information to assess carcinogenicity.

TETRACHLOROETHYLENE

First aid: *Oral:* Activated charcoal slurry may be given; gastric lavage should be administered if a large amount was ingested within the past hour. Treat CNS and respiratory depression as needed. *Inhalation:* Move the person to fresh air. Administer ventilator assistance if CNS and respiratory depression are present. *Dermal:* Remove the contaminated clothing and wash the exposed skin with soap and water. *Eye:* Irrigate with water for 15 min.

Target organ(s): Eyes, skin, respiratory system, liver, kidneys, CNS

Occupational exposure limits: OSHA PEL: 100 ppm 8-h TWA; NIOSH: lowest feasible concentration; ACGIH TLV: 25 ppm 8-h TWA, 100 ppm STEL

Reference values: ATSDR Acute and chronic inhalation MRLs: 0.2 ppm and 0.04 ppm; Acute oral MRL: 0.05 mg/kg/day

EPA: RfC: 0.04 mg/m³, RfD: 0.006 mg/kg/day

Risk/safety phrases: 40–51/53; (2-)23-36/37-61

BACKGROUND AND USES

Tetrachloroethylene (1,1,2,2-tetrachloroethylene, CASRN 127-18-4) is used primarily for the commercial dry cleaning of garments, textile preparation, and as feed stock for chlorofluorocarbon production. It is also used in metal cleaning and degreasing and as an insulator in electrical transformers. It has been used historically as a pesticide fumigant and as an anthelmintic treatment option.

PHYSICAL AND CHEMICAL PROPERTIES

Tetrachloroethylene (molecular weight = 165.83 g/mol) is a colorless liquid with a sweet odor. It is a volatile compound with a vapor pressure of 18.5 mmHg at 25 °C. It is relatively insoluble in water (2.1×10^2 mg/l) but is miscible with ethyl ether, ethanol, hexane, chloroform, and benzene.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Tetrachloroethylene may be found in the environment due to the accidental release at dry cleaning sites and waste streams from chemical facilities producing chlorofluorocarbons. It exists in the atmosphere as a gas, where it is degraded over a half-life of 96 days. Tetrachloroethylene is moderately mobile in soil and evaporates quickly from dry soil and surface waters. Very slow biodegradation to trichloroethylene is possible in soil. It is not expected to be adsorbed to sediments and suspended particles. Bioaccumulation in fish may be high (BCF = 26–115) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

The 2-h EC₅₀ (immobility) and LC₅₀ for tetrachloroethylene in *D. magna* was 7.5 and 18 mg/l, respectively. The 2-h LC₅₀ in zebrafish was 9.3 mg/l (EPA, 2013).

Chronic Effects

The lowest concentration producing death in flagfish after 28 days was 3.7 mg/l (EPA, 2013).

MAMMALIAN TOXICOLOGY

Acute Effects

Both human and animal data indicate CNS depression as the primary acute effect of high tetrachloroethylene exposure. Changes in visual evoked potentials (Altmann et al., 1990), EEG changes (Hake and Stewart, 1977), and reduced visuo-spatial memory and cognition errors (Echeverria et al., 1995) were reported in humans. Rats exhibited changes in flash-invoked potential after inhaling 800 ppm (Mattsson et al., 1998).

Liver injuries in dry cleaners were indicated by increased serum levels of a liver enzyme as well as sonographic indicators and were associated with TWA inhalation exposures to 12–16 ppm tetrachloroethylene (Brodkin et al., 1995; Gennari et al., 1992). Mice inhaling 9 ppm or ingesting 100 mg/kg/day for 30 days exhibited liver toxicity more so than rats (Odum et al., 1988; Kjellstrand et al., 1984; NTP, 1986).

Studies of drycleaner workers exposed to tetrachloroethylene were suggestive of increased incidences of spontaneous abortions but are equivocal (Lindbohm et al., 1990; Olsen et al., 1990). Rats inhaling 300 ppm gave birth to pups having significantly reduced birth weights (Tinston, 1994).

Chronic Effects

Chronic exposure in humans may result in vision effects, changes in color vision, and deficits in spatial memory.

Occupational inhalation exposure to 8–15 ppm (TWA) has been associated with kidney toxicity and end-stage renal disease, indicated by increased urinary protein levels (Verplanke et al., 1999; Calvert et al., 2011). Renal damage in rats has been reported at an inhalation exposure of 50 ppm (NTP, 1986).

Tetrachloroethylene-induced bladder cancer (Lynge et al., 2006; Blair et al., 2003), multiple myeloma (Radican et al., 2008), and non-Hodgkin lymphoma (Radican et al., 2008; Calvert et al., 2011) have been suggested in epidemiology studies. Rats inhaling ≥200 ppm tetrachloroethylene exhibited increased incidence of mononuclear cell leukemia, while mice inhaling ≥100 ppm developed increased incidences of liver cancer (NTP, 1986).

Chemical Pathology

Proximal tubule damage in human kidneys was indicated by elevated urinary levels of lysozyme and β -glucuronidase (Franchini et al., 1983). Rats exhibited enlarged renal cell nuclei, cast formation, and glomerular nephrosis (NTP, 1986).

Liver pathology seen in laboratory studies of mice inhaling tetrachloroethylene include liver enlargement, centrilobular necrosis, cytoplasmic vacuolation, inflammatory cell infiltrates, cell pigmentation, hyperplasia, and regenerative foci (Odum et al., 1988; Kjellstrand et al., 1984; NTP, 1986).

Mode of Action(s)

Renal tubule toxicity may be caused by metabolism of tetrachloroethylene to the GSH conjugates TCVC and TCVCS, as indicated by multiple animal studies.

The mode(s) of action for liver and kidney cancer seen in rodents is/are not known but may include mutagenicity, PPAR α -activation, α 2-globulin nephropathy (in male rats), cytotoxicity from GSH-derived conjugates (Ripp et al., 1999; Dreessen et al., 2003; Lash and Parker, 2001).

SOURCES OF EXPOSURE

Occupational

Workers in the dry-cleaning industry may be exposed to tetrachloroethylene via inhalation and dermal contact.

Environmental

The general population may be exposed to tetrachloroethylene in ambient air or via ingestion of contaminated drinking

water. Closet storage of garments dry-cleaned with tetrachloroethylene has resulted in air levels of up to 30 times that of ambient air levels. Some adolescents sniffing typewriter correction fluids for abusive narcosis may be exposed to tetrachloroethylene.

INDUSTRIAL HYGIENE

Use gloves, goggles, and skin-covering clothing when in contact with tetrachloroethylene. OSHA has set the PEL for tetrachloroethylene at 100 ppm as an 8-h TWA. NIOSH recommends exposure to lowest feasible concentrations. ACGIH set a TLV for tetrachloroethylene at 25 ppm as an 8-h TWA.

RISK ASSESSMENTS

ATSDR: Acute and chronic inhalation MRL: 0.2 and 0.04 ppm; Acute oral MRL: 0.05 mg/kg/day

EPA: RfC: 0.04 mg/m³, RfD: 0.006 mg/kg/day, Likely to be carcinogenic to humans.

IARC: Group 2A: Probably carcinogenic to humans.

Reference values: ATSDR: Acute and intermediate inhalation MRLs: 2 ppm and 0.1 ppm; Acute oral MRL: 0.2 mg/kg/day. EPA: RfC: 1.9×10^{-4} mg/m³, RfD: 5.1×10^{-4} mg/kg/day

Risk/safety phrases: 40–52/53; (2)-23-36/37-61

BACKGROUND AND USES

Trichloroethylene (CASRN 127-18-4) is used in metal cleaning in the electronics industry and as a chemical intermediate in the production of larger halogenated hydrocarbons. Historically, it was used extensively for the commercial dry cleaning of garments (replaced by tetrachloroethylene), in pesticide formulations, and as an anesthetic.

PHYSICAL AND CHEMICAL PROPERTIES

Trichloroethylene (molecular weight = 131.39 g/mol) is a colorless liquid with a sweet odor. It is a volatile compound with a vapor pressure of 69 mmHg at 25 °C. It is slightly

soluble in water (1.3×10^3 mg/l) but is miscible with ethyl ether, ethanol, carbon tetrachloride, and chloroform. Open flames and heated surfaces, as well as the presence of an alkaline environment, may cause the pyrolysis of this compound to phosgene.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Trichloroethylene found in the environment may result from historical releases, from dry cleaning and metal cleaning sites, and waste streams from electronic component production. It exists in the atmosphere as a gas, where it is degraded by hydroxyl and nitrate radicals over a half-life of 7 and 114 days, respectively. Trichloroethylene is mobile in soil and evaporates quickly from dry soil and surface waters. Aerobic biodegradation to trichloroethylene in soil may be fairly rapid, while anaerobic degradation is slow. Trichloroethylene is adsorbed to sediments and suspended particles. Bioaccumulation in aquatic organisms may be moderate (BCF = 4-39) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

No acute ecotoxicological data were identified for trichloroethylene (EPA, 2013a).

Chronic Effects

No chronic ecotoxicological data were identified for trichloroethylene (EPA, 2013b).

MAMMALIAN TOXICOLOGY

Acute Effects

Trichloroethylene vapors are mildly irritating to the mucous membranes in some individuals. Trichloroethylene can act on the skin as a primary irritant and defatting agent, which may aggravate existing eczematous lesions. Narcotic effects produced by acute exposure to trichloroethylene include lack of coordination, dizziness, confusion, drowsiness, and eventual loss of consciousness. The peripheral and central nervous systems may be involved in acute narcosis. Although symptoms may rapidly disappear with the cessation of exposure, persistent headache or hallucinations may remain, likely caused by contaminants (Smith, 1966). Excitatory or euphoric stage narcosis may lead to repeated intentional inhalation of the vapor (Harenko, 1967). Feldman and Mayer (1968) have demonstrated a slowing of conduction time in

peripheral nerves, which is reversible over the course of months. Historical trichloroethylene use as an anesthetic, in high level occupational exposures and suicide attempts involving oral ingestion, has resulted in cardiac arrhythmias leading to death (Smith 1966; Gutch et al., 1965; Pembleton, 1974). Acute trichloroethylene (TCE) poisoning in humans resulted in increased *N*-acetyl- β -D-glucosaminidase (NAG) levels, a nonspecific biomarker of renal damage (Carrieri et al., 2007). High level inhalation exposures (≥ 1000 ppm) of rodents resulted in significantly increased instances of renal tubule damage (Chakrabarti and Tuchweber, 1988).

Chronic Effects

Chronic exposure may lead to changes in vestibular (as seen in acute exposure) and trigeminal nerve function. Trichloroethylene workers exposed to > 100 ppm trichloroethylene exhibited well-defined dose responses for loss in trigeminal nerve function (Barret et al., 1987). In a case report of high level of trichloroethylene exposure (Feldman et al., 1988), facial nerve latency and muscle function returned to normal after 120 weeks but not full facial sensation and pupillary response. However, the cause of these effects could not be attributed to trichloroethylene with certainty. Loss of auditory function was reported in children and workers (Rasmussen et al., 1993) exposed to trichloroethylene via oral or inhalation routes, respectively. However, these data were limited by self-reporting of effects, a paucity of objective measurements, and uncertainties in exposure. Rats exposed to high levels (> 2000 ppm) of trichloroethylene have an increased auditory threshold and mid to high frequency loss in brain auditory-evoked responses (Rybäk, 1992; Crofton and Zhao, 1997).

Liver effects in metal degreasers exposed to TCE include elevation of serum enzymes indicative of impaired liver function. The dose response for these effects in workers is uncertain due to uncertainties and inconsistencies in exposure estimation as well as confounders such as alcohol consumption. Data for liver cancer in humans are extremely limited to indicate a causal association. Liver toxicity reported in rodents includes liver weight increases, hepatocyte hypertrophy, and proliferation of peroxisomes. Cytotoxicity and regenerative proliferation do not appear to be the significant effects of TCE exposure in rodents. Liver tumors were seen in TCE-exposed mice more so than rats, possibly because of the higher metabolism of TCE in mice.

Proximal tubule damage was reported in workers exposed to high levels of trichloroethylene alone or in conjunction with other compounds. Increased urinary levels of several nonspecific biomarkers of kidney function were reported, including α 1- and β 2-microglobulin, total protein, and NAG (Jacob et al., 2007). Mice and rats exhibited significantly increased instances of nephropathy, cytomegaly, and karyomegaly following chronic oral trichloroethylene exposures,

while inhalation bioassays produced these effects in male rats only. Epidemiological studies of various designs and locations have reported significant associations between occupational trichloroethylene exposure and renal cancer, particularly in cohorts estimated to have the highest exposure. Renal tubule tumors developed in male rats but not in mice or hamsters.

Occupational exposure has been associated with autoimmune mediated scleroderma, with increased levels of inflammatory cytokines observed similar to those seen in laboratory animal studies of immunotoxicological endpoints.

High TCE exposure in rodents resulted in decreased sperm quality and CNS, ocular, kidney/liver, skeletal, cardiac, and respiratory developmental effects. Human data for TCE-induced birth defects are too limited to show a causal link.

Mode of Action(s)

It is unclear whether the proposed modes of action for carcinogenicity observed in laboratory animals are relevant to human exposures to TCE. In several cases, metabolite pathways are qualitatively similar between humans and animals (although different quantitatively), resulting in the formation of TCE metabolites, which may be involved in toxic insult if produced in sufficient concentrations. The proposed modes of action for liver cancer include peroxisome proliferation-receptor α activation, increased hepatic glycogen stores, oxidative stress, and epigenetic changes (EPA, 2011). However, data are inadequate to indicate which mode of action is responsible for animal hepatocarcinogenicity or if they are relevant to humans.

The mode of action for kidney cancer seen in rats and suggested in TCE workers may be due to sequential *in situ* renal metabolism of TCE to dichlorovinylcysteine (DCVC), downstream glucuronidation of DCVC, and transformation to reactive species that are mutagenic in *in vitro* and *in vivo* animal studies. It is unclear if the mode of action is dominated by mutagenic alterations of DNA of renal tubules, cytotoxic cell proliferation, or a combination of both and if the putative carcinogenic metabolite in rat is also present in human kidneys at sufficiently high levels.

The mode of action for cancer is not well understood. Studies of genotoxic effects in humans, animals, and *in vitro* systems were inconclusive. Chromosomal abnormality reported in studies of trichloroethylene workers was confounded by issues of unbalanced study design, simultaneous exposure to other organic solvents, and tobacco smoke (Rasmussen et al., 1988; Konietzko et al., 1978; Nagaya et al., 1989). Likewise, the dose response for DNA strand breaks in mice and rats was either very different or was not observed. These data suggest that the carcinogenic mechanism for trichloroethylene in rodents may not be genotoxic.

SOURCES OF EXPOSURE

Occupational

Workers in the halogenated hydrocarbon production and electronics manufacturing industries may be exposed to trichloroethylene via inhalation and dermal contact.

Environmental

The general population may be exposed to trichloroethylene via inhalation in ambient air or via ingestion of contaminated drinking water. Exposure via indoor air may also occur via vapor intrusion from migrating groundwater contaminant plumes.

INDUSTRIAL HYGIENE

Use gloves, goggles, and skin-covering clothing when in contact with trichloroethylene. OSHA has set the PEL for trichloroethylene at 25 ppm as an 8-h TWA. NIOSH set 2 ppm as a 60-min ceiling value. ACGIH set a TLV for trichloroethylene at 25 ppm as an 8-h TWA.

RISK ASSESSMENTS

ATSDR: Acute and intermediate inhalation MRLs: 2 ppm and 0.1 ppm; Acute oral MRL: 0.2 mg/kg/day

EPA: RfC: 1.9×10^{-4} mg/m³, RfD: 5.1×10^{-4} mg/kg/day, carcinogenic to humans

IARC: Group 1: Carcinogenic to humans.

OTHER HALOGENATED HYDROCARBONS

MICHAEL H. LUMPKIN

Some brominated, chlorinated, and fluorinated hydrocarbons have been used historically in industry, but have since been banned for production and use in the United States and other nations. The Montreal Protocol of 1987 was enacted to phase out ozone-depleting chemicals such as chlorofluorocarbons and hydrofluorocarbons. Manufacturing and use bans enacted by the U.S. federal government in the 1970s have removed a substantial volume of brominated insecticides and halogenated biphenyls from commerce. Nonetheless, legacy uses of these compounds (i.e., polychlorinated biphenyls in electrical equipment), as well as their long-lived persistence in the environment, maintain ongoing concern for their exposure to workers today. This chapter includes a subset of chemicals that have been banned but are still of concern, or have ongoing scientific and regulatory decisions to be made regarding their risk to workers and to the general public.

BROMOBENZENE

First aid: *Inhalation:* Remove to fresh air. Take deep breaths.

Check for wheezing, coughing, shortness of breath, or burning in the mouth, throat, or chest. Call physician if these symptoms persist. *Dermal:* Remove contaminated clothing while washing exposed skin with soap and water.

Eye: Irrigate with water or normal saline for 15–20 min

Target organ(s): Eyes, CNS, liver, kidney

Occupational exposure limits: OSHA PEL: None; NIOSH: None; ACGIH TLV: None

Reference values: EPA: subchronic RfC—0.06 mg/m³, subchronic RfD—0.008 mg/kg/day

Risk/safety phrases: 10-38-51/53; (2)-61

BACKGROUND AND USES

Bromobenzene (phenyl bromide, CASRN 108-86-1) is used as a reagent in chemical synthesis and has been used as an additive to motor oils. It has also been used as a high density solvent for chemical recrystallization (NLM, 2013).

PHYSICAL AND CHEMICAL PROPERTIES

Bromobenzene (molecular weight = 157.02 g/mol) is a colorless liquid with a pungent, aromatic odor. It is a volatile organic compound with a vapor pressure of 4.18 mm Hg at 25 °C. It is insoluble in water, but soluble in most organic solvents.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Bromobenzene found in the environment may result from industrial releases. It will exist in the atmosphere in the vapor phase, where it is degraded over a half-life of 21 days. Bromobenzene is moderately mobile in soil; and will evaporate quickly from dry soil and surface waters. It is expected to be absorbed to sediments and suspended particles, and is not expected to bioaccumulate (BCF = 8.8–190) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

The EC₅₀ for immobility in *Daphnia magna* is 1600 µg/l. The LC₅₀ for *C. dubia* is 5800 µg/l. The 4-h LC₅₀ for fathead minnow is 5600 µg/l (EPA, 2013).

Chronic Effects

There are no data for chronic ecotoxicological effects of bromobenzene.

MAMMALIAN TOXICOLOGY

Acute Effects

No acute health effects data for bromobenzene in humans are available. No acute inhalation toxicity data are available in animals. In mice, oral administration of ≥ 300 mg/kg/day bromobenzene for 5 days resulted in liver pathology indicated by centrilobular inflammation and hepatocytic necrosis (NTP, 1985a). In rats ingesting 600 mg/kg/day for 13 weeks, were reported in daily ataxia, malaise, and ocular discharge (NTP, 1985a).

Chronic Effects

No chronic health effects data for bromobenzene in humans are available. Chronic inhalation of up to 300 ppm bromobenzene in rats for 13 weeks was resulted in renal tubule regeneration, but without associated necrosis. No liver pathology was reported (NTP, 1985a). Mice inhaling 300 ppm for 13 weeks exhibited liver damage, including hepatocytic necrosis and mineralization (NTP, 1985b). In rats ingesting 600 mg/kg/day for 13 weeks, resulted in emaciation, as well as liver and kidney cellular damage (NTP, 1985c). Decreased renal glutathione (GSH) levels and increased blood urea nitrogen were observed in rats following bromobenzene administration (Monks and Lau, 1988), suggesting adverse effects to the kidney.

Chemical Pathology

Liver and kidney effects seen in rodents after high inhalation or oral subchronic exposures to bromobenzene were marked by histological effects, including renal tubular degeneration and hepatocyte necrosis (NTP, 1985a-d).

Mode of Action(s)

Bromobenzene is oxidized by cytochrome P450 (CYP) monooxygenases to a reactive 3,4-oxide and subsequently to 4-bromophenol and 4-bromoquinone. One or more of these metabolites may be the putative toxicant binding to macromolecules resulting in cytotoxicity and necrosis in hepatocytes. A GSH conjugate of the quinone may be transported to the kidney, where it is converted to

cysteine derivative, undergoing redox cycling, and causing kidney damage through the generation of reactive oxygen species.

SOURCES OF EXPOSURE

Occupational

Workers using bromobenzene in specific chemical synthesis reactions may receive inhalation or dermal exposures.

Environmental

The general population is unlikely to be exposed to bromobenzene in the environment.

INDUSTRIAL HYGIENE

Bromobenzene is highly flammable; heavier than air vapors may travel along the ground to an ignition source. Goggles, rubber gloves, and a protective apron should be used when working with bromobenzene.

RISK ASSESSMENTS

EPA: subchronic RfC—0.06 mg/m³, subchronic RfD—0.008 mg/kg/day, inadequate information to assess the carcinogenic potential.

ETHYLENE DIBROMIDE

First Aid: *Inhalation:* Remove to fresh air. Call physician if cough or breathing difficulty develops or persists. *Oral:* Do not induce vomiting; but administer an activated charcoal slurry. *Dermal:* Remove contaminated clothing and wash exposed skin with soap and water. *Eye:* Irrigate with water for 15 min.

Target organ(s): Eyes, skin, respiratory system, liver, kidneys, reproductive system

Occupational exposure limits: OSHA PEL: 20 ppm 8-h TWA; NIOSH: 0.45 ppm 10-h TWA

Reference values: EPA: RfC— 0.009 mg/m³, RfD— 0.009 mg/kg/day

Risk/safety phrases: 45-23/24/25-36/37/38-51/53; 53-45-61 Note E

BACKGROUND AND USES

Ethylene dibromide (1,2-bromomethane, CASRN 106-93-4) is used as an antiknock additive for leaded fuels, a solvent, and a catalyst for Grignard reagent preparations, and as an intermediate in the production of dyes and pharmaceutical agents and as a pesticide fumigant. It was historically used as a pesticide fumigant for food crops (NLM, 2013).

PHYSICAL AND CHEMICAL PROPERTIES

Ethylene dibromide (molecular weight = 187.86 g/mol) is a colorless liquid at ambient temperature with a sweet chloroform odor. It is a volatile compound with a vapor pressure of 11.2 mm Hg at 25 °C. It is moderately soluble in water, but highly soluble in solvents such as acetone, ethanol, ethyl ether, and benzene.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Ethylene dibromide found in the environment may result from waste stream releases from aviation fuel blending, chemical synthesis, and dye and pharmaceutical manufacturing operations. It will exist in the atmosphere as a vapor, where it is degraded over a half-life of 64 days. Ethylene dibromide is highly mobile in soil, and will evaporate quickly from dry soil and surface waters. It is not expected to be absorbed to sediments and suspended particles, and is not expected to bioaccumulate in aquatic organisms (BCF = <1–14.9) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

The EC₅₀ for behavioral effects in *D.magna* is 116 mg/l. The 4-h LC₅₀ for Japanese medaka is 32.1 mg/l. The 4-h LC₅₀ for fathead minnow is 5600 µg/l (EPA, 2013).

Chronic Effects

The 28-day no effect concentration (NOAEL) for growth of Japanese medaka is 5.8 mg/l.

MAMMALIAN TOXICOLOGY

Acute Effects

Two workers died cleaning a tank previously filled with ethylene bromide, exhibiting metabolic acidosis, CNS depression, liver damage, and renal failure (Letz et al., 1984). A case of oral lethality was reported in adult female ingesting ethylene dibromide-containing capsules. Reported effects included agitation, abdominal pain, nausea, vomiting, and diarrhea, followed by death at 54 h post-ingestion (Olmstead, 1960).

Chronic Effects

Some epidemiologists suggest that ethylene dibromide adversely affects the male reproductive system. Abnormal sperm morphology, and decreased sperm count, motility, ejaculate volume, and overall reproductive function were reported in workers having a long-term inhalation exposure to ethylene dibromide (Ratcliffe et al., 1987; Schrader et al., 1988; Wong et al., 1979). However, these studies were confounded by possible exposure to other reproductive toxicants.

In animals, ethylene dibromide exposure via inhalation or oral exposure routes resulted in both reproductive and developmental effects (Short et al., 1978). Decreased testicular weight and serum testosterone, testicular atrophy, and reduced reproductive performance were reported in male rats inhaling 89 ppm, while testicular atrophy was observed in male mice inhaling 32 ppm. Oral doses of 4 mg/kg/day ethylene dibromide resulted in decreased sperm motility, altered sperm morphology, and decreased sperm number in seminiferous tubules of bulls (Amir and Ben-David, 1973). Developmental effects in both species at levels that also produced frank parental toxicity (38 ppm) included reduced fetal weights, increased resorptions, and decreased fetus viability.

Inhalation studies in rodents indicate nasal respiratory tissue toxicity as the most sensitive endpoint, with

noncancerous lesions also occurring in the liver, kidney, testis, and eyes (NTP, 1982). Oral studies in rodents resulted in forestomach lesions, decreased weight gain, high mortality, and testicular atrophy (NCI, 1978).

No epidemiological studies provided strong evidence for occupational carcinogenicity due to ethylene dibromide exposure, but rodents exhibited tumor development at multiple sites following chronic exposure. Increased nasal tumors and splenic hemangiosarcoma occurred in rats, and lung tumors in mice, inhaling ≥ 10 ppm for a lifetime. Rats ingesting 40 mg/kg/day over a lifetime developed squamous cell carcinoma of the forestomach, as well as hemangiosarcoma in liver, kidney, spleen, and pancreas when ingesting 80 mg/kg/day (NCI, 1978).

Chemical Pathology

Proliferative lesions in nasal epithelium, including focal epithelial hyperplasia of the nares, and diffuse respiratory hyperplasia were reported in mice inhaling ethylene dibromide for 13 weeks (Stinson et al., 1981; Nitschke et al., 1981). Megalocytic bronchiolar cells in rodents were also reported following inhalation exposures (NTP, 1982). Liver and kidney lesions were reported in mice/rats following inhalation exposures for a lifetime (NTP, 1982). Testicular pathology following chronic inhalation or oral exposure in rodents (NCI, 1978; NTP, 1982).

Mode of Action(s)

Cytotoxic lesions observed in rodent liver, kidney, nasal, and forestomach tissues were likely mediated by cytochrome P-450-dependent metabolism of ethylene dibromide to 2-bromoacetaldehyde, which, in turn, was responsible for lipid peroxidation, GSH depletion, protein binding, and, in the kidney, generation of glutathione-based metabolic toxicants (Khan et al., 1993; Masini et al., 1986; Novotna and Duverger-Van Bogaert, 1994). The genotoxic mode of action for ethylene dibromide appears to be mediated by GSH-mediated metabolites, as evidenced by observation of S-[2-(N₇-guanyl)ethyl]glutathione as the prominent DNA adduct (Cmarik et al., 1992).

SOURCES OF EXPOSURE

Occupational

Workers in the chemical and petrochemical industries involving use of ethylene dibromide may experience inhalation or dermal exposures.

Environmental

The general population is not likely to be exposed to ethylene dibromide unless contact is made with waste streams released from industries utilizing it.

INDUSTRIAL HYGIENE

Protective clothing should be worn when working with ethylene dibromide, to include gloves, bib-type aprons, boots, and overshoes. Gloves should not be made of neoprene rubber or many types of plastic. A half-mask respirator should be donned if ethylene dibromide concentrations are ≥ 10 ppm.

RISK ASSESSMENTS

EPA: RfC—0.009 mg/m³, RfD—0.009 mg/kg/day, likely to be carcinogenic to humans.

METHYL BROMIDE

First aid: *Inhalation:* Remove to fresh air. Check for bronchitis, pneumonitis, or severe respiratory tract irritation if cough or breathing difficulty develops or persists. *Dermal:* Remove contaminated clothing and wash exposed skin with soap and water. *Eye:* Irrigate with water for 15 min.

Target organ(s): Eyes, skin, respiratory system, central nervous system

Occupational exposure limits: OSHA PEL: 20 ppm 8-h TWA with skin notation; NIOSH: Minimize exposure to lowest possible level due to possible carcinogenicity; ACGIH TLV: 1 ppm 8-h TWA with skin notation.

Reference values: EPA: RfC—0.005 mg/m³, RfD—0.014 mg/kg/day.

ATSDR: Acute, intermediate, and chronic inhalation MRLs—0.05, 0.05, and 0.005 ppm, intermediate oral MRL—0.003 mg/kg/day

Risk/safety phrases: 23–36/37/38–50/53–59; (1/2–)15–27–36/37/39–38–45–59–61

BACKGROUND AND USES

Methyl bromide (bromomethane, CASRN 74-83-9) is used in limited applications as a fumigant pesticide. Historically, it was used as a fumigant for disinfection of products, soil, and crops stored in mills, warehouses, ships, and freight cars. In nature, it is found in the ocean in concentrations of 1–2 ng/l, formed possibly by algae or kelp. As of 2013, the amount of methyl bromide used in the United States allowed by critical use exemptions was 2.1% of 1991 levels (EPA, 2013a).

PHYSICAL AND CHEMICAL PROPERTIES

Methyl bromide (molecular weight = 94.94 g/mol) is a colorless gas (easily liquefied) with a burning taste and a sweet chloroform-like odor at high concentrations. It has a solubility in water by weight of 2% and a vapor pressure of 1.9 atm. Relative vapor density with reference to air is 3.36. It is a highly volatile compound with a vapor pressure of 1620 mm Hg at 25 °C. It is soluble in water, ethanol, ethers, ketones, and other halogenated hydrocarbon solvents.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Methyl bromide is unlikely to be found in the environment, as its production and use have been banned in the United States (with the exception of critical use exemptions) and other countries. It will exist in the atmosphere as a gas, where it is degraded over a half-life of 1.2 years. Methyl bromide is extremely mobile in soil, and will evaporate quickly from dry soil and surface waters. It is not expected to be absorbed to sediments and suspended particles, and is not expected to bioaccumulate in aquatic organisms (BCF = 3) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

The 2-h EC₅₀ for behavioral effects in *D. magna* is 1.7 mg/l. The 2-h LC₅₀ for *D. magna* is 2.2 mg/l. No mortality or behavioral effects were seen in Japanese medaka exposed to 320 µg/l for 91 h (EPA, 2013b).

Chronic Effects

No chronic ecotoxicological data for methyl bromide were identified.

MAMMALIAN TOXICOLOGY

Acute Effects

High exposure to methyl bromide via inhalation may result in neurological and respiratory effects, with skin lesions induced by dermal contact. Headaches, eye irritation, as well as persistent throat irritation and cough lasting up to 3 weeks (Rathus and Landy, 1961; Herzstein and Cullen, 1990). High exposures may result in ataxia, tremors, seizures, and death (Behrens and Dukes, 1986). Pulmonary edema and focal hemorrhagic lesions in the lung, progressing to hypoxia, cyanosis, and respiratory failure, have been reported (Greenberg, 1971; Marraccini et al., 1983; Behrens and Dukes, 1986). Oral exposure may result in irritation of the gastrointestinal tract, such as nausea and vomiting.

Skin contact has been reported to cause subepithelial blisters (Alexeef and Kilgore, 1983; Zwaveling et al., 1987). A diffuse infiltration of neutrophils was also reported (Yamamoto et al., 2000). No systemic effects were reported.

F-344 rats exposed to 150 ppm methyl bromide for 6 h/day had depleted GSH and GST levels in the brain (Davenport et al., 1992). Pretreatment with glutathione S-transferase (GST) inhibitor partially prevented the depletion of GSH and completely blocked the depletion of GST.

Chronic Effects

Fumigators chronically exposed to methyl bromide had a higher prevalence of muscle aches and fatigue tested lower than controls in 23 of 27 neurological tests than unexposed controls (Anger et al., 1986), indicating neurological effects. A worker is a vegetable house fumigated with methyl bromide presented with unstable gait, vertigo, and paresthesia of both feet (Suwanlaong and Phanthumchinda, 2008).

In several 1-year or lifetime animal bioassays, rats exhibited increased incidences of nonneoplastic nasal lesions (90 ppm), but did not indicate carcinogenicity (Mitsumori et al., 1990; Reuzel et al., 1991). Neurological effects were seen in mice inhaling 100 ppm over a lifetime, including tremors, hypoactivity, abnormal posture, and limb paralysis (NTP, 1990).

Rats orally treated with 10 mg/kg/day methyl bromide exhibited hyperplastic changes in forestomach epithelium, progressing to severe hyperplasia at 50 mg/kg/day (Danse et al., 1984). Dogs ingesting 178 mg/kg/day for 1 year displayed excessive salivation, lethargy, and periodic diarrhea (Rosenblum et al. 1960).

Chemical Pathology

Goergens et al. (1994) reported increased SCE rates in lymphocytes of fumigators exposed to methyl bromide. DNA adducts have been identified in rats exposed to methyl bromide via inhalation or gavage (Gansewendt et al., 1991).

Inhalation of 30 ppm methyl bromide in rats for 29 months led to mild hyperplasia of the nasal, esophageal, and heart (Reuzel et al., 1991).

Mode of Action(s)

Methyl chloride exerts its acute CNS effects via a solvent depression mode of action.

SOURCES OF EXPOSURE

Occupational

Due to ban on general production and uses, occupational exposures would be limited to pesticide applicators using methyl bromide.

Environmental

Due to ban on general production and uses, the general population is unlikely to be exposed to methyl bromide. Any exposure would likely arise from contact with limited waste stream releases from methyl bromide production.

INDUSTRIAL HYGIENE

The most common route of exposure to methyl bromide is inhalation. Workers who fumigate homes or fields may be exposed to high levels if proper safety precautions are not followed (Fuortes, 1992). Fumigation workers are at risk of accidental exposure even if they wear personal protection devices because methyl bromide may penetrate rubber, tape, and other materials. In soil and greenhouse fumigation, workers not involved in the fumigation may be overexposed when reentering the area if proper precautions are not taken (Van Den Oever et al., 1982; Herzstein and Cullen, 1990; Bishop, 1992; Hustinx et al., 1993). Overexposures typically result from lack of management controls, inadequate training of personnel or inadequate protective equipment. In response to this problem, the EPA allows only licensed professional fumigation workers to buy or use methyl bromide.

RISK ASSESSMENTS

EPA: RfC—0.005 mg/m³, RfD—0.014 mg/kg/day, not classifiable as to human carcinogenicity

ATSDR: Acute, intermediate, and chronic inhalation MRLs—0.05, 0.05, and 0.005 ppm, intermediate oral MRL—0.003 mg/kg/day

IARC: Group 3—not classifiable as to its carcinogenicity to humans

POLYCHLORINATED BIPHENYLS

First aid: *Inhalation:* Remove to fresh air. Check for bronchitis, pneumonitis, or severe respiratory tract irritation if cough or breathing difficulty develops or persists. *Oral:* Do not induce vomiting. The efficacy of charcoal slurry administration is unknown. Monitor patient for increased serum liver enzymes and development of chloracne. *Dermal:* Remove contaminated clothing and wash exposed skin multiple times with soap and water. *Eye:* Irrigate with water for 15 min.

Target organ(s): Skin, eyes, liver, reproductive system

Occupational exposure limits: OSHA PEL: 0.5 mg/m³ 8-h TWA with skin notation; NIOSH: 0.001 mg/m³ 10-h TWA.

Reference values (Arochlor 1254): EPA: RfD—20 ng/kg/day ATSDR: Intermediate and chronic oral MRLs—30 and 20 ng/kg/day

Risk/safety phrases: 33-50/53; (2)-35-60-61 Note C

BACKGROUND AND USES

Polychlorinated biphenyls (PCBs) are a class of chemicals produced in large scale in the United States from 1929 until their ban in 1979. There are 209 individual PCBs, or congeners. PCBs are mixtures of biphenyl congeners having varying degrees of chlorine substituents. The more common mixtures produced historically were Arochlor 1260, 1254,

1242, and 1016 (CASRNs 11096-82-5, 11097-69-1, 53469-21-9, and 12674-11-2), trade names of the Monsanto chemical products whose numerical nomenclature convention denoted the number of carbon atoms by the first two digits, and the percentage of chlorine (by mass) by the last two digits. Polychlorinated biphenyls were used historically in the manufacture of plasticizers, fire retardant fabric treatments, adhesives, paints, and electrical equipment. Since their ban in 1979, PCBs have been utilized for “enclosed uses,” such as insulating oil in electrical transformers and capacitors and in hydraulic fluids.

PHYSICAL AND CHEMICAL PROPERTIES

Polychlorinated biphenyls (molecular weight = 291.98–360.86 g/mol) vary in physical appearance from oily liquids to rigid noncrystalline resins, and are generally non-odorous. They are semi-volatile compounds. They are extremely insoluble in water, but soluble in organic solvents. Their low flammability and dielectric properties made them desirable for use in electrical equipment.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Polychlorinated biphenyls are highly persistent compounds, and may be found in the environment as a result of leakage from older electrical equipment, migration from older building materials into surrounding construction substrates, and as a result of historical spills or releases. Mono-, di-, and trichlorinated biphenyls biodegrade rapidly, tetrachlorinated species degrade more slowly, and higher chlorinated species are quite resistant to environmental degradation. They can exist in the atmosphere in the vapor or particulate phase, depending on the level of volatility. Vapor-phase PCBs are photolytically degraded over a half-life of 3.3–490 days. Polychlorinated biphenyls are not mobile in soil, but vapor-phase components will evaporate from dry soil and surface waters. They absorbed extensively to sediments and suspended particles, and are expected to bioaccumulate in aquatic organisms, especially fish ($\log \text{BCF} = 4.4\text{--}6.2$) (NLM, 2013).

ECOTOXICOLOGY

The ecotoxicological database for PCBs is extensive. Representative values for Arochlor 1254 are provided here.

Acute Effects

Decreased growth was reported in *X. laevis* frogs exposed to 1 mg/l, but not 100 µg/l, Arochlor 1254 for 3 days. *D. magna*

exposed for 14 days had an LC₅₀ of 24 µg/l. The 2-day LC₅₀ for striped bass was 0.5–1.0 mg/l (EPA, 2013).

Chronic Effects

Atlantic croaker exposed to 1.0 mg/l for 30 days displayed reduced organ weights and protein content, relative to body weight. Atlantic char exposed to 100 mg/l for 330 days exhibited significantly increased growth rate (EPA, 2013).

MAMMALIAN TOXICOLOGY

Acute Effects

Acute effects in humans have been reported for individual cases and large-scale incidents. High oral and dermal exposures may result in the development of acne (termed “chlor-acne”) and rashes (Rice and Cohen, 1996). A mass poisoning in Japan in 1968, known as Yusho incident, involved ingestion of PCB- and dibenzofuran-contaminated rice oil and resulted in over 14,000 people reporting skin and eye lesions (conjunctival pigmentation, swollen eyelids), reduced immune function, and changes in menstrual cycles (Chang et al., 1981; Rogan, 1989). Another mass poisoning in 1977 occurred in Taiwan, known as the Yu-Cheng incident, also involved ingestion of contaminated rice oil. Reported effects seen in this cohort include those of the Yusho incident, as well as an increased risk of goiter and increased urinary porphyrin excretion (Gladen et al., 1988; Guo et al., 1999).

Chronic Effects

Effects from long-term exposure of humans to PCBs include possible changes in neurological development, endocrine and immune function and cancer. Cohorts of children born to women who consumed PCB-containing fish from the Great Lakes, New York state, North Carolina, and Europe report an association between PCB body burdens and memory deficits, learning, and IQ scores (Fein et al., 1984; Lonky et al., 1996; Rogan et al., 1986; Koopman-Esseboom et al., 1994; Winneke et al., 1998; Govarts et al., 2012; Forns et al., 2012). Epidemiology studies in electrical capacitor manufacturing workers are suggestive of increased risk for liver, intestinal, and skin cancer (Brown and Jones, 1981; Gustavsson and Hogstedt, 1997; Bertazzi et al., 1987).

Studies in animals indicate that monkeys are more sensitive to PCB-induced immunological, dermatological, and neurological toxicity than other species. Liver damage was indicated by elevated hepatic serum enzymes, fatty liver, fibrosis, and necrosis in rats given ≥ 7 mg/kg/day (Bruckner et al., 1973) and in monkeys given 0.1–0.2 mg Aroclor 1254 or 1248/kg/day (Tryphonas et al., 1986). Vitamin A storage in the liver was also impaired in rats and rabbits (Bank et al., 1989). Rat fetuses exhibited significantly reduced plasma

thyroid hormone levels following maternal ingestion of 2.5 mg/kg/day (Collins and Capen, 1980). Changes in auditory threshold occurred in rats ingesting 10 mg/kg/day (Lilienthal et al., 2011; Gu et al., 2009). Rodent and monkeys exhibited reduced immune function as indicated by decreased antibody responses to SRBC, increased susceptibility to bacterial infections, decreased response to mitogens, altered lymphocyte T-cells, and histopathological changes in the thymus, spleen, and lymph nodes (Talcott et al., 1985; Allen and Barsotti, 1976; Tryphonas et al., 1986, 1991).

Reproductive effects reported in rodents and monkeys include impaired conception, reduced implantation, and increased incidences of resorptions and stillbirths (Steinberg et al., 2008). These effects occurred at doses as low as 0.02 mg/kg/day in nonhuman primates (Sager and Girard, 1994; Gellert and Wilson, 1979; Arnold et al., 1990). Decreased birth weight and reduced weight gain was reported in monkeys (Arnold et al., 1993).

Liver cancer occurred in rats ingesting ≥ 2.5 mg/kg/day Aroclor 1260 for 21 months (Kimbrough et al., 1975; NCI, 1978).

Chemical Pathology

Chloracne reported in occupational exposures presents as inflammatory folliculitis and keratin plug formation in the pilosebaceous orifices (Rice and Cohen, 1996).

Mode of Action(s)

Coplanar PCBs and mono-ortho-PCBs may mediate toxic responses via binding to aryl hydrocarbon receptor (AhR), a gene transcription factor that, if activated abnormally, may disrupt normal cellular control function. The ranking of PCBs using toxic equivalency factors (TEF) is based on their relative ability to activate AhR, with dioxin (ATSDR, 1998) assigned a factor of 1.0.

Di-ortho-substituted noncoplanar PCBs may interfere with calcium-dependent intracellular signal transduction, leading to neurotoxicity (Kodavanti and Tilson, 1997). Ortho-PCBs may disrupt thyroid hormone transport by binding to transthyretin (Cheek et al., 1999).

Some PCB congeners bind to the 17β -estradiol receptor, affecting the regulation of hormone expression and control (Jansen et al., 1993).

SOURCES OF EXPOSURE

Occupational

Occupational exposures to PCBs may occur in workers handling older PCB-containing devices, such as electrical capacitors and transformers, PCB-containing construction

materials, or soil/sediment/water at waste sites at which PCBs were disposed.

Environmental

The general population may be exposed to PCBs via contact with or proximity to the failure and leakage of PCB-containing devices, contact with PCB-containing construction materials, and dermal or oral ingestion of PCB-contaminated soil, sediment, or water.

INDUSTRIAL HYGIENE

When working with PCBs, protective clothing should include long-sleeved overalls, boots, overshoes, bib-type aprons, gloves, and safety glasses with side shields. Respirators should be used in the proximity of PCB vapors and when installing, removing, or repairing PCB-containing devices or containers.

RISK ASSESSMENTS

(Arochlor 1254):

EPA: RfD—20 ng/kg/day

ATSDR: Intermediate and chronic oral MRLs—30 and 20 ng/kg/day

PERFLUOROOCTANOIC ACID

First aid: *Inhalation:* Remove to fresh air. Check for bronchitis, pneumonitis, or severe respiratory tract irritation if cough or breathing difficulty develops or persists. *Dermal:* Remove contaminated clothing and wash exposed skin with soap and water. *Eye:* Irrigate with water for 15 min

Target organ(s): Liver, pancreas, testis, endocrine system (in animals)

Occupational exposure limits: None

Reference values: EPA: Provisional Health Advisory—
0.4 µg/l drinking water

Risk/safety phrases: None

BACKGROUND AND USES

Perfluorooctanoic acid (PFOA) (CASRN 335-67-1) is fluorinated surfactant used, primarily as its ammonium salt (APFO), as an aid in the chemical synthesis of fluoropolymers and fluoroelastomers. As such, it may be found in nonstick cookware and utensils, stain-repellent fabric treatments, and water-proofing treatments for garments. Although an effort is underway by the U.S. EPA to reduce use of and replace perfluoroalkyls with other substances, PFOA is still used in United States industry.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluorooctanoic acid (molecular weight = 414.09 g/mol) is a white to off-white powder. It is very soluble in water.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Perfluorooctanoic acid found in the environment may result from waste stream releases from manufacture of cosmetics, lubricants, paints, polishes, adhesives, fabric treatments, and fire-fighting compounds. It can partition to the vapor phase in the atmosphere, where it is degraded atmospherically with a

half-life of 31 days. It is very resistant to hydrolysis, and immobile in soil. It will not likely evaporate from soil (depending on soil pH) or surface waters. It is not expected to be absorbed to sediments and suspended particles. Perfluorooctanoic acid is not expected to bioaccumulate in aquatic organisms (BCF = 3.1–9.4) (NLM, 2013).

ECOTOXICOLOGY

Acute Effects

The 2-h EC₅₀ for decreasing mobility of *D. magna* was 477 mg/l. The 4-day LC₅₀ for zebrafish was >500 mg/l (EPA, 2013a).

Chronic Effects

An 80–90% decrease in survival of *D. magna* was seen following a 21-day exposure to 12.5–50 mg/l. Decreased survival was seen in Japanese medaka exposed to 0.1 mg/l for 28 days (EPA, 2013a).

MAMMALIAN TOXICOLOGY

Acute Effects

No acute adverse effects have been reported in humans as a result of PFOA exposure.

Hepatocytic necrosis was exhibited in rats inhaling 8 mg/m³ PFOA for 2 weeks (Kennedy et al., 1986). No teratogenic effects were reported in pups born to rats inhaling up to 25 mg/m³ (Staples et al., 1984).

Liver effects have been reported in rats administered oral PFOA doses. Rats given 50 mg/kg/day for 21 days exhibited enlarged livers and hepatocyte necrosis (Son et al., 2008).

Rats ingesting ≥30 mg/kg/day for 2 weeks exhibited reduced serum testosterone and increased estradiol levels. The same oral exposures for 2 years resulted in Leydig cell adenomas (Biegel et al., 2001). Pups born to mice given 1–20 mg/kg/day experienced reduced litter weights, live births, and postnatal survival, with delayed ossification of several bones. Male mice born to treated dams matured more quickly than females or control males (Lau et al., 2006; Wolf et al., 2007; Yahia et al., 2010; Macon et al., 2011). Female mice exposed via lactation to PFOA from dams given 5 mg/kg/day had delayed mammary gland development (White et al., 2009).

Immunological effects were reported in mice given ≥50 ppm PFOA in drinking water for 21 days, including changes in T-lymphocyte phenotypes and cytokine expression (Son et al., 2009).

The rat oral LD₅₀ was 540 mg/kg (Griffith and Long, 1980); the inhalation LC₅₀ was 980 mg/m³ (Kennedy et al., 1986).

Dermal doses of 0.5 g in rabbits for 24 h resulted in mild irritation, while doses of 2000 mg/kg for 10 days in rats resulted in contact site dermal necrosis as well as hepatic necrosis (Kennedy, 1985).

Chronic Effects

Epidemiological data in occupational and geographic population cohorts have reported associations of PFOA levels in the blood with inconsistent changes in lipid endpoints and renal disease, but convincing evidence of disease or mortality causation has not been shown (Gilliland and Mandel, 1993; Leonard, 2006; Steenland et al., 2010; Steenland and Woskie, 2012; Savitz et al., 2012; Okada et al., 2012).

Multigenerational oral exposures of 5 mg/kg/day in mice resulted in delayed mammary gland development across three generations (White et al., 2011).

Rats administered 0.64 mg/kg/day for 13 weeks had increased liver weight and reversible hepatocyte hypertrophy (Perkins et al., 2004). Cancers of the liver, pancreas, and testis have been reported in rats ingesting APFO in the diet (Biegel et al., 2001; Butenhoff et al., 2012).

Chemical Pathology

Hepatocytic cytomegaly and liquefaction necrosis was seen in rats orally administered ≥ 50 mg/kg/day for 21 days (Son et al., 2008). Splenic hypertrophy of white, but not red, pulp was reported in mice administered 250 ppm PFOA in drinking water for 21 days (Son et al., 2009).

Mode of Action(s)

The mode of action for liver toxicity and liver, pancreas, and testis cancer in rodents appears to be mediated via PPAR- α expression resulting in changes in lipid metabolism (Klaunig et al., 2012).

Lipid and glucose homeostatic regulation in fetal mice appear to be perturbed by PFOA via a PPAR- α expression (Abbott et al., 2012). However, mammary gland development in mice by PFOA is mediated by increased steroid hormone production in ovaries and increased levels of mammary gland growth factors, independent of PPAR- α expression (Zhao et al., 2010).

SOURCES OF EXPOSURE

Occupational

Occupational exposure to PFOA may occur via inhalation and dermal contact at manufacturing facilities where it is produced or used.

Environmental

Blood monitoring data indicate that the general population has been exposed to PFOA, and may be further exposed due to inhalation of ambient air, dietary and drinking water ingestion, and dermal contact with consumer products that contain PFOA.

INDUSTRIAL HYGIENE

A full-face particle respirator (type N100 or type P3) should be used as a backup to engineering controls. Gloves, a face shield, and safety glasses or goggles should be donned when working with PFOA.

RISK ASSESSMENTS

A risk assessment of PFOA performed by ATSDR (2009) did not provide derivations of toxicity/risk values for PFOA. The EPA is currently performing a risk assessment of PFOA (EPA, 2013b). A risk assessment has been published in the peer-reviewed literature, including a serum PFOA-based margin of exposure (MOE) analysis, identifying an MOE of 1600 for liver weight increases and 8900 for Leydig cell adenomas (Butenhoff et al., 2004).

AROMATIC HYDROCARBONS

RAYMOND D. HARBISON, AMORA MAYO-PEREZ, DAVID R. JOHNSON, AND MARIE M. BOURGEOIS

BENZENE

Target Organ(s): Eyes, skin, respiratory system, blood, CNS, bone marrow.

Occupational exposure limits: NIOSH REL: Ca; TWA: 0.1 ppm; ST: 1 ppm. OSHA PEL: TWA: 1.0 ppm; ST: 5 ppm.

Risk/safety phrases: Leukemia.

First aid: Eye: Immediate irrigation; skin: soap wash immediately; breath: respiratory support; swallow: seek medical attention immediately.

Conversion: 1 ppm = 3.19 mg/m³.

BACKGROUND AND USES

Benzene is an industrial solvent, which can also be found in cigarette smoke, petroleum, and as a consequence of biomass combustion. Exposure at high levels is generally from occupational sources such as shoe production and petrochemical factories. Airborne benzene is the most common route of exposure. Even at low doses of airborne benzene (<1 parts per million (ppm)), urban populations—especially those working around car exhaust fumes such as taxi drivers, bus drivers, traffic policemen, and gasoline station attendants—show higher levels of benzene metabolites in the urine such as S-phenylmercapturic acid (SPMA) and *trans, trans*-muconic acid (ttMA) (Arnold et al., 2013; Fustinoni et al., 2010; Rappaport et al., 2013). Although inhalation exposure is the most common, dermal exposure is also prevalent. As a result of inhalation exposure, lungs are the major site of benzene metabolism (Arnold et al., 2013).

PHYSICAL AND CHEMICAL PROPERTIES

Benzene (benzol, phenyl hydride, CASRN 71-43-2) is a colorless to light-yellow liquid with a sweet, aromatic odor. Its solubility in water is 0.07% and it has a vapor pressure of 75 mmHg. It is highly flammable and soluble in water at 1.8 g/l. It has a specific gravity of 0.8787 at 15 °C and a vapor pressure of 95.2 mmHg. It has a flashpoint of –11 °C, with a melting point and boiling point of 5.5 °C and 80.1 °C, respectively (IPCS, 2004).

In the environment, benzene partitions to air and photodegrades in approximately 1 week. It has been known to persist for 10–20 days in soil and groundwater under aerobic conditions. Under anaerobic conditions, it may persist for many years. It can be metabolized by the avocado fruit or grapes to carbon dioxide. It is also found to occur naturally in some foods. It can undergo rapid volatilization near the soil surface and in water. Biodegradation occurs in aerobic water conditions but not under anaerobic. It will not be expected to significantly adsorb to the sediment, bioconcentrate in aquatic organisms, or hydrolyze. Varying experiments show that the half-life of benzene is from 1 week to 17 days due to photodegradation. Atmospheric benzene exists predominantly in the vapor phase. Gas phase benzene will not be subject to direct photolysis, but it will react with photochemically produced hydroxyl radicals with a half-life of 13.4 days calculated using an experimental rate constant for the reaction. The reaction time in polluted atmospheres that contain nitrogen oxides or sulfur dioxide is accelerated with the half-life being reported as 4–6 h. Products of photo-oxidation include phenol, nitrophenols, nitrobenzene, formic acid, and peroxyacetyl nitrate. Benzene is fairly soluble in

water and gets removed from the atmosphere during rains. The primary routes of exposure are inhalation of contaminated air, especially in areas with high traffic, and in the vicinity of gasoline service stations and consumption of contaminated drinking water (USEPA, 2009).

MAMMALIAN TOXICOLOGY

Acute Effects

At high concentrations, benzene has a narcotic effect on the central nervous system (CNS). Inhalation of 7500 ppm for 30 min to 1 h may cause loss of consciousness and death from respiratory failure. Levels of 3000 ppm may cause euphoria and excitation followed by fatigue, dizziness, and nausea. Acute effects include light-headedness, headache, excitement, unsteady gait, euphoria, confusion, nausea, vertigo, and drowsiness. If exposure continues, respiratory paralysis and death, sometimes with convulsions, may occur. Inhalation is the most common route of exposure, but dermal exposure can cause edema, burning, and blistering.

In one incident, 15 shipyard workers were exposed to concentrations of benzene over 653 ppm. These workers reported mucous membrane irritation, peculiar taste, dyspnea, dizziness or light-headedness, nausea, headache, cough, drowsiness, fatigue, and skin irritation. One year later, 40% had abnormally high levels of large granular lymphocytes in their hematological profiles (Midzenski et al., 1992).

Chronic Effects

The chronic effects of benzene exposure depend on the level of exposure, and the symptoms are typically vague. Enlarged liver and spleen, loss of appetite, diarrhea, pallor, pain in bones, fever, and hemorrhage have all been reported. Chronic benzene intoxication creates a disturbance in the hematopoietic system, which may affect every cell line (Nwosu et al., 2004). Chronic exposure to benzene has a depressive effect on the bone marrow (Galbraith et al., 2010; Schnatter et al., 2005). Some studies attribute increased risk of acute myelogenous leukemia (AML), aplastic anemia, and myelodysplasia to benzene exposure (Aksoy et al., 1976, 1985; Crump, 1994; Galbraith et al., 2010; Infante et al., 1977; Infante, 2006; Rinsky, 1989; Rinsky et al., 1981, 2002). Some have concluded that benzene increases the incidence of all leukemias. However, the association between benzene exposure and chronic myelogenous leukemia and multiple myeloma is not strong. Additionally, there is a long estimated latency period between benzene exposure and the development of a malignancy (Finkelstein, 2000; Galbraith et al., 2010; Huff et al., 1989; Schnatter et al., 2012; Sharpe, 1993). Benzene-induced leukemia has been associated with a latency period up to 20 years, with the strongest correlation within the first

10 years (Finkelstein, 2000). A cohort of rubber hydrochloride (Pliofilm) workers exposed to benzene without concomitant exposure to other possible carcinogens has served as the basis for estimations of the potency of benzene to produce cancer (particularly AML) in humans. Among the 1868 members of the cohort with benzene exposures beginning in the 1930s and ending in 1965, there have been 481 total deaths as of December 31, 1987, of which 72 were caused by cancer. Among the cancer deaths, 14 were caused by leukemia. For the leukemia deaths, benzene exposure began during or before 1950 and, exposures were considerably higher than after 1950. This information led Paxton et al. (1994) to conclude:

The newly gathered information continues to be consistent with a threshold model for leukemogenesis by benzene. The leukemia deaths in the entire cohort occurred exclusively among individuals who commenced their work in Pliofilm production in 1950 or earlier. This suggests that the initial occupational environments at the plants in both Akron and St. Mary may have differed from those to which workers starting their Pliofilm employment later may have been exposed.

This conclusion was based on an analysis of standardized mortality ratios (SMRs). Paxton et al. (1994) analyzed SMR data by cumulative benzene exposure (represented as ppm-years benzene exposure). Among the three exposure characterizations that have been developed for the Pliofilm cohort, SMRs increase as the dose increases. However, there was a distinct relationship between cumulative dose and SMR that Paxton et al. (1994) described:

Note, however, that for none of the three sets of exposure estimates is there a statistically significant increase in the SMRs for cumulative exposures less than 50 ppm-years. This is consistent with the hypothesis that exposure in excess of some threshold value, here suggested to be greater than 50 ppm-years, is necessary for leukemogenesis.

Schnatter et al. (1996) have also concluded that the risk of leukemogenesis is shown only above a critical concentration of benzene exposure of 50–60 ppm using a median exposure estimate. In 2012, Schnatter and his colleagues continued the work on benzene exposure.

The Pliofilm cohort has been reevaluated periodically. Rinsky et al. (2002) reported that the relative risk of leukemia from chronic exposure diminished over time. Since 6 of the 15 workers' deaths due to leukemia were >30 years after exposure, the likelihood of the occupational exposure playing a role in the disease is low. This is due to the latency period estimated for benzene that is much less than 30 years (Galbraith et al., 2010). This was further supported by the mortality studies of California petrochemical workers and French utility workers who showed no significant increase in mortality among these workers from leukemia (Satin et al., 2002). Although Guenel et al. (2002)

found an increased risk of leukemia among workers whose first exposure was before 1964, it was not significant.

Further studies of benzene occupational exposures conclude that leukemia incidence is not statistically different from the general population as seen in the studies performed by Wong (2002), Lewis et al. (2003), and Gun et al. (2006). These studies found that total leukemia incidence and total leukemia mortality are not significantly elevated; additionally two factors such as the duration of employment and magnitude of exposure do not seem to be related to leukemia incidence (Richardson, 2008). Glass et al. (2006) did find that there was a significant increase in the risk of acute nonlymphatic leukemia in workers with exposures >8 ppm-years. Lin et al. (2007) also performed a cohort mortality study that included more than 10,621 employees from 1948 to 2003 and found that there was no significant increase in leukemia or leukemia subtype among these workers.

Hematotoxicity Inhalation exposure targets the hematopoietic system, which can lead to the depression of multiple lineage blood cells known as pancytopenia. Most studies test the effects of higher exposure to the hematopoietic system with outcomes on complete blood counts (CBC) of the participants. Three major blood components are usually monitored, namely, erythrocytes, leukocytes, and platelets; however, the lymphocytes, red blood cells, and hemocrit are also monitored. Rothman et al. (1995) found a decrease in the lymphocytes at a median concentration of 31 ppm with an 8-h time-weighted average (TWA) and those workers exposed to 8 ppm concentration at an 8-h TWA.

The hematologic parameters of this study (total white blood cells [WBC], absolute lymphocyte count, platelets, red blood cells, and hematocrit) were decreased among workers exposed to 31 ppm concentration of benzene compared to the controls. However, workers exposed to lower levels (i.e., 8 ppm) had a higher red blood cell mean corpuscular volume (MCV) than the controls.

Physiologically based pharmacokinetic (PBPK) modeling can be used to determine key toxicological end points. There are some limitations as this model does not accurately determine the fate of benzene metabolites nor repeated exposures; this model also cannot predict urinary benzene—it is best with blood benzene concentrations. Although in several species this model can simulate acute inhaled benzene (Arnold et al., 2013). High exposures to benzene over many years consistently show an increased risk of AML; however, a consistent causal relationship has not been established (Galbraith et al., 2010). Benzene is observed to have as a dose-dependent effect on biological processes (McHale et al., 2010, 2012).

Genotoxicity One hundred and twenty-five workers exposed to various levels (24.7, 7.2, 0.8, and 0.3 ppm) of benzene were monitored to determine the gene expression profiles of these individuals over the controls. In the

study by McHale et al. (2010), various genes were altered compared to controls. These genes represented impacts to the cellular pathways such as T-cell receptor signaling, oxidative phosphorylation, AML, apoptosis, B-cell receptor signaling pathway, and Toll-like receptor signaling. Not surprisingly, genes in the AML pathway are strongly associated with multiple exposure levels of benzene (Glatt et al., 1989; Nwosu et al., 2004). Additionally, benzene has been shown to have adverse effects on oxidative stress and mitochondria (McHale et al., 2010; Whysner et al., 2004).

Mechanisms of Action

Typically *in vivo* experiments are used to elucidate the possible mechanisms of toxicity of various compounds in humans. Unfortunately, no animal model closely approximates benzene's toxicity in humans. Tremendous differences exist in benzene toxicity and metabolism between experimental animals. Mice have a much higher rate of benzene metabolism and higher levels of biomarkers for metabolic pathways leading to toxic metabolites than rats (Schlosser et al., 1993). Benzene was pancarcinogenic to mice exposed orally and by inhalation in one study (Huff et al., 1989). Benzene in drinking water has also been studied in transgenic mice, and it suppressed the proliferation of progenitor cells due to altered gene expression (Galbraith et al., 2010; Paustenbach et al., 1993). However, cancers developed by mice in long-term studies did not remotely resemble cancers that benzene is suspected of causing in humans (Smith et al., 2007; Snyder, 2007; Henderson et al., 1991). There are also significant differences in pharmacokinetics between various animal species and humans (Nakajima et al., 1993). For instance, Sato and Nakajima (1979) found that combined exposures to toluene and benzene slowed the rate of metabolism of each in rats. Similar experiments with humans exposed to levels close to the threshold limit value (TLV) found no such antagonistic relationship. Differences in benzene metabolism between male and female rats may be attributed to differences in cytochrome P450 2E1 (CYP2E1) activity (Kenyon et al., 1996; Tamie et al., 1993). One commonality between experimental animals studied and humans is that benzene pathways are saturated at a low exposure level and yield high affinity toxic metabolites (Henderson et al., 1991).

A brief overview of benzene metabolism as described by Snyder and Hedli (1996) illustrates the biotransformation of benzene by the liver enzyme CYP2E1 that adds an oxygen to yield benzene oxide, which spontaneously rearranges to benzene oxepin and finally to phenol (Steinmaus et al., 2008; Weed, 2010). Benzene oxide may be transformed to a metabolite found in urine as a biomarker, tTMA (Snyder et al., 1993; Snyder, 2012). The candidate mechanisms for benzene hematotoxicity include the generation of reactive oxygen species, direct chromosomal damage, inhibition of

topoisomerase II, immune dysfunction, DNA methylation, and the accumulation of toxic metabolites in the liver (Galbraith et al., 2010; McHale et al., 2010; Steinmaus et al., 2008). Numerous *in vitro* studies have investigated the effect of benzene and its metabolites on human cells. HL60 cells, a leukemia cell line, have attracted special attention. Zhang et al. (1993) demonstrated that HL60 cells exposed to the benzene metabolite 1,2,4-benzenetriol *in vitro* had micronuclei and oxidative damage that was potentiated by copper ions. Kolachana et al. (1993) found that the HL60 cells showed a higher level of oxidative deoxyribonucleic acid (DNA) damage when exposed to phenol, hydroquinone, and 1,2,4-benzenetriol. Increased oxidative damage was also observed in mice *in vivo*.

Tough and Brown (1965) reported that benzene may have been responsible for chromosomal aberrations found among factory workers. They found chromosomal aberrations in peripheral lymphocytes similar to those produced by radiotherapy, although there was no evidence of exposure to radiation. Yardley-Jones et al. (1990) also found increased chromosomal aberrations in benzene workers. Benzene has also been shown to induce sister chromatid exchanges and chromosomal aberrations in bone marrow cells of mice (Tice et al., 1980). Rothman et al. (1995) report that benzene produces gene-duplicating mutations but not gene-inactivating mutations at the glycophorin A locus in humans exposed to high benzene levels. This evidence supports the theory that chromosomal damage and mitotic recombination are important in the etiology of benzene-induced leukemia.

Seaton et al. (1994) investigated the effect of low level benzene exposures on human liver microsome metabolism. They demonstrated that there is a great variation between individuals in levels of CYP2E1 and that this affects the metabolites produced by the benzene metabolism. Phenol was usually the predominant metabolite, but hydroquinone was the primary metabolite in some individuals. Metabolism by experimental animal liver microsomes fell within the range of human liver microsome metabolism in this study. The differences between various species and strains may be partially explained by the differences in distribution of cytochrome P-450 isozymes (Nakajima et al., 1993). Mutagenicity assays demonstrated that only the *trans*-1,2 dihydrodiol metabolite of benzene exhibited mutagenic activity (Glatt et al., 1989). This activity was not dependent on the activation by the S9 liver fraction. Several other assays indicate that benzene has a mutagenic potential (Vainio et al., 1985). Benzene can induce aneuploidy and chromosomal aberrations in mice (Nakajima et al., 1993; Schlosser et al., 1993).

Although benzene is thought to require bioactivation to cause toxicity, none of its metabolites alone create a similar toxic effect (Medinsky et al., 1994). Combinations of these metabolites are needed to duplicate benzene toxicity. Benzene was not found to be directly embryotoxic to rat fetuses (Chapman et al., 1994).

However, phenol, a primary benzene metabolite, was found to be embryotoxic (Chapman et al., 1994).

Benzene is not only metabolized in the liver but also in the lungs during the common route of exposure, inhalation. Cytochrome P450 2E1 is an important enzyme that metabolizes benzene. Although other enzymes such as CYP2F1 are also involved in metabolism, CYP2E1 has the highest activity toward benzene (McHale et al., 2012; Sheets et al., 2004). Benzene is oxidized by CYP2E1 to an intermediate molecule, benzene oxide. A series of reactions occurs with intermediate metabolites such as phenol, hydroquinone, catechol, trihydroxybenzene, and *o*-benzoquinones (BQs) (Arnold et al., 2013; McHale et al., 2012). The elimination of benzene and its metabolites varies depending on the route of exposure. However, all metabolites are excreted in the urine no matter the route of exposure. Inhaled benzene has now been proposed to be metabolized in the lung by CYP2F1 and CYP2A13 at low doses (Klaunig, 2010; McHale et al., 2012).

McHale et al. (2012) has proposed a mode of action (MOA) approach to determine the risk assessment. Although it has its limitations, there are five key events associated with benzene toxicity: (a) metabolism of benzene to a benzene oxide metabolite; (b) interaction of benzene metabolites with target cells; (c) formation of mutated target cells; (d) selected clonal proliferation of target cells; and (e) formation of the neoplasm (Lamm et al., 2009, 2005).

Chemical Pathology

Benzene carcinogenicity is thought to be due to 1,4-benzoquinone (BQ), a metabolite of benzene (McHale et al., 2012). NAD(P)H:quinone oxidoreductase 1 (NQO1) has been shown to protect mice against benzene-induced myelodysplasia and can thus prevent benzene hematotoxicity (McHale et al., 2012).

SOURCES OF EXPOSURE

Occupational

Occupational exposures have been examined extensively in case-control cohort studies around the world. Since 1950, workplace benzene concentrations have been reduced significantly in the United States and other Western societies (Galbraith et al., 2010). As a result, the workers exposed to benzene and benzene-related illnesses have consistently been reduced. However, in developing countries where occupational and environmental controls are more lax, health-related illness due to benzene remains a measurable risk (Galbraith et al., 2010; Ruchirawat et al., 2010). Low level exposures have been evaluated as well, which also result in a lower incidence of adverse effects (Galbraith et al., 2010; Raabe and Wong, 1996; Williams et al., 2011).

Environmental

There is mounting evidence that most people are exposed to a sufficiently small dose each day, which will not increase the risk of disease (Johnson et al., 2009; Galbraith et al., 2010). Kim et al. (2006) has shown that benzene metabolism is different in those exposed to low doses versus workers consistently exposed to higher concentrations. Peak exposure periods are considered between 15 and 30 min per day (Djurhuus et al., 2012). These exposures generally are as low as 10 ppm. However, these peak exposures are not appreciably different from 8 ppm-h (Irons, 2000; Knutsen et al., 2013; Rappaport et al., 2009). Environmental exposure from non-occupational sources are typically below 50 µg/m³; most of these daily exposures are from car exhaust and first- and secondhand smoke (Capleton and Levy, 2005; Liu et al., 2009).

INDUSTRIAL HYGIENE

In the late 1800s and early 1900s, acute exposures to benzene in the United States and Europe were not unusual (Sharp, 1993). Exposures were commonplace in leather making, shoemaking, and rubber manufacture. Workers exposed to benzene inside factories are generally at greater risk than petrochemical workers who typically work outside with better ventilation. Those temporarily exposed to benzene in confined spaces, such as those who degas an oil tanker, are at especially a high risk (Midzenski et al., 1992).

The American Conference of Governmental Industrial Hygienists (ACGIH) (ACGIH, 2009) intends to adopt a benzene-skin TLV of 0.5 ppm (1.6 mg/m³). The ACGIH also plans to change the carcinogen rank of benzene from A2 to A1 (suspected to confirmed human carcinogen). The National Institute for Occupational Safety and Health (NIOSH) classifies benzene as a human carcinogen. The recommended exposure limit (REL) is 0.1 ppm, with a short-term exposure limit (STEL) of 1 ppm for 15 min (1 ppm = 3.19 mg/m³). The Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) is 1 ppm with a STEL of 5 ppm. The notable exception is for some employees of the petrochemical industry for which the standards are a PEL of 10 ppm with a ceiling of 25 ppm and a 50 ppm STEL for a maximum of 10 min (ICS, 1993). A benzene level of 500 ppm is considered Immediately Dangerous to Life and Health (IDLH) (ATSDR, 2008; NIOSH, 2007).

Biomonitoring The current OSHA standards have reduced benzene exposure to industrial employees. For routine biomonitoring, the ACGIH recommends measurement of end of shift total urinary phenols or benzene in exhaled air. Urinary ttMA is a major metabolite of benzene, and thus is used as a biomarker (Tunsaringkarn et al., 2013). Blood concentrations of hemoglobin, hemocrit, and eosinophils are all decreased as ttMA urine

levels increase (Tunsaringkarn et al., 2013). A level of 20 mg phenol/g creatinine in urine can be expected in a worker consistently exposed to the TLV (ACGIH, 2009). The biological exposure index (BEI) for benzene in exhaled air (measured before next shift) of workers exposed to the TLV should be as follows: mid-exhaled = 0.08 ppm, end exhaled = 0.12 ppm (ACGIH, 2009). A previous controlled experiment indicates that this BEI may not accurately predict the TLV exposure and therefore may not protect the workers (Thomas et al., 1996).

Although biomonitoring through urine and exhaled air may be the most common methods, they are not the most accurate, especially for low levels of exposure. Biomonitoring of urinary phenol may be confounded by some over-the-counter drugs such as Pepto-Bismol® and Chloraseptic® lozenges. These products contain zinc phenyl sulfonate and sodium phenolate, respectively, both of which have been shown to increase urinary phenol levels and interfere with biomonitoring (Fishbeck et al., 1975). Dietary factors may also have a significant impact on urinary phenol (Fishbeck et al., 1975; Ling and Hänninen, 1992). Another factor confounding the biomonitoring of benzene is an exposure to complex mixtures of chemicals, especially other solvents (Fustinoni et al., 2010; Ong and Lee, 1994). Studies have shown that an exposure to toluene and xylene significantly complicate the estimation of benzene exposure (Ikeda, 1995).

High performance liquid chromatography (HPLC) determination of ttMA has been shown to be a more accurate indicator of benzene exposure at low concentrations than current standard methods. Direct measurement of benzene in the urine and blood also closely reflects low levels of exposure (Ong and Lee, 1994).

Risk assessment for benzene is complex because of the mechanism of its toxicity (Yardley-Jones et al., 1991). This is complicated further by the low incidence of leukemias, which are suspected to result from chronic benzene exposure (Glass et al., 2004; Glass et al. 2005). As mentioned, animal studies are of limited usefulness when trying to elucidate the actual toxicity of benzene in humans.

The lack of a satisfactory animal model and the availability of industrial exposure data have provoked an unprecedented number of risk assessments based on the epidemiological data. The scope of epidemiological studies and risk assessments is too extensive to be discussed here in their entirety. There have been several epidemiological studies of benzene and leukemia risk, although the epidemiological relationship between benzene and leukemia is tenuous (Aksoy et al., 1985; Infante et al., 1977; Ott et al., 1978; Rinsky et al., 1981; Wong, 1987; Alexander and Wagner, 2010; Galbraith et al., 2010; National Cancer Institute, 2005). The scientific consensus is that Rinsky's data from the Ohio Pliofilm cohort are the most reliable, even though they have some shortcomings. The data from Rinsky et al. (1987) have been reanalyzed for risk assessment many times by the authors and others (Austin et al.,

1988; Crump, 1994; Utterback and Rinsky, 1995). Some claim that the Rinsky data seriously underestimate the levels of exposure at the Pliofilm plants studied, thereby overestimating the risk from low level exposure. Dermal exposures were not taken into account for the Rinsky data; however, many of these claims of higher exposure are based on observations by Pliofilm employees that are of questionable scientific relevance. Depending on the assumptions of the model, the estimated risk from benzene exposure may increase or decrease by an order of magnitude (Bird et al., 2010; Brett et al., 1989; Kane and Newton, 2010; Khalade et al., 2010).

A cohort study from China appears to add new data that may reduce the limitations of the Pliofilm cohort studies (Yin et al., 1994). Perhaps this study may serve as a basis for more risk assessments with greater certainty on the effects of benzene exposure. The problem of risk assessment for benzene will almost certainly continue to provoke numerous epidemiological studies and risk analysis.

MEDICAL MANAGEMENT

A biomarker for benzene is urinary benzene for low exposure testing. The test for urinary benzene has been shown to be relevant at exposures as low as 10 µg/m³ (Fustinoni et al., 2012; Lovreglio et al., 2010). Diagnosis of chronic benzene poisoning should include blood cell analysis because of the vague nature of the associated symptomatology. Benzene can adversely alter the hematopoietic system producing aplastic anemia, leukopenia, and thrombocytopenia (Khan, 2007).

Treatment of benzene exposure is primarily symptomatic. If benzene is inhaled, patients should be given oxygen and evaluated for cough, respiratory irritation, bronchitis, and pneumonia. Blood transfusions and corticosteroids may also be given in cases of severe anemia.

In cases of ingestion, induced vomiting is not advised. Gastric lavage may be performed shortly after ingestion.

PHENOL

Target organ(s): Eyes, skin, respiratory system, liver, kidneys.

Occupational exposure limits: NIOSH REL: TWA 5 ppm (19 mg/m³); C 15.6 ppm (60 mg/m³); OSHA PEL: TWA 5 ppm (19 mg/m³).

Risk/safety phrases: None.

First aid: Eye: Immediate irrigation; skin: wash with soap immediately; breath: respiratory support; swallow: seek medical attention immediately.

Conversion: 1 ppm = 3.85 mg/m³.

BACKGROUND AND USES

Phenol (carbolic acid, hydroxybenzene, monohydroxy benzene, phenyl alcohol, phenyl hydroxide, CASRN 108-95-2) is a colorless to light pink crystalline solid with a sweet, acrid odor with a sharp burning taste (IPCS, 1999). It has a vapor pressure of 0.4 mmHg and a solubility in water by weight of 9% (25 °C [77°F]). Commonly used for the treatment of wounds in the 1800s, phenol is thought to have poisoned many patients and physicians (Merliss, 1972). Currently, phenol is found in dilute forms in some pharmaceuticals for external use and in throat lozenges. Some common products containing phenol are calamine lotion (1–2%), and Campho-Phenique (4.75% phenol, 10.86% camphor in aromatized liquid petroleum) (ATSDR, 2008).

PHYSICAL AND CHEMICAL PROPERTIES

Phenol has limited solubility in water at room temperature; however, it is completely soluble above 68 °C (IPCS, 1999). The melting point is 43 °C, while the boiling point is 181.75 °C (IPCS, 1999). The flashpoint is 80 °C. It is an A4, Group D carcinogen—it is not classifiable as a human carcinogen (HSDB, 2010). Benzene oxide undergoes a nonenzymatic rearrangement to phenol. Phenol is produced by hydrolysis to a dihydrodiol ring opening to tMA. Additional oxidation can be catalyzed by enzyme CYP2E1 to hydroquinone and catechol.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute effects of phenol intoxication include lethargy, nausea, vomiting, metabolic acidosis, diarrhea, cardiac arrhythmia and bradycardia, hypotension, tachypnea, respiratory arrest, convulsive seizures, and coma (Haddad et al., 1979). Dermal exposure to concentrated phenol may cause burns because of its defatting and caustic properties (Anderson, 2006; Philip and Marraffa, 2012). The half-life of conjugated phenol has been reported to be as low as 1 h and as high as 5 h (IPCS, 1999).

Chronic Effects

In many situations, it is often unclear whether formaldehyde is the primary causative agent of phenol marasmus or carbol marasmus can be an effect of chronic phenol exposure. This type of exposure has become rare, since the use of higher concentrations of phenol for medical purposes was discontinued in the late 1800s (Merliss, 1972).

Mechanisms of Action

Phenol is one of the major metabolites of benzene. It is also formed by the degradation of other organic wastes (Miller, 1942). It can be endogenously produced during the breakdown of certain protein metabolites, resulting in normal concentrations of phenol in urine to be <20 mg/l (Rogers et al., 2013; Wetherill et al., 2007).

In mice, more than 65% of phenol administered orally or intravenously was recovered in 48 h (Kenyon et al., 1995). Formation of various phenol metabolites was dependent on the dose and route of administration. The gastrointestinal tract is active in phenol metabolism. Renal damage is caused by unconjugated phenol, which damages the glomeruli and tubules as well as produces hypovolemic shock leading to renal ischemia (Becerro de Bengoa Vallejo et al., 2012; Kenyon et al., 1995; Powell et al., 1974; Stasiuk and Kozubek, 2010; Zambito Marsala, 2010).

Phenol has been shown to be embryotoxic in rats when administered with a bioactivating system (Chapman et al., 1994). Some phenol metabolites, (hydroquinone, catechol, and benzoquinone) have been demonstrated to be directly embryotoxic.

Chemical Pathology

Lethal doses can range from 1 to 15 g in adults (IPCS, 1999). Phenol can have a depressant effect on the central nervous system (Haddad et al., 1979). Some reactive metabolites of phenol can activate leukocytes as shown in some *in vitro* studies (IPCS, 1994). No-observed-adverse-effect level (NOAEL) values in two multiple dose rat studies were 40 and 60 mg/kg/day (IPCS, 1994).

SOURCES OF EXPOSURE

Occupational

Occupational exposures occur at increased rates among laboratory workers, morticians, and house cleaners. The general population can be exposed to phenol in consumer products such as disinfectants and other household cleaners, throat lozenges, and ointments. Workers in the petroleum industry that manufacture nylon, epoxy resin, herbicides, and wood preservatives have an increased risk of phenol exposure (Bergé et al., 2012; Wasi et al., 2013). Any worker exposed to benzene is also exposed to phenol.

Environmental

Anthropogenic sources of phenol are paper mills and wood treatment plants. Phenol is rapidly degraded in air by hydroxyl radicals; degradation occurs within 19 h (Geens et al., 2012). It has an estimated half-life in air of 14.6 h. Soil can retain phenol for a half-life of <5 days (Bergé et al., 2012; Merliss, 1972). Plants can readily metabolize phenol and can be ingested by humans when plants are grown in phenol-rich soil—although exposure through this route is minimal. Phenol is also produced by first- and secondhand smoke. It is readily absorbed through the skin (Brown et al., 1975; Horch et al., 1994; Kucheki and Simi, 2010; Wasi et al., 2013). It is commonly measured in several point sources such as effluents, ambient water, drinking water, groundwater, rain, sediment, and ambient air (Bergé et al., 2012; Hoffman et al., 2001; Ryan et al., 2001).

INDUSTRIAL HYGIENE

Phenol is still commonly used in industry for the production of other aromatic hydrocarbons, explosives, fertilizers, paints, paint removers, wood preservatives, synthetic resins, textiles, pharmaceuticals, and perfumes (Allan, 1994). In fact, total phenol production in the United States increased approximately 9% in the late 1980s.

The NIOSH, OSHA, and the ACGIH have each set the REL, PEL, and TLV for phenol at 5 ppm (19 mg/m³) with a ceiling of 15.6 ppm (60 mg/m³) for 15 min with a skin notation (NIOSH, 2007). Phenol levels of 250 ppm or above are considered IDLH.

The ACGIH (2009) has determined that workers exposed to the TLV for phenol will have approximately 250 mg phenol/g creatinine in their urine at the end of their shift (Heistand and Todd, 1972). Levels of phenol in urine are also monitored to estimate the exposure to benzene (Arnold et al., 2013). However, the expected value for workers exposed to the benzene TLV would be 50 mg phenol/g creatinine. Methods for evaluating phenol in exhaled air by gas

chromatography have been reported (Pendergrass, 1994). Elevated blood levels may also be used to determine the exposure for clinical purposes.

MEDICAL MANAGEMENT

Dermal exposure is most common. Contaminated areas on the body will appear red and swollen. Diagnosis may be made by examination of clinical chemistry. Normal blood concentrations of phenol are as follows: free phenol approximately 0.4 mg/100 ml; conjugated phenol approximately 0.1–2 mg/100 ml; and total phenol approximately 0.15–7.96 mg/100 ml (Horch et al., 1994; Ruedemann and Deichmann, 1953). Exposed individuals will have dramatically elevated levels of blood phenol commensurate with the intensity of exposure. Severe or prolonged exposures may result in proteinuria, oliguria, anuria, and uremia (typically dark urine) (Wasi et al., 2013; Zambito Marsala, 2010).

Treatment of any phenol exposure should include basic life-support measures as necessary. For dermal exposure, wound decontamination is recommended by sponging burns with undiluted polyethylene glycol (PEG) 300 or 400 and showering after treatment. Any wound should be treated with PEG until all traces of phenol smell disappear. Ethanolic PEG solutions are better phenol solvents but are not recommended for the treatment because of their flammability, odor, and skin absorption. A high density shower is recommended if available, low intensity without PEG treatment may increase phenol absorption. Intravenous Ringer's lactate solution may be administered. Scalds can be covered with silver sulfadiazine dressings (Horch et al., 1994). For ocular exposure, patients' eyes should be washed thoroughly with room temperature water for at least 15 min. If pain and irritation persist, an ophthalmologist must be consulted.

If ingestion occurs, dilution should be avoided as it may enhance absorption. Solutions containing >5% phenol can result in oral burns.

CRESOL

Target organ(s): Eyes, skin, respiratory system, CNS, liver, kidneys, pancreas, and cardiovascular system.

Occupational exposure limits: NIOSH REL: TWA: 2.3 ppm (10 mg/m³). OSHA PEL: TWA: 5 ppm (22 mg/m³).

Risk/safety phrases: None.

First aid: Eye: Immediate irrigation; Skin: wash with soap immediately; breath: respiratory support; swallow: seek medical attention immediately.

Conversion: 1 ppm = 4.43 mg/m³.

BACKGROUND AND USES

Cresol (cresylic acid, hydroxymethyl benzene, hydroxytoluene, methylphenol CASRN 1319-77-3 for all isomers combined) is a derivative of coal tar that occurs in ortho-, meta-, and para isomers (Table 60.1). In most cases, all forms exist in a mixture. All isomers have a characteristic sweet, tarry odor and a solubility in water by weight of 2%. Cresols are monomethyl derivatives of phenol, which are commonly used in household disinfectants, dyes, explosives, fragrances, pesticides, and germicides. Cresol used as a disinfectant is

TABLE 60.1 Cresol Isomers

	Cresol Isomers	CAS Number	Description	Vapor Pressure at 25 °C, mmHg
ortho-	2-Cresol	95-48-7	White crystals darken with age	0.29
meta-	3-Cresol	108-39-4	Colorless to yellowish liquid	0.14
para-	4-Cresol	106-44-5	Solid	0.11

usually a mixture of the three isomers of methylphenol—2-cresol, 3-cresol, and 4-cresol—known commonly as *o*-cresol, *m*-cresol, and *p*-cresol, respectively. Isomers of cresol in air react with the hydroxyl radicals.

M-cresol is used as an antimicrobial in insulin and other pharmaceuticals. Cresol is approximately three times as effective as phenol as a bactericide. It is also found in wire enamel solvents, phenolic resins, and tricresyl phosphate.

Cresols should not be confused with creosote or cresylic acids. Creosote is a wood preservative composed of phenol derivatives, including cresols, from the distillation of coal and wood tars. Cresylic acids are mixtures of cresols, xylenols, and phenol. These compounds are part of a class of molecules known as protein-bound uremic retention toxins, which lead to nephrotoxicity. Many cresol isomers are used in cosmetics as a biocide and preservative as well as a common ingredient in fragrances (Andersen, 2006).

PHYSICAL AND CHEMICAL PROPERTIES

Cresols at room temperature are solid except *m*-cresol, which is a liquid. The melting points of *o*-cresol, *m*-cresol, and *p*-cresol are 30.9, 12.2, 34.7 °C, respectively (Andersen, 2006). The density of cresol isomers is 1.034 g/ml, except *o*-cresol which has a density of 1.047 g/ml. The concentration of cresol isomers in air may be 4.5 mg/m³ (0.22 ppm) (ATSDR, 2008). Isomeric cresols have a vapor pressure of 0.11 ± 0.30 mmHg at 25.5 °C (ATSDR, 2008; NIOSH, 2007). Cresol isomers have a relatively high water solubility of 21.52–25.95 g/l, which allows wet deposition to remove cresols from the atmosphere; however, they do not travel long distances from the point of release. Soil absorption coefficients are 17.5–117, suggesting high mobility in soil (ATSDR, 2008). Cresols do not bio-concentrate in fish or aquatic organisms and are unlikely to concentrate in humans.

Emission studies have shown an estimated ambient mean concentration of 31.7 ng/m³ for all cresols combined (ATSDR, 2008). Cresol has a low deposition in soil and water. Usually

when cresols isomers are found in soil or water, it is due to spillage of petroleum products, although they can be degraded in water within days by microorganisms (ATSDR, 2008). Contaminated drinking water can create volatilized cresol during showering, bathing, and cooking. Cresols are degraded in air within 1–2 days and can be removed by rain. Cresols can be removed from air caused by hydroxyl radicals during the day and nitrate radicals at night.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute exposures to cresol in an industry are not common. When exposures do occur they are usually dermal. Cresol is not volatile enough to pose an inhalation hazard. Skin and eye contact with cresol causes burns similar to phenol exposure only slightly more severe (Pegg and Campbell, 1985). Eye exposure may cause conjunctivitis, corneal burns, and keratitis. Cresol is absorbed more slowly than phenol, resulting in less severe systemic effects.

Cresols can be absorbed through the skin, respiratory tract, and digestive tract (Andersen, 2006). They are processed by first-pass metabolism in the liver (Dix et al., 2007). The metabolites are excreted by the kidney as glucuronide and sulfate metabolites (Andersen, 2006). Cresol poisoning can attack several systems of the body leading to corrosion of the gastrointestinal tract, respiratory distress, uremia, cardiovascular disturbances, hepatotoxicity, and nephrotoxicity (Chapman et al., 1994; Seak et al., 2010; Yan et al., 2005).

Inhalation exposure at concentrations of 6 mg/m³ (*o*-cresol) can cause respiratory irritation. All isomers of cresol are neurotoxic; ingestion of household cleaning products made with mixed cresol has been shown to cause unconsciousness and coma in humans (ATSDR, 2008; Sakai et al., 1999). Exposure to *p*-cresol by ingestion can cause death. *P*-cresol has a high serum protein-binding affinity, which can cause uremic toxicity (Yan et al., 2005).

Chronic Effects

There have been reports of sensitization to *m*-cresol when used as a pharmaceutical preservative.

Mechanisms of Action

Cresol is metabolized by conjugation and oxidation. It is rapidly absorbed in the body where it denatures and precipitates cellular proteins causing direct toxicity to cells (Boatto et al., 2004; Monma-Ohtaki et al., 2002; Zhu et al., 2012). All modes of exposure: oral, dermal, and inhalation can be absorbed rapidly and produce cresol intoxication. Exposure to cresols may affect the CNS and respiratory system, as well as cause renal, hepatic, dermal, and ocular effects (Merliss,

1972). Rats exposed to cresol did exhibit weight gain, increased excitability, increased oxygen consumption, changes in liver and lung tissues, and decreased gamma-globulin content of serum. Cresol is metabolized primarily to 4-hydroxybenzylalcohol in the liver by oxidation of the methyl group and further oxidation forms 4-hydroxybenzaldehyde (Chang et al., 2011; Mutsaers et al., 2013; Yan et al., 2005). Oxidation of *p*-cresol forms a reactive electrophile quinine methide whose intermediates are primarily mediated by CYP2E1, although other P450s are also involved to a lesser extent such as 2D6, 2C19, 1A1, and 1A2 (Yan et al., 2005). Quinine methide is highly reactive, and it alkylates cellular proteins and nucleic acids (Yan et al., 2005). An alternative chemical pathway also occurs when 4-methyl-*ortho*-hydroquinone is also formed by oxidation of the benzene ring and further oxidized to a reactive intermediate as 4-methyl-*ortho*-benzoquinone (Yan et al., 2005). Cresol metabolites can form stable conjugates when they bind to proteins such as glutathione (GSH) where it can be detected (Yan et al., 2005). According to Yan et al. (2005) quinine methide is reactive with DNA forming adducts.

Cresol isomers may produce significantly different effects. In experiments using rat liver slices, *p*-cresol was determined to be five to ten times more potent as a cytotoxin than *o*-cresol and *m*-cresol (Thompson et al., 1994). *P*-cresol was also shown to rapidly deplete GSH, whereas *o*- and *m*-isomers had a less dramatic effect. This study suggests that *p*-cresol may have a different mechanism of action than other isomers. *P*-cresol is generated by protein breakdown as a metabolite of tyrosine and phenylalanine, thus it is normally found in the body (Chang et al., 2011; Cuoghi et al., 2012). It is absorbed from the intestine and excreted through urine. Healthy subjects have been found to have a mean concentration of 8.6 µmol/l (0.93 mg/l) of *p*-cresol in their serum (De Smet et al., 2003).

The exact mechanism of action of cresol remains unknown. In one study, a mixture of cresol isomers was negative in the Ames mutagenicity test. DeWolf et al. (1988) demonstrated that *p*-cresol inactivates dopamine beta-hydroxylase by covalently modifying its structure. This is significant because beta-hydroxylase catalyzes the hydroxylation of dopamine to norepinephrine. Several studies using rat liver slices and human liver microsomes confirm that rat and human metabolism of *p*-cresol is similar (Thompson et al., 1994; Yan et al., 2005).

Administration of *o*-cresol seems to lessen the carcinogenic effect of benzo-alpha-pyrene in mice (Calderón-Guzmán et al., 2005; Yanyshewa et al., 1993). In an amphibian model, *m*-cresol was found to dramatically increase the biological activity of insulin (Gallucci and Micelli, 1992). Dietary factors, such as meat consumption, can significantly alter excretion of cresol in humans (Ling and Hänninen, 1992). Additionally, in mice there was evidence of mild atrophy of the female reproductive organs as well an extended estrous cycle (ATSDR, 2008; NTP, 1992).

Chemical Pathology

Animal studies have shown that exposures between 9 and 50 mg/m³ produce fatty degeneration and necrosis of the liver. Cresols can impair the stratum corneum (as seen in dermal exposures) and produce coagulation necrosis. In the 1990s, Thompson et al. (1994, 1996) studied the toxicity of rat liver slices using lactate dehydrogenase that suggests a possible mechanism of cresol toxicity.

SOURCES OF EXPOSURE

Occupational

Occupational exposures to cresols can occur in coal-, wood-, or petroleum-fueled electricity-generating facilities or solid waste incinerators from all types of industry. Co-exposure can occur in conjunction with toluene. Cresols can be formed from photochemical reactions with toluene and hydroxyl radicals. Workers and residents who live near these facilities may be exposed; however, the short half-life of cresols makes them less of an exposure risk than first- and secondhand cigarette smoke.

Environmental

Cresols are emitted by automobile exhaust where low levels remain in the atmosphere. In addition cresols are emitted during the combustion of solid waste, wood, coal and in cigarette smoke. Cresols biodegrade rapidly in aerobic freshwater but degrade much slower under anaerobic conditions and in salt water. The average ambient concentration of cresol isomers is 31.7 ng/m³ (ATSDR, 2008). Due to the short half-life and reactions during the day and at night, cresols have a short deposition in the atmosphere. At various sites around the world, cresols have been found in water at average low concentrations of 0.05 µg/l, with some areas as high as 390 µg/l (ATSDR, 2008). Cresols are bio-waste of mammals and thus can be found in sewage at high concentrations. Cresols in soil are broken down by microorganisms and are biotransformed.

INDUSTRIAL HYGIENE

The OSHA has set the PEL for all isomers of cresol at 5 ppm (22 mg/m³). The NIOSH (2007) has set the REL for all cresol isomers significantly low at 2.3 ppm (10 mg/m³). Cresol levels above 250 ppm are considered IDLH. The ACGIH (2009) has established a TLV for all cresol isomers at 5 ppm (22 mg/m³) for skin exposure.

MEDICAL MANAGEMENT

Short-term exposures can cause respiratory irritation (Boatto et al., 2004). Acute exposures can cause respiratory failure,

tachycardia, and ventricular fibrillation. Additionally patients can suffer from abdominal pain, vomiting, and corrosive lesions in the gastrointestinal tract (Dix et al., 2007; Monma-Ohtaki et al., 2002). More serious complications can occur such as methemoglobinemia, leukocytosis, hemoysis, hepatocellular injury, renal alterations, skin damage, metabolic acidosis, and even unconsciousness (Lin and Yang, 1992; Sakai et al., 1999; Seak et al., 2010). Hemodialysis has not proven to be effective for reducing blood phenol levels (Evers et al., 1994). Another method for reducing levels of cresols in the body appears to be forced diuresis (Arthurs et al., 1977). Sodium bicarbonate is indicated to reduce the patient's urinary pH, thereby decreasing precipitation of hemoglobin in the renal tubules (Lin and Yang, 1992). The use of sodium bicarbonate may be indicated anyway to reverse metabolic acidosis that results from a large burn surface area and high levels of blood phenol.

Treatment of cresol burns should include PEG in the manner described for the treatment of phenol burns. Severe poisoning can be at serum levels of 10 µg/ml and lethal at 100 µg/ml (Sakai et al., 1999). Cresol can be absorbed quickly and excreted into the urine (Boatto et al., 2004; Brown et al., 1975). Acute poisoning is usually presented clinically by black urine that can be accompanied by hemoglobinuria, melanuria, porphyrinuria, alcaptonuria, myoglobinuria, and tyrosinuria (Seak et al., 2010). Treatment requires an aggressive intensive supportive care in order to manage cresol poisoning (Seak et al., 2010).

Cresol absorption can result in the depression of the CNS, hypothermia, hypotension, pulmonary edema, and intravascular hemolysis (Sakai et al., 1999). Dermal exposure to cresol can cause severe burns and should be washed thoroughly and treated with swabs of PEG sponges prior to a high density shower (Sakai et al., 1999). Dermal absorption rates are based on the surface area of the skin exposed and the duration of contact (Sakai et al., 1999).

TOLUENE

Target organ(s): Eyes, skin, respiratory system, CNS system, liver, and kidneys. The primary target is the CNS.

OSHA PEL: TWA 200 ppm (750 mg/m³; ceiling 300 ppm; peak 500 ppm (10 min). Toluene levels of 500 ppm (1885 mg/m³) or greater are considered IDLH.

The NIOSH has set the REL for toluene at 100 ppm (375 mg/m³), with a STEL of 150 ppm (560 mg/m³) (NIOSH, 2010).

The ACGIH has set a TLV for exposure to toluene at 20 ppm (75 mg/m³) (ACGIH 2007). Toluene is classified as an A4 carcinogen indicating that not enough information is available to determine whether it is carcinogenic in humans. The International Agency for Research on Cancer (IARC) has classified toluene as Group 3 (*not*

classifiable as to its carcinogenicity in humans) with a supporting statement that there is inadequate evidence in humans and evidence suggesting a lack of carcinogenicity of toluene in experimental animals (IARC, 1999).

Reference values for toluene: Oral reference dose (RfD) = 0.08 mg/kg-day; inhalation reference concentration (RfC) = 5 mg/m³. NOAEL (average): 34 ppm (128 mg/m³); NOAEL (ADJ): 46 mg/m³. Agency for Toxic Substances and Disease Registry (ATSDR) minimal risk level (MRL): 1 ppm (acute). .08 ppm (chronic).

Risk/safety phrases: Inhalation risk; irritant.

BACKGROUND AND USES

Millions of metric tons of toluene (toluol, phenyl methane, methylbenzene, methylbenzol; CASRN 108-88-3) are produced each year, making it one of the most abundantly produced chemicals in the United States. It is obtained primarily from the distillation of crude petroleum. It is added to gasoline, used to produce benzene, and used as a solvent. It is found in glue, paint, paint thinners, synthetic fragrances, nail polish, cigarette smoke, and transmission fluid; it has been used as a solvent in many industrial processes and as a solvent in coatings, inks, adhesives, and cleaners. It is also used in the production of nylon, plastics, plastic soda bottles, pharmaceuticals, dyes, and polyurethanes and in the manufacture of organic chemicals such as toluene diisocyanate, toluene sulfonates, nitrotoluenes, vinyl toluene, phenol, benzyl alcohol, and saccharin. As a historical note toluene was once used as a medicinal anthelmintic agent against roundworms and hookworms (ATSDR, 2000; EPA, 2012; Filley et al., 2004; Hannigan and Bowen, 2010).

PHYSICAL AND CHEMICAL PROPERTIES

At room temperature, toluene is a clear to amber colorless liquid with a pungent, benzene-like odor. It has a vapor pressure of 28.4 mmHg and solubility in water of 0.59 mg/ml at 25 °C. It has a structural formula: C₆H₅CH₃, molecular weight: 92.14, density: 0.867 gm/ml. Conversion factor 1 ppm = 3.77 mg/m³, 1 mg/m³ = 0.265 ppm (25 °C, 760 mmHg)

HEALTH EFFECTS

Acute Health Effects

Toluene is irritating to the skin, eyes, and respiratory tract. Eye contact can cause reversible conjunctivitis and keratitis. The vapor can cause eye irritation and respiratory tract irritation.

Acute inhalation exposures to toluene produce symptoms that are similar to other organic solvents and may include dizziness, headache, lethargy, inebriation, "drunkenness,"

exhilaration, drowsiness, staggering gait, tremor, euphoria, disorientation, hallucinations, and CNS depression. Other signs and symptoms may include ventricular arrhythmias, chemical pneumonitis, respiratory depression, nausea, vomiting, and electrolyte imbalances. Higher concentrations lead to collapse, loss of consciousness, coma, and death (Van Oettingen et al., 1942a, 1942b; Boor and Hurtig, 1977; Xiao and Levin, 2000; ATSDR, 2000).

At relatively low levels of ambient exposure to toluene, just above 200 ppm, fatigue, headache, paresthesias, and slowed reflexes are seen; above 600 ppm, confusion may occur; and above 800 ppm, euphoria is experienced (Greenberg, 1997). The acute encephalopathic effects of toluene are generally reversible and have not been associated with neuroimaging changes (Filley et al., 2004). A study by Deschamps et al. (2000) did not support the notion of the persistence of cognitive effects of toluene after elimination of the solvent from blood in the setting of low dose occupational exposures.

There are multiple studies of subacute and chronic occupational exposures to toluene below 200 ppm that have shown various and often inconsistent findings of subtle neurotoxic, neuropsychiatric, neurobehavioral and neuromuscular effects, color discrimination, and cognitive performance (ATSDR, 2000; USEPA, 2005b; Meyer-Baron, 2005). Limitations of the studies include lack of clear data regarding past duration and intensity of exposure, variations in subject baseline neurobehavioral and intellectual capacity, coexistent exposures and lack of adjustment for confounders, inconsistent effect sizes, diversity of study groups, the use of diverse tests of neuropsychiatric function, and the degree of test reliability (Meyer-Baron, 2005).

Chronic Health Effects

The health effects of toluene reported in the literature can be misleading unless a distinction is made between high dose exposures experienced by toluene abusers vs. the relatively low dose exposure seen in most occupational and environmental settings. A distinction also needs to be made between the acute effects of toluene exposure that are usually reversible and the long-term chronic effects of high levels of exposure (as in chronic toluene abusers) that may not be reversible.

Gericke et al. (2001) studied 1007 male volunteers in the rotogravure (printing) industry in Germany and found no clear-cut evidence of adverse health effects of long-term (more than 20 years) exposure to toluene at the lower levels experienced at work. In Germany, the initially tolerable maximal toluene concentration at the workplace (MAK-value) of 200 ppm was reduced in 1985 to 100 ppm and to 50 ppm in 1993.

Toluene leukoencephalopathy (damage to white brain matter and an ominous sequel of toluene abuse) has not been shown to be caused by toluene exposure at the permissible levels set by the OSHA.

Chronic exposure to extremely high levels of toluene may lead to the gradual development of headache, fatigue, irritability, memory impairment, depression, emotional instability, sleep disturbance, alcohol intolerance, loss of libido or potency, and loss of interest in daily activities. Most occupational settings do not generate ambient levels of toluene capable of producing these symptoms in workers.

Toluene abusers that have been exposed for long periods of time have been reported to exhibit a variety of neurologic manifestations, including hyperreactive tendon reflexes, ataxia, tremor, anosmia, sensorineural hearing loss, cognitive dysfunction, dementia, corticospinal tract dysfunction, bilateral sensorineural hearing loss, abnormal brainstem auditory-evoked potentials, and epileptic seizures. Neurobehavioral deficits seen include inattention, apathy, memory dysfunction, visuospatial impairment, and preserved language (Hormes et al., 1986). MRI findings in toluene abusers include generalized cerebral, cerebellar, and brainstem atrophy; atrophy of the corpus callosum; loss of gray white matter discrimination; multifocal high signal intensity in the cerebral white matter; and hypointensity of the thalamus on T2-weighted images. Optic neuropathies with dyschromatopsia, blindness, changes in pattern visual-evoked potentials, pendular nystagmus, ocular flutter, opsonclonus (irregular rapid eye movement), bilateral internuclear ophthalmoplegia, and retinal impairment have been reported in those who sniffed toluene or toluene-based glue (Hormes et al., 1986; Holló and Varga, 1992; Xiao and Levin, 2000; ATSDR, 2000; USEPA, 2005b).

Risk assessment for toluene is problematic. There are ample data on human exposures because of toluene abuse; however, these are not controlled experiments, and the dose is unknown. In general, the exposure of abusers is exponentially greater than occupational exposures, and abusers often expose themselves to a variety of other recreational drugs. Extrapolation of symptoms and effects from abusers to lower level chronic exposures of workers is not appropriate.

Central Nervous System Toxicity Damage to the brain myelin has been well documented with chronic toluene abuse; however, there have been few autopsies probably because chronic toluene abuse is under recognized by pathologists. The CNS is the primary target organ for toluene toxicity, and the acute and chronic effects are described above. Chronic encephalopathy and leukoencephalopathy are known outcomes of chronic toluene abuse. Autopsy reports include peripheral neuropathy, long tract degeneration, cerebral and cerebellar atrophy, severe thinning of the corpus callosum, diffuse demyelination, neuronal loss in the cerebral cortex, basal ganglia and cerebellum, intense reactive gliosis, and giant axonal degeneration in the long tracts of the spinal cord. The brunt of toluene toxicity is directed toward the CNS white matter. The severity of myelin damage differs from one case to another and such differences could be due to variations in the

duration and intensity of toluene exposure, coexistent abuse of other chemicals, and host factors such as genetic polymorphisms, defective metabolism, and the age of onset of abuse (Filley et al., 2004). While leukoencephalopathy has not been shown to result from occupational exposure, it has been suggested that advanced neuroimaging techniques may in the future be able to detect subtle brain changes, if they exist, caused by lower level exposures that occur in the workplace.

Reproductive Toxicity Toluene is capable of crossing the placenta and has been detected in animal fetal-placental compartments 24 h after exposure (Ghantous and Danielsson, 1986). Lindbohm et al. (1992) found an association between occupational toluene exposure and spontaneous abortion (odds ratio 2.3); however, exposure levels were not reported in this study. Current data do not provide convincing evidence that an occupational exposure to toluene causes reproductive effects in humans. Reports that an occupational exposure to toluene may lead to an increased incidence of spontaneous abortion have not been supported by the results of animal testing. In animal studies toluene has been shown to be fetotoxic but not teratogenic. On the other hand, Hannigan and Bowen (2010) summarized the evidence to suggest that the risk for pregnancy problems, as well as developmental delays and neurobehavioral difficulties, is higher for the children of women who have been exposed to high concentrations of organic solvents (toluene abuse) during pregnancy than for those who have not. They further stated that the risks appear to be higher in cases of abuse exposure to solvents such as toluene, particularly in comparison to the risk for teratogenic outcomes with occupational solvent exposure. Children of toluene abusers exposed to toluene prenatally have been shown to have low birth weight, shorter gestation, dysmorphic features similar to fetal alcohol syndrome, microcephaly, abnormal muscle tone, and blunt fingertips with small fingernails (Hersh et al., 1985; Wilkins-Haug and Gabow, 1991; Arnold et al., 1994; Sheeres and Chudley, 2001). Children prenatally exposed to toluene may exhibit behavioral problems such as hyperactivity, head banging, and aggressive behavior. Deficiencies are also apparent in speech and cognitive and motor skills (Arnold et al., 1994).

Renal Toxicity Studies of chronic toluene abusers, occupationally exposed workers, and laboratory animals have provided little support for serious kidney damage due to inhaled toluene. Chronic abuse of toluene can produce acidosis, but in most cases, renal dysfunction is transient and normal function returns when exposure ceases (Vyskocil et al., 1991; ATSDR, 2000).

Carcinogenicity The IARC (IARC, 1999) and the US Environmental Protection Agency (USEPA, 2005a) consider toluene as “not classifiable” as to human carcinogenicity (Groups 3 and D, respectively).

Mechanism of Action

The mechanisms underlying the observed neurotoxicity of toluene are not fully understood but appear to be related to concentrations of the parent compound, rather than metabolites, reaching the brain (van Asperen et al., 2003; Benignus et al., 2007; Bushnell et al., 2007; Aylward et al., 2008). Toluene is distributed in lipid-rich regions of the brain; however, the pathologic action of toluene after localizing in the white matter is uncertain (Filley et al., 2004).

Unger et al. (1994) studied T2-weighted MRI scans of eight patients with histories of toluene abuse. They found marked hypointensity in thalamus and moderate hypointensity in the basal ganglia. The authors suggested that toluene is partitioned in the lipid membranes of cells in the cerebral tissue, which accounts for the hypointensity of basal ganglia. Rosenberg et al. (1988) studied MRI scans of six chronic toluene abusers. They found diffuse cerebral, cerebellar, and brainstem atrophy; loss of differentiation between gray and white matter throughout the CNS; and increased periventricular white matter signal intensity on T2-weighted images. The authors suggested that these changes may be due to the increased water content of the white matter or toluene-induced metabolic changes in myelin. Further studies showed a correlation between the levels of diffuse white matter damage and impaired neuropsychological functioning (Filley et al., 1990).

In vitro work with guinea pig hippocampal slices showed that toluene had a depressive effect on postsynaptic responses (Ikeuchi and Hirai, 1994). Longer exposures produced lasting effects without visible morphological changes.

High levels of toluene have been shown to induce some cytochrome P-450 isozymes in rat livers (Nakajima and Wang, 1994). Although occupational levels are probably too low to induce P-450 isozymes, they may be induced by an acute exposure among toluene abusers.

Bowen et al. (2006) reviewed 10 years of mechanistic studies using animal models of inhalant abuse and reported the following possible mechanisms: the action of toluene may exert effects through interaction with *N*-methyl-D-aspartate (NMDA) receptor inhibition and modulation; through inhibition of nicotinic acetylcholine receptors (nAChRs); by altering membrane permeability; by increasing the ionic currents activated by serotonin through 5HT₃ receptors; by inhibiting voltage-gated calcium channels; by increased activity of the dopaminergic system involving gamma-aminobutyric acid (GABA) and glutamatergic systems; and through interactions with various other ion channels. Validation of these mechanisms needs further studies.

SOURCES OF EXPOSURE

Occupational

Absorption occurs via inhalation, dermal contact, and ingestions; however, inhalation of the vapor is generally the most

important route. The NIOSH (2010) estimates that 4.8 million workers are exposed to toluene, the fourth largest number for an individual chemical. The primary source of occupational exposures is industrial the manufacturing of toluene diisocyanate, toluene sulfonates, nitrotoluenes, vinyl toluene, phenol, benzyl alcohol, saccharin, glue, paint, and transmission fluid. Common occupational exposures occur in printing operations and painting.

Environmental

The airborne toluene level inside and outside homes is usually <1 ppm in cities and suburbs that are not close to an industry. Automobile emissions are the principal source of toluene to the ambient air. Toluene may also be released to the ambient air during the production, use, and disposal of industrial and consumer products that contain toluene (USEPA, 2012).

Significant nonoccupational exposure to toluene occurs in hobbyists involved with model making or any craft utilizing toluene-containing glue. Drug abusers are exposed through sniffing (nasally inhaled) or huffing (orally inhaled) toluene-based products from a plastic or paper bag, can, plastic bottle, saturated rag or coat sleeve, or directly from the container. Inhalation of solvents, especially toluene, is a common and often overlooked form of chemical abuse. The inhalation of paint fumes and glue sniffing are popular forms of toluene abuse (Meadows et al., 1996; Filley et al., 2004).

INDUSTRIAL HYGIENE

Employers should use engineering controls, personal protective equipment (PPE) and clothing, and worker education programs to reduce exposures to toluene and other organic solvents at least to the concentrations specified in existing guidelines.

BIOMONITORING

Potential biomarkers of toluene exposure include blood samples for toluene; urine samples for toluene, hippuric acid, *ortho*-cresol, *S*-toluylmercapturic acid, or *S*-benzylmercapturic acid; and breathe samples for toluene (Aylward et al., 2008).

A large study of Chinese workers exposed to toluene found that the level of hippuric acid in urine per gram creatinine had a strong linear relationship with toluene exposure (Liu et al., 1992). However, an earlier study by Foo et al. (1991) noted that urine hippuric acid did not correlate well with low level exposure to airborne toluene and that measuring toluene in the expired air of workers was a more sensitive biomonitoring technique at the lower exposure levels. Additional research by Kawamoto et al.

(1994) reported that toluene metabolism and hippuric acid concentrations vary among genotypes. As would be expected, hippuric acid has been shown to be present in the urine of toluene abusers who are exposed to high concentrations of toluene (Raikhlin-Eisendraft et al., 2001). Yoshida et al. (2005) reported a semi-quantitative colorimetric method for screening of hippuric acid in toluene sniffers' urine.

Urinary *o*-cresol has also been investigated as a method for monitoring toluene exposure (Inoue et al., 1994, 2008). It did not prove to be as strong an indicator as hippuric acid, because the results were confounded by cigarette smoking and alcohol consumption.

Using gas chromatography, Inoue et al. (2008) evaluated blood toluene levels, against urine samples analyzed for benzyl alcohol, benzymercaptopuric acid, *o*-cresol, hippuric acid, and toluene. They concluded that urine benzyl alcohol, benzymercaptopuric acid, hippuric acid, and *o*-cresol correlated well with toluene in the air only when exposures were intense (e.g., 50 ppm or above), but did not correlate well when airborne exposures were low (e.g., 2 ppm). Blood toluene and urine toluene levels correlated well with both high and low airborne exposure levels leading to the conclusion that blood and urine toluene may be employed to estimate toluene exposure at low levels. Biomonitoring for toluene may use either urine or venous blood (ACGIH, 1996; Kawai et al., 1992). Venous blood containing 1 mg/l of toluene (end of shift) would be average for a worker exposed to the TLV. For hippuric acid in urine, a level of 2.5 g/g creatinine (end of shift—last 4 h) would be considered average for workers exposed to the TLV.

Aitio et al. (1984) suggested that the painters' habit of washing their hands with solvents after a workday may artificially elevate biomonitoring data for toluene. It is known that benzyl alcohol, benzymercaptopuric acid, or hippuric acid will not be formed after inhalation of benzene, hexane, or xylenes. It is also known that no metabolic interaction will take place between organic solvents when the exposure is low, that is, below occupational exposure limits (Inoue et al., 2008). Ethanol has been shown to have an effect on the metabolism of toluene (Ingren et al., 1996). Even a low blood concentration of ethanol has yielded dose-dependent decreases in toluene metabolism that could confound research and biomonitoring (Baelum et al., 1993; Imbirani and Ghittori, 1997).

MEDICAL MANAGEMENT

Adults seeking hospitalization for muscle weakness, nausea, vomiting and abdominal pain, or neurological problems should be asked about solvent inhalation. Laboratory findings of hyperchloremia, hypobicarbonatemia, hypokalemia, hypophosphatemia, and acidosis with a normal or increased

anion gap associated with distal renal tubular acidosis indicate the potential involvement of toluene. Profound hypokalemia can cause muscle weakness (Streicher et al., 1981; Baskerville et al., 2001).

Management of acute toluene intoxication includes supportive care as needed, including cardiac monitoring for potential arrhythmias. The treatment should focus on correction of the resulting metabolic disorders and careful monitoring of serum electrolytes combined with aggressive electrolyte replacement with intravenous (IV) potassium, magnesium, and phosphate (Wilkins-Haug and Gabow, 1991). Bicarbonate replacement may be needed in severe acidosis with a pH < 7.2. Recovery is usually rapid with replacement of the electrolyte disorders (Baskerville et al., 2001; Camara-Lemarroy et al., 2012). Induction of vomiting should be avoided if hydrocarbon ingestion has occurred due to the risk of pulmonary aspiration. Dextrose-containing solutions and tocolysis with terbutaline should be avoided because they may further lower electrolytes. Poison control centers can provide excellent assistance for managing any overdose or intoxication. Contacting the Poison Control Center national hotline number (1-800-222-1222) connects the caller with the local poison control center in the area code where the call originates. If toluene abuse is suspected, admission into an abuse treatment program is advisable.

XYLEMES

Target organ(s): Eyes, skin, CNS, respiratory system, liver, and kidneys. The primary target is the CNS.

OSHA PEL 100 ppm (435/m³ as an 8-h TWA).

The NIOSH (2007) has set the REL for xylene at 100 ppm (435/m³ TWA); with a STEL of 150 ppm (655 mg/m³); and an IDLH concentration of 900 ppm.

The ACGIH has set a TLV for exposure to xylene at 100 ppm (435/m³ TWA) with a STEL of 150 ppm (655 mg/m³ STEL).

Xylene is classified as an A4 carcinogen indicating that not enough information is available to determine whether it is carcinogenic in humans.

Inhalation RfC = 0.1 mg/m³. NOAEL 50 ppm; LOAEL 100 ppm.

Oral RfD 0.2 mg/kg-day; NOAEL 250 mg/kg-day; LOAEL 500 mg/kg-day.

ATSDR (2007) inhalation MRL: Acute: 2 ppm (\leq 14 days); intermediate: 0.6 ppm (15–364 days); chronic: 0.05 ppm (\geq 1 year). Oral MRL: Acute: 1 mg/kg/day (\leq 14 days); intermediate: 0.4 mg/kg/day (15–364 days); chronic: 0.2 mg/kg/day (\geq 1 year).

Risk/safety phrases: Inhalation risk; irritant.

BACKGROUND AND USES

Xylenes are used as industrial solvents, synthetic intermediates, and as solvents in commercial products such as paints, coatings, adhesives, adhesive removers, inks, dyes, cleaning products, paint thinners, and varnish thinners. Some paints contain more than 50% xylenes. It is used as a solvent in printing, rubber, and leather industries and is used in the production of phthalic anhydride, plasticisers, and polyesters. It is commonly found in degreasers as well as solvents for resins and gums. It is found in small quantities in airplane fuel, gasoline, and cigarette smoke. In medical technology and industry, it is widely used as a solvent. In dentistry, it is used in histological laboratories for tissue processing, staining and cover slipping, and also in endodontic retreatment (Earnstgard et al., 2002; Jacobson and McLean, 2003; Kandyala et al., 2010).

PHYSICAL AND CHEMICAL PROPERTIES

The xylene in commercial use is composed of a mixture of the three isomers ortho-xylene, meta-xylene, and para-xylene; the meta isomer predominates in these mixtures. *o*-Xylene and *m*-xylene are clear, colorless, flammable liquids that have characteristically sweet, balsam-like odors. At low temperatures (below 13 °C [56°F]), the para-isomer occurs in the form of clear, colorless plates. Common impurities include ethylbenzene, trimethylbenzene, phenol, and pyridine.

The CAS numbers, vapor pressures, and solubility for the *meta*, *ortho*, and *para* forms of xylene are listed in Table 60.2. All isomers are colorless liquids with aromatic odors at standard temperature and pressure.

Xylene has a structural formula: C₆H₄(CH₃)₂, molecular weight: 106, boiling point (760 torr): 135–145 °C (275–293°F), specific gravity (water = 1): 0.86 at 20 °C (68°F), vapor density (air = 1 at boiling point of xylene): 3.7, melting point: -25 °C (-13°F), vapor pressure at 20 °C (68°F): 7–9 torr, and evaporation rate (butyl acetate = 1): 0.6. It is relatively insoluble in water, but it is soluble in alcohol, ether, acetone, and benzene.

ACUTE AND CHRONIC HEALTH EFFECTS

All routes of exposure to xylene affect primarily the CNS, inhalation can affect the respiratory tract, and at high levels of oral exposure xylene can adversely affect the liver and kidney. Acute excessive inhalation exposures are rare because xylene vapor is irritating to the eyes, nose, and throat at high concentrations. Many of the observations available about the acute effects for xylene are derived

TABLE 60.2 Xylene Isomers

Xylene Isomers	CAS Number	Vapor Pressure at 68°F/mmHg	Solubility in Water at 88°F, % by Weight
<i>ortho</i> -	1,2 Dimethylbenzene	95-47-6	7
<i>meta</i> -	1,3 Dimethylbenzene	108-38-3	9
<i>para</i> -	1,4 Dimethylbenzene	106-42-3	9

from household accidents or suicide attempts. Commonly cited symptoms due to xylene exposure include headache, fatigue, irritability, lassitude, motor incoordination, and impairment of equilibrium. Gastrointestinal disturbances such as anorexia and nausea can occur. Flushing, redness of the face, a sensation of increased body heat, increased salivation, tremors, dizziness, confusion, and cardiac irritability have also been reported.

High levels of xylene exposure have been associated with polyuric renal failure, respiratory failure, hemorrhages, and necrosis in the brain, liver, kidneys, and heart. Other effects of high level exposures include agitation, headache, light-headedness, dysphasia, shivering, respiratory tract irritation, ataxia, slurred speech, dyspnea, hyperreflexia, vertigo, inebriation, diffuse opacity of lungs, and unconsciousness (Langman, 1994). An exposure to xylene has also been reported to cause urticaria in medical workers (Palmer and Rycroft, 1993).

Subjective symptoms of nose and throat irritation have been reported following single exposures to xylene vapor at concentrations between 50 and 700 ppm, repeated intermediate-duration exposure at 100 ppm, or chronic duration occupational exposure at 14 ppm. The NOAEL for acute CNS effects in humans has been reported to be about 70 ppm for a 4-h exposure (Earnstgard et al., 2002). Mild CNS effects (subjective symptoms of intoxication, headache, fatigue, and dizziness) have been observed following acute duration exposure of humans to *m*-xylene at 50 ppm and chronic duration exposure to mixed xylene at 14 ppm. Effects in humans exposed to 100–150 ppm *p*-xylene for 1–7.5 hs/day, 5 days per week for 4 weeks included increased subjective symptoms of irritation of the nose and throat; however, no significant alterations in objective measures of neurologic or respiratory function were found (NIOSH 2007; ATSDR, 2007). Experimental studies indicate that an acute exposure to 100 ppm mixed xylene or 200 ppm *m*-xylene causes impaired short-term memory, impaired reaction time, performance decrements in numerical ability, and alterations in equilibrium and body balance. Isolated cases of unconsciousness, amnesia, brain hemorrhage, and seizures, and even death have been associated with accidental acute inhalation exposure to unknown concentrations of xylene (estimated in one case as 10,000 ppm).

An acute exposure to xylene is typically through inhalation, although xylene vapor can be absorbed directly through the skin (McDougal et al., 1990). Skin exposures can cause drying, erythema, scaling, and blistering because of xylene's defatting action.

The signs and symptoms of chronic exposure to xylene may include conjunctivitis; dryness of the nose, throat, and skin; dermatitis; and kidney and liver damage. Shipyard workers exposed to xylene were found to have decreased peripheral nerve function (Ruijten et al., 1994). Xylene is also suspected of causing hearing loss and may result in other CNS symptoms (Gagnaire and Langlais, 2005).

A large occupational study with worker mean exposures of about 14 (geometric mean) and 21 ppm (arithmetic mean) showed an increased prevalence of subjective symptoms in the exposed workers, including local effects on the eyes, nose, and throat; however, hematology and serum biochemistry with respect to the liver and kidney functions were generally negative, indicating that xylenes are not toxic to the hematopoietic organs, liver, or kidney in low dose exposure of occupational settings (Uchida et al., 1993).

Carcinogenicity

Current data are inadequate for an assessment of the carcinogenic potential of xylenes (USEPA, 2003). Adequate human data on the carcinogenicity of xylenes are not available, and the available animal data are inconclusive as to the ability of xylenes to cause a carcinogenic response. Evaluations of the genotoxic effects of xylenes have consistently given negative results.

MECHANISM OF ACTION

Xylene is highly lipophilic and is rapidly absorbed, rapidly distributed and rapidly eliminated from the body. The lipophilic nature of xylene is thought to be responsible for the narcotic and anesthetic effects on the CNS. The mechanisms of anesthesia are not well understood but probably involve xylene interaction with the neuronal membranes resulting in alteration of nerve impulse transmission. A study by Ito et al. (2002) suggested that experimentally induced high levels of *m*-xylene in rat brains increased GABA release and/or enhanced GABA_A receptor function in the cerebellum, which could cause adverse effects on motor coordination. Various studies have suggested possible adverse effects of xylene on CNS neurotransmitters and lipid compositions in areas of the brain; death of cochlear hair cells and ototoxicity; and inhibition of pulmonary microsomal enzymes. The cytotoxicity of *m*-xylene has been associated with reductions in cellular antioxidant status and studies

have suggested that hydroxyl radicals may play a role in xylene toxicity (Coleman et al., 2003; Foy and Schatz, 2004).

Xylene causes an increase in cytochrome P-450 enzymes and several other liver enzymes, proliferation of the smooth endoplasmic reticulum, and enlargement of the rough endoplasmic reticulum in laboratory animals (Ungváry, 1990). Although xylene can result in these morphological changes, it is not hepatotoxic at occupational or environmental levels of exposure. A study of liver function in paint workers exposed to xylene supports this conclusion (Chen et al., 1991).

The mechanisms for xylene renal toxicity are also unknown; however, several mechanisms have been suggested, including formation of reactive metabolites and subsequent irritation or direct membrane fluidization; generation of oxidative intermediates and subsequent necrosis; and apoptosis via activation of mitochondrial enzymes.

The effect of xylene exposure on pregnancy outcome has been reported. Women exposed to xylene in one case-control study had a greater risk (odds ratio 3:1) of poor pregnancy outcome (Taskinen et al., 1994). Saillenfait et al. (2003) concluded that developmental toxicity of *m*- and *p*-xylenes in standard animal bioassays is largely related to maternal toxicity. Xylene exposure was associated with a reduction in maternal weight gain and decreases in fetal body weights; however, there was no evidence of teratogenic effects. More research must be completed before xylene's effect on reproduction can be reliably determined.

Studies on rats indicate that *m*-xylene is more efficiently absorbed through the skin than toluene, benzene, or hexane (McDougal et al., 1990). Experiments with mice indicate xylene-enhanced liver damage in virus-infected mice (Selgrade et al., 1993). Ethanol may be an antagonist to xylene toxicity (Padilla et al., 1992). Xylene has been shown to cause hearing loss in rats (Rybäk, 1992; Morata et al., 1994). Human experimental exposure to *m*-xylene has been reported to cause minor changes in electroencephalogram, although no adverse effects were noted (Seppäläinen et al., 1991).

SOURCES OF EXPOSURE

Possible exposure routes for xylene include inhalation, ingestion, eye contact, and to a small extent, through the skin.

Occupational

Occupational exposures to xylene occur in painters, laboratory workers, workers involved with distillation and purification of xylene, industries using xylene as a raw material, the petroleum industry, rubber and leather industries. Increased exposures have been observed for wood processing plant workers, painters, gas station employees, metal workers, and furniture refinishers (Kandyala et al., 2010). See paragraph above on background and abuses.

Environmental

Xylenes are released into the atmosphere from industrial sources (e.g., petroleum refineries, chemical plants), in automobile exhaust, and through volatilization from their use as solvents. Discharges into waterways and spills on land result primarily from use, storage and transport of petroleum products, and waste removal. Xylene concentrations range from 1 to 30 parts per billion (ppb) in outdoor air and 1–10 ppb in indoor air. Xylene has been detected in <5% of samples from groundwater surveys and the median concentrations have been less than or equal to 2 ppb. People can also be exposed to xylenes through smoking, consumption of xylene, and dermal contact with consumer products containing xylene. Inhalation is the main route of exposure to xylene. Xylene and toluene are chemicals known to be released from emission sources into the environment. A study in Japan found no difference between the indoor and outdoor concentrations of xylene and that levels of xylene in the living environment were not likely to cause adverse health effects (Sekizawa et al., 2007). No adverse health effects have been associated with background levels of xylene to which the general population is typically exposed.

INDUSTRIAL HYGIENE

Methods that can be used to control occupational exposures include process enclosure, local exhaust ventilation, general dilution ventilation, and as a last resort, PPE. The PPE can include safety goggles, a face shield, gloves, aprons, boots, and for high level ambient air concentrations a NIOSH-approved air-purifying respirator.

BIOMONITORING

The major pathway for metabolism of xylene involves mixed function oxidases in the liver, resulting mainly in the formation of isomers of methylhippuric acids (MHAs) in urine that can be measured in biomonitoring for xylene exposure. Workers exposed to the ACGIH TLV of 100 ppm should have 1.5 g MHA per gram creatinine (ACGIH, 2001) in their urine (end of shift). Other methods for biomonitoring, such as measurement of xylene in exhaled air, are also available (Glaser et al., 1990). Gas chromatography analysis of blood xylene has the lowest detection limit (Kawai et al., 1992). Jacobson and McLean (2003) reported that biological monitoring of occupational xylene exposure at levels <15 ppm using urinary MHA showed good correlation with airborne levels and is a valid complement to ambient monitoring. They added that recent exposure to xylene prior to biological monitoring can affect the results and should be considered. Their work predicted a

MHA concentration in post-shift urine of 1.3 g/g creatinine after exposure to a TWA of 100 ppm xylene, similar to the end of shift concentration previously described by the ACGIH. The highly lipophilic properties of xylene result in rapid absorption, rapid distribution, and quick elimination from the body. Measurement of blood levels of xylene is limited by the rapid metabolism of xylene. Measurement of xylene exposure by means of MHA in the urine should occur soon after exposure.

MEDICAL MANAGEMENT

Treatment of acute intoxication by xylene should include supportive care as needed, similar to other aromatic hydrocarbons. Fluid and electrolyte status as well as electrocardiogram (ECG) and vital signs must be monitored carefully. The clinician should also monitor for kidney failure and for pulmonary edema and respiratory failure, which may be delayed 24–72 h.

If xylene is ingested, induction of vomiting is generally not recommended due to the risk of hydrocarbon aspiration and chemical pneumonitis. Gastric lavage may be performed shortly after ingestion if significant amounts have been consumed (>5 ml) and the benefits outweigh the risk of aspiration. The volume of return should approximate the volume given.

In case of ocular exposure, the eyes should be irrigated for at least 15 min with warm water. If irritation persists, an ophthalmologist must be consulted.

Poison control centers can provide assistance for managing any overdose or intoxication. Contacting the Poison Control Center national hotline number (1-800-222-1222) connects the caller with the local poison control center in the area code where the call originates.

POLYAROMATIC HYDROCARBONS

Target organ(s): Kidneys, liver, adipose tissue.

OSHA PEL: The OSHA PEL for PAHs in the workplace is 0.2 mg/m³. OSHA has not established a substance-specific standard for occupational exposure to PAHs.

NIOSH (REL): 0.1 mg/m³ for coal tar pitch volatile agents.

The ACGIH (2005) has set a TLV for exposure to 0.2 mg/m³ for benzene-soluble coal tar pitch fraction.

Reference values: Vary by compound.

Risk/safety Phrases: Vary by compound.

BACKGROUND AND USES

Polycyclic aromatic hydrocarbons (PAHs), also known as polynuclear aromatics or polycyclic organic matter, are a large class of organic compounds consisting of three or more fused aromatic rings containing only carbon and hydrogen. The most common PAHs include benzo(a)anthracene, benzo(a)pyrene (BaP), benzo(e)pyrene, benzo(g,h,i)perylene, benzo(k)fluoranthene, chrysene, coronene, dibenz(a,h)acridine, dibenz(a,h)anthracene, and pyrene. They are found naturally in

petroleum products such as asphalt and tar. They are produced by incomplete combustion, pyrolysis, or pyrosynthesis of organic matter. They are produced naturally by forest fires and volcanoes; in ambient air from burning of coal, wood, oil or petroleum products; and during coke production and refuse burning (Cherng et al., 1996). They are also found in motor vehicle exhaust fumes. They are found in industries that produce or use coal tar, coke, or bitumen; they are also produced in coal gasification plants, smokehouses, incinerators, and aluminum production facilities.

They can be found in a number of common domestic items. Cooking foods at high temperatures, especially grilling and smoking meats, increases the PAH content of the food. Combustion of fuels in home heating and cooking appliances contributes to domestic PAH levels. Humans expose themselves directly to PAHs in cigarette smoke, mineral oils, skin care products and shampoos, medicines, dyes, and plastics. Polycyclic aromatic hydrocarbons are found in nearly all soils, where concentrations will vary depending on whether the local surroundings are rural, urban, or agricultural.

PHYSICAL AND CHEMICAL PROPERTIES

Polycyclic aromatic hydrocarbons are typically solids with low volatility at room temperature. Solubility varies by substance; however, they are soluble in most organic solvents and are relatively insoluble in water. Most of them can be photooxidized and degraded to simpler substances. Table 60.3 provides an identification of some carcinogenic and some noncarcinogenic PAHs, including their CASRNs and the IARC classifications of the carcinogenic compounds.

ENVIRONMENTAL FATE AND BIOACCUMULATION

According to the ATSDR (1995), background PAHs concentrations in ambient air vary from 0.02–1.2 ng/m³ in rural areas to 0.15–19.3 ng/m³ in urban areas (ATSDR, 1995).

TABLE 60.3 Polycyclic Aromatic Hydrocarbons

Carcinogenic	Noncarcinogenic
Benzo(a)pyrene (CASRN 50-32-8) IARC 1	Acenaphthene (CASRN 83-32-9)
Benzo(a)anthracene (CASRN 56-55-3) IARC 2	Anthracene (CASRN 120-12-7)
Benzo(b)fluoranthene (CASRN 205-99-2) IARC 2B	Benzo(g,h,i)perylene (CASRN 191-24-2)
Benzo(k)fluoranthene (CASRN 207-08-9) IARC 2B	Dibenzofuran (CASRN 132-64-9)
Benzo(g,h,i)perylene (CASRN 191-24-2) IARC 3	Fluoranthene (CASRN 206-44-0)
Chrysene (CASRN 218-01-9) IARC 2B	Fluorene (CASRN 86-73-7)
Dibenzo(a,h)anthracene (CASRN 53-70-3) IARC 2B	2-Methylnaphthalene (CASRN 91-57-6)
Indeno(1,2,3-c,d)pyrene (CASRN 193-39-5) IARC 2B	Naphthalene (CASRN 91-20-3)
	Phenanthrene (CASRN 85-01-8)
	Pyrene (CASRN 129-00-0)

Airborne deposition accounts for most of the PAHs found in soil. As previously stated, PAHs are found in nearly all soils with concentrations varying depending on the specific PAH and the environment. They can mobilize out of the soil and into ground- and surface waters. Spills may also lead to contamination of the soil and water. They do bioaccumulate.

ECOTOXICOLOGY

Quantitative information on PAHs varies from compound to compound. Based on solubility, PAHs are not expected to accumulate in water but may accumulate in sediments and soil. Soils near oil refineries and other industrial complexes may be as high as 200,000 µg/kg of dried soil.

MAMMALIAN TOXICOLOGY

Acute Effects

Polycyclic aromatic hydrocarbons have a low degree of acute toxicity in humans. There are minor hazards associated with acute occupational or environmental exposure to PAHs as a class. The NIOSH has set supplementary exposure limits for several PAHs, namely, asphalt fumes (BaP), carbon black and coal tar pitch volatiles. Supportive treatment is recommended for any acute skin, eye, or respiratory irritation.

Chronic Effects

Chronic exposure to PAHs may be associated with increased risk of lung and skin cancers and possibly urological, gastrointestinal, laryngeal, and pharyngeal cancers based on several epidemiological studies, some of which are only suggestive and not conclusive (Clavel et al., 1994; Eisen et al., 1994; Partanen and Boffetta, 1994; Murata et al., 1997; Armstrong et al., 2004; Kim et al., 2013). These studies provide only qualitative evidence of the carcinogenic potential of PAHs in humans because of the presence of multiple PAHs and other exposures to putative carcinogens and the lack of quantitative monitoring data.

Chronic PAH exposure is associated with multiple non-carcinogenic toxicities (Brucker et al., 2013). Long-term reduction in antibody responsiveness can follow administration of 7,12-dimethylbenz-(a)anthracene and BaP to mice (Stjernsward, 1966; Ward et al., 1986). Mice exposed to BaP showed depressed responses to B- and T-cell mitogens (Dean et al., 1993). Exposure of pregnant female mice to BaP resulted in severe depression of antibody responses in pups immediately after birth (Urso and Gengozian, 1980). This suppression persisted for well over 1 year and was accompanied by an increase in the incidence of tumors in adults. 3-Methylcholanthrene, another carcinogenic PAH,

may suppress formation of cytotoxic T-cells (Wodjani and Alfred, 1984). 7,12-Dimethylbenzo(a)anthracene produced long-term immunosuppression of antibody production, natural killing, and cytotoxic T-lymphocyte cytotoxicity (Ward et al., 1986). Thus, 7,12-dimethylbenzo(a)anthracene appeared to affect all phases of immunologic protection in mice, including mechanisms of tumor resistance. Immunological suppression of tumor-resistance mechanisms by PAHs tends to correlate with the carcinogenic potency of the chemical. Immunosuppressive PAHs tend to be carcinogenic, but nonimmunosuppressive congeners are not (Ward et al., 1985).

A study of roofers exposed to PAHs suggested an excess of lung, stomach, and bladder cancer (Partanen and Boffetta, 1994). A 10-year longitudinal study reported by Hansen (1992) revealed that Danish stokers exposed to PAH and benzene had an excess mortality, especially from cancer and circulatory diseases. Hansen et al., 2004, determined that bus drivers in Denmark excreted more 1-hydroxypyrene (1-OHP) in their urine than did mail carriers. This mirrored their PAH exposures.

MECHANISM OF ACTION

Cells most likely affected by PAH exposure appear to be those with rapid replicative turnover such as those in pulmonary, dermal, and reproductive tissues. Tissues with lower turnover rates, such as the liver, are less susceptible. The liver is the main site of metabolism of PAHs, although metabolism can also occur in extrahepatic tissues. Metabolic bioactivation appears to be necessary for production of the proximate carcinogenic form of PAHs.

After absorption, PAHs enter the lymph, circulate in the blood, are metabolized primarily in the liver and kidney, and are excreted in both bile and urine. Additionally, metabolism of PAHs occurs in the adrenal glands, testes, thyroid, lungs, skin, sebaceous glands, and small intestine. Metabolic activation of PAHs is primarily catalyzed by the cytochrome P-450-dependent microsomal enzyme system, aryl hydrocarbon hydroxylase (AHH) (Andrysik et al., 2007). Polycyclic aromatic hydrocarbons are metabolized by AHH initially to epoxides, which are converted by epoxide hydrolases to dihydrodiol derivatives and diol-epoxides (Levin et al., 1982). These metabolites are the reactive carcinogenic intermediates resulting from metabolism and may be detoxified by further conjugation with GSH or other substrates. Glucuronide and sulfate conjugates of these metabolites are excreted in the bile. Glutathione conjugates are further metabolized to mercapturic acid metabolites in the kidney and are excreted in the urine. Polycyclic aromatic hydrocarbons are generally non-mutagenic or very slightly mutagenic *in vitro*; however, their metabolites or derivatives may be potent mutagens. They may induce some of the isozymes of the cytochrome P-450 enzyme

system leading to increased metabolism, thereby generating greater amounts of reactive intermediates (electrophiles) capable of forming PAH-DNA adducts at a site critical to cell differentiation and growth.

More than 1500 PAHs have been identified and approximately 16 are commonly monitored. A number of specific toxicities are associated with exposure to PAHs. They have been shown to suppress the immune responses in animals and induce microsomal enzymes; many are carcinogenic in animal models. Benzo(a)pyrene is one of the most potent animal carcinogens of this class. Human exposure to this compound is widespread. It is estimated that annual airborne emission of BaP exceeds 900 tons in the United States alone. Of the PAHs tested, only benzo(a,h)anthracene has been shown to have greater carcinogenic potency than BaP (Krewski et al., 1989), although others, including perylene, cyclopenta(cd) pyrene, and fluoranthene have been shown to have greater mutagenic potency than BaP (Slaga et al., 1981). With the exception of benzo(a,h)anthracene, all other PAHs are much less potent carcinogens than BaP; some lack carcinogenic potency altogether.

SOURCES OF EXPOSURE

Human exposure to PAHs can occur through inhalation, ingestion, and eye or skin contact. The National Academy of Science has estimated that a member of the general population has an average daily intake of 0.21 µg PAHs from air, 0.03 µg from water, and 1.6–16 µg from food (National Academy of Science, 1986).

Occupational

As early as 1775, Sir Percival Pott reported cancer of the scrotum in chimney sweeps as a result of exposure to soot containing PAHs. In 1992, Southam and Wilson reported that 48% of the men diagnosed with scrotal cancer were engaged in mulespinning in the cotton industry, where their thighs and scrotum came in frequent contact with the oil. A causal association between scrotal squamous cell carcinoma in the northwest of England and exposure to PAHs was suggested by Lee, Alderson, and Downes in 1972. These early reports followed by several epidemiological studies have suggested an increased risk of cancer of the skin, lung, bladder, gastrointestinal tract, and scrotum associated with PAH exposure (Southam and Wilson, 1992). Among these, the lungs and skin are the most frequently reported target organs (Lee et. al., 1972).

The atmospheric concentrations of PAHs found during occupational exposures may range from <10 to >10,000 ng/m³, depending on the source of exposure and on the workplace (Linstedt and Sollenberg, 1982). In cities with coke ovens, the concentration of airborne PAHs may reach 150 ng/m³ of air (the permissible workplace exposure limit for coke oven

emissions is 150,000 ng/m³). Coal tar pitch and creosote produced in coke ovens contain significant amounts of BaP and other PAHs. Water contamination may occur as a result of industrial effluents and accidental spills from oil shipments at sea. The background level of PAHs in drinking water ranges from 4 to 24 ng/l. Polycyclic aromatic hydrocarbon levels as high as 200 ng/kg of dried soil were documented in soil near oil refineries. The levels can go up as much as 10-fold in soil samples obtained near cities and areas with heavy vehicular traffic. They can leach from the soil into water. The Environmental Protection Agency's (EPA) proposed maximum level of contamination for BaP in drinking water is 0.2 ppb. The concentrations of PAHs in foodstuffs vary. Charring meat or barbecuing other food over a charcoal fire greatly increases the concentration. Smoked fish may contain up to 2.0 µg/kg of BaP. Roasted peanuts and coffee, refined vegetable oil, and many other food items contain PAHs. Cigarette smoke contains PAHs. One cigarette yields 10–50 ng of BaP, 18 ng chrysene, 40 ng dibenzo(a)anthracene, and 12–140 ng benzo(a)anthracene. Asphalt and tar, as well as medicated shampoo and ointments, may contain significant quantities of PAHs.

Industries with workers at greatest risk of PAH exposure are aluminum, asphalt, carbon black, chimney cleaning, coal gasification, coke oven operation, fisheries (coal tar nets), graphite electrodes, industries that employ machinists and mechanics (automobile and diesel engines), printing, road paving, roofing, steel foundries, and tire and rubber manufacturing. Workers exposed to creosote may be carpenters, farmers, railroad workers, tunnel construction workers, and utility workers.

The routes of exposure may be inhalation of PAH aerosols and gas or dermal absorption, and PAHs can also be ingested via the food and water, if contaminated. The predominant route of exposure will be determined by the industry involved and safety precautions taken. Alternate exposures to coal tar may be while being used to treat patients with atopic dermatitis, psoriasis, dermatitis, and chronic eczema. Studies by Hansen et al. (1993a, 1993b) of patients treated with coal tar revealed a dramatic increase in urinary PAH metabolites. Concentrations of 1-hydroxyperylene reached levels about 100 times that of pretreatment levels during the first week of treatment. Levels of alpha-naphthol increased 5–10 times that of 1-hydroxyperylene because of the higher levels of naphthalene in coal tar. Two weeks after the treatment was begun, levels of both metabolites had dropped to a third or less of their peak. Polycyclic aromatic hydrocarbon exposure may have induced liver enzymes to effectively metabolize PAH or the skin may become less permeable to PAHs.

A protective airstream helmet was shown to significantly reduce exposure and lower the dose of PAHs received (Jongeneelen et al., 1990). The TLV for PAHs, based on the benzene soluble fraction of sampled dust, is 0.2 mg/m³ (ACGIH, 2005).

Environmental

The general population may be exposed to various PAHs through contact with contaminated soils or sediments, ingestion of drinking water and foods, and inhalation of air (HSDB, 2003). Polycyclic aromatic hydrocarbons are found in vehicle exhaust, coal, asphalt fumes, coal tar fumes, hazardous waste sites, wildfires, and cigarette smoke.

BIOMONITORING

Determination of PAH exposure can be made with HPLC analysis of 1-hydroxyrene in urine (Jongeneelen et al., 1990; Buchet et al., 1992; Hansen et al., 1993a; Hansen et al., 1993b; Boogaard and van Sittert, 1994; Øvrebø et al., 1994). This measurement is usually expressed in milligram of 1-hydroxyrene per milligram creatinine or nanogram per millimole of creatinine. To date, this is the most effective method for determining the level of PAH exposure in workers. However, this method is time consuming, inconvenient, and expensive if used for large-scale screening. It is also useful only for exposures that have occurred in the previous 18 h. Further research has attempted to find a more convenient method by which both long- and short-term PAH exposure could be determined. Moreover, quantitative evaluation of 1-hydroxyrene in urine does not provide any information useful for evaluating the amount of PAH interaction with DNA.

Because binding of PAH metabolites to DNA is the key to the initiation of cancer, attempts have been made to quantitate PAH–DNA adducts in nucleated white blood cells and also to measure blood protein adducts (albumin and hemoglobin) and use these as surrogates for the target tissue to assess exposure and estimate risk.

Analytical techniques for monitoring DNA adducts in the peripheral blood cells of exposed subjects include immunological methods such as ultrasensitive enzymatic radioimmunoassay (USE-RIA), enzyme-linked immunosorbent assay (ELISA), and ³²P-postlabeling assay, and a chemico-physical assay-synchronous fluorescence spectrometry (SFS) (dell’Omo and Lauwerys, 1993). All these methods are sensitive enough to detect PAH–DNA adducts resulting from environmental and occupational exposure. However, a direct comparison of adduct levels measured by different techniques may be misleading because they measure different end points. Reports from different laboratories cannot be compared because of the lack of interlaboratory standardization of the methodology.

Immunoassays use polyclonal antibodies (antisera) or monoclonal antibodies to detect specific DNA adducts. As known universally, ELISA uses a substrate for the enzyme-linked second antibody, which generates either colored or fluorescent products. The procedure for USE-RIA involves a radiolabeled substrate instead of a nonradiolabeled substrate

as used in ELISA. Results from human samples are calculated with reference to benzo(a)pyrene diol epoxide (BaPDE)–DNA adduct curves, and antisera recognize multiple PAH–DNA adducts. Data are usually expressed as levels of BaPDE–DNA antigenicity (in femtomole BaPDE per microgram DNA), which give the equivalent percentage of inhibition. These assays with antisera detect one BaPDE–DNA adduct per 107–108 bases in DNA. A higher sensitivity has been reached with a fiber-optic antibody-based fluoroimmunosensor used to detect BaP tetrols released from placental DNA by mild acid hydrolysis. Rabbit antisera raised against BaPDE-modified DNA have been used in biomonitoring groups occupationally exposed to PAH (i.e., coke-oven workers, foundry workers, roofers, and firefighters) (dell’Omo and Lauwerys, 1993).

Herikstad et al. (1993) have developed a relatively sensitive radioimmunoassay to determine levels of PAH in urine. Their method measures the level of eight PAH metabolites per nanomole creatinine. Although their results reflected seasonal variation (lower levels in winter, higher in summer), the assay does appear to be sensitive enough to rank levels of exposure. This method still has the shortcoming of only reflecting short-term exposure. Immunoassays couple high sensitivity with a relatively simple technique and are particularly suitable for a large number of samples. Principal drawbacks include production and characterization of specific antisera and monoclonal antibodies, as well as rigorous standardization of the methodology.

Several epidemiological studies (Phillips et al., 1988; Hemminki et al., 1990) have involved the ³²P-postlabeling assay for the analysis of PAH–DNA adducts. It is a nonspecific procedure detecting several aromatic/hydrophobic adducts, hence providing total adduct levels resulting from interaction with DNA with a host of chemicals in an occupational exposure situation. This method detects the presence of 1 DNA adduct in 107–108 nucleotides (Gupta et al., 1982). A higher sensitivity of up to 1 adduct in 10⁴-degree nucleotides can be achieved using the nuclease P1 procedure for the enrichment of DNA digests. However, results may be underestimated because it is not usually known how resistant unknown aromatic adducts are to nuclease P1 digestion. It is claimed to be particularly useful for the measurement of adducts derived from exposure to complex mixtures from unknown carcinogens. It is technically complex and hence can be unsuitable for screening in an occupational health practice. Moreover, different enrichment procedures should be investigated for better adduct recovery, and the final step of adduct detection should be improved to increase specificity.

Synchronous fluorescence spectrometry has been used to analyze BaP–DNA adducts in human lymphocytes because of the intrinsic fluorescence associated with BaP and its metabolites. This method can identify 1 adduct per 107 nucleotides. The specificity is sometimes not enough to detect the chemical of interest in complex mixtures. The

specificity can be increased using HPLC as a separating method before quantitation (HPLC/SFS) (Weston et al., 1989). Synchronous fluorescence spectrometry has been used in several epidemiological studies for the detection of BaPDE-DNA adducts (Harris et al., 1985; Vahakangas et al., 1985; Haugen et al., 1986). After isolation using immunoaffinity chromatography, BaP tetrols from placental DNA extracts also have been quantitated by second-derivative SFS (Weston et al., 1989).

Numerous studies have attempted to find a relationship between PAH exposure and levels of PAH-DNA adducts. Results have been conflicting. In some studies, subjects exposed in the workplace to PAH had higher levels of PAH-DNA adducts, whereas in others there was no appreciable difference (Reddy et al., 1991; Szyfter and Hemminki, 1992; Øvrebø et al., 1994). Even in studies that reported differences between those occupationally exposed and controls, there was no strong association between levels of DNA adducts and actual exposure level. Studies of exposure to PAHs resulting from environmental pollution and levels of PAH-DNA adducts also failed to find a correlation (Hemminki et al., 1990). An overall evaluation indicates that these methods of detection of PAH-DNA adducts can presently be applied for assessing PAH exposure on a group basis, but they are not suitable for assessing exposure or predicting adverse health effects on an individual basis because neither normal nor toxic levels have been determined.

Studies, although few, have been conducted to determine whether a correlation between PAH exposure and PAH-hemoglobin adducts exists. Results suggest that, although those exposed to PAHs may have higher concentrations of adducts, there is not a direct mathematical correlation to exposure level (Ferreira et al., 1994; Perera et al., 1994).

Somatic gene mutation at the hypoxanthine guanine phosphoribosyl transferase (HPRT) locus in lymphocytes has been tested as an indicator for exposure to environmental mutagenic agents like PAHs. According to Perera et al. (1994), HPRT mutation frequency shows a direct correlation with PAH-DNA binding, which is consistent with experimental studies involving BaP (Arce et al., 1987; MacLeod et al., 1988). Further research is required to analyze spectra of HPRT mutation in the workers exposed to PAH, which may provide a signature mutation(s) for this exposure.

The ACGIH (2005) has recommended 1-OHP, the metabolite of the common PAH pyrene, for use as an end of shift/end of workweek indicator of PAH exposure. This assessment is complicated because 1-OHP is an accepted marker of exposure to PAHs for traffic-related air pollution. In general, biological monitoring can be an effective indicator of possible PAH exposure, but it is still difficult to assess the extent of exposure and the resultant dose, especially with low level environmental or occupational exposure. This difficulty results from several factors, including interindividual variability, confounding effects of drugs or cigarettes, and nonspecificity of monitoring

techniques. Twenty-two hydroxylated PAH metabolites were measured in urine specimens as part of the National Health and Nutrition Examination Survey (NHANES) among participants aged 6 years and older during 2007–2008. The NHANES survey found the geometric mean for urinary 1-OHP was 119 ng/mg creatinine (CDC, 2013).

MEDICAL MANAGEMENT

Polycyclic aromatic hydrocarbons are associated with a low order of acute toxicity in humans. Acute exposures should be addressed based on the symptoms. Contaminated clothing should be removed from exposed persons as soon as possible. The skin is decontaminated by gently scrubbing it with soap and water. Ocular contamination can be treated with irrigation of the eye with saline or water followed by a complete eye examination. For an acute inhalation exposure, ventilatory support is tailored to the patient's clinical condition.

HYDROQUINONE

Occupational exposure limits: 2 mg/m³ (OSHA PEL); 2 mg/m³ (NIOSH REL, 15-min ceiling); 2 mg/m³ (ACGIH TLV); derived no effect level (DNEL); DNEL inhalation, systemic effects, long term: 7 mg/m³; DNEL inhalation, local effects, long term: 1 mg/m³; DNEL dermal, systemic effects, long term: 128 mg/kg-bw/day (NIOSH, 1994).

Reference values: DNEL inhalation, systemic effects, long term: 1.74 mg/m³; DNEL inhalation, local effects, long term: 0.5 mg/m³; DNEL dermal, systemic effects, long term: 64 mg/kg-bw/day.

Hazard statements: H302—harmful if swallowed; H317—may cause an allergic skin reaction; H318—causes serious eye damage; H341—suspected of causing genetic defects; H351—suspected of causing cancer; H410—very toxic to aquatic life with long-lasting effects (ACGIH, 1995).

Precautionary statements: P201—obtain special instructions before use; P261—avoid breathing dust/fume/gas/mist/vapours/spray; P273—avoid release to the environment; P280—wear protective gloves/protective clothing/eye protection/face protection; P305 + P351 + P338—if in eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P310—immediately call a poison center or doctor/physician.

Risk phrases: R22—harmful if swallowed; R40—limited evidence of a carcinogenic effect; R41—risk of serious damage to the eyes; R43—may cause sensitization by skin contact; R50—very toxic to the aquatic organisms; R68—possible risk of irreversible effects.

Safety phrases: S2—keep out of the reach of children; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S36/37/39—wear suitable protective clothing, gloves, and eye/face protection; S61—avoid release to the environment. Refer to special instructions/safety data sheets.

BACKGROUND AND USES

Hydroquinone (*p*-benzenediol, 1,4 benzene diol, dihydroxy benzene, 1,4 dihydroxy benzene, quinol, CASRN 123-31-9) exists as colorless to light-tan or light-gray crystals under standard conditions. It has a vapor pressure of 0.00001 mmHg and a solubility in water by weight of 7%.

Skin bleaching creams containing 4% hydroquinone are currently available for use according to a physician's supervision (Arndt and Fitzpatrick, 1965; Spencer, 1965; Brody, 1989). The bleaching effect produced is reversible. Hydroquinone is widely used in photography as a developer (Nowak et al., 1995). It is also produced *in vivo* as a metabolite of benzene. In nature, it is found in several arthropods and in the African plant Noogoora burr (*Xanthium pungens*). Concentrations of hydroquinone in this plant are adequate to poison pigs and cattle.

HEALTH EFFECTS

Acute Effects

Acute excessive exposures to hydroquinone in industry are unusual. When they occur, the symptoms produced resemble an acute exposure to phenol. Symptoms include hypersensitivity, hyperactive reflexes, dyspnea, and cyanosis. Exhaustion, hypothermia, convulsions, coma, and death may follow. Methemoglobin occurs quickly and can produce anoxia. If death occurs, it is usually as a result of respiratory failure. Dusts can adhere to the eyes and cause localized damage. Ingestion of small amounts can cause gastroenteritis (Hooper et al., 1978).

Chronic Effects

Hydroquinone is thought to have caused corneal damage and severe astigmatism in some hydroquinone workers (Naumann, 1966). There have been reports of hepatitis and anaplastic anemia in darkroom workers exposed to hydroquinone (Nowak et al., 1995).

TARGET ORGANS AND MECHANISM OF ACTION

Hydroquinone did not produce covalent adducts in kidneys in male and female rats (English et al., 1994). No reproductive effects were noted in rats dosed with hydroquinone (Blacker et al., 1993). It has been shown to cause chromosomal breakage *in vitro* (Dobo and Eastmond, 1994).

Hydroquinone promotes skin bleaching by inhibiting melanogenesis. In an amphibian model, hydroquinone simultaneously induced indole amine 2,3-dioxygenase and inhibited tyrosinase (Chakraborty et al., 1993).

Chronic exposure to hydroquinone can cause brown discoloration of the cornea and stromal degeneration (Naumann, 1966). This may account for the severe astigmatism reported by hydroquinone workers.

In vivo hydroquinone is metabolized to quinone, a more toxic metabolite. It is also oxidized to quinone in the presence of sunlight or air.

INDUSTRIAL HYGIENE

The OSHA has set the PEL for hydroquinone at 2 mg/m³. The NIOSH REL is slightly more stringent, with 2 mg/m³ being the 15-min ceiling (NIOSH, 1994). Concentrations of 50 mg/m³ or greater are considered to be IDLH.

The ACGIH (1995) has set a TLV for hydroquinone at 2 mg/m³. The ACGIH has also proposed designating hydroquinone as an A3 carcinogen, indicating that it is a carcinogen in experimental animals.

TREATMENT

Treatment is essentially symptomatic. Because acute poisonings from hydroquinone are rare, information on treatment is limited. Exposures should be treated in a similar manner to phenol exposure. If ingested, dilution with water or milk is suggested. Vomiting may be induced if the patient is not experiencing seizures. However, it is not indicated whether seizures are likely to occur because it could induce seizures. Gastric lavage may be performed if it is done soon after ingestion or if the patient is comatose or at risk of convulsions. Other symptomatic treatment should be undertaken as necessary.

OTHER HETEROCYCLIC COMPOUNDS

TURPENTINE

Occupational exposure limits: 100 ppm (OSHA PEL, NIOSH REL, ACGIH TLV); DNEL; DNEL inhalation, systemic effects, long term: 11.3 mg/m³; DNEL inhalation, local effects, long term: 0.77 mg/m³; DNEL dermal, systemic effects, long term: 1.6 mg/kg-bw/day.

Reference values: DNEL oral, systemic effects, long term: 0.57 mg/kg-bw/day.

Hazard statements: H225—highly flammable liquid and vapor; H302—harmful if swallowed; H304—may be fatal if swallowed and enters the airway; H312—harmful if it comes in contact with the skin; H315—causes skin irritation; H317—may cause an allergic skin reaction; H319—causes serious eye irritation; H332—

harmful if inhaled; H411—toxic to aquatic life with long-lasting effects.

Precautionary statements: P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking; P233—keep container tightly closed; P240—ground/bond container and receiving equipment; P241—use explosion-proof electrical/ventilating/lighting/ . . . /equipment; P242—use only non-sparking tools; P243—take precautionary measures against static discharge; P280—wear protective gloves/protective clothing/eye protection/face protection; P303 + P361 + P353—if on skin (or hair), remove/take off immediately all contaminated clothing; rinse the skin with water/shower; P370 + P378—in case of fire, use . . . for extinction; P403 + P235—store in a well-ventilated place; keep cool; P501—dispose of contents/container to . . . ; P264—wash . . . thoroughly after handling; P270—do not eat, drink, or smoke when using this product; P301 + P312—if swallowed, call a poison center or doctor/physician if you feel unwell; P330—rinse mouth; P280—wear protective gloves/protective clothing/eye protection/face protection; P302 + P352—if on skin, wash with plenty of soap and water; P312—call a poison center or doctor/physician if you feel unwell; P322—specific measures (see . . . on the label); P363—wash contaminated clothing before reuse; P261—avoid breathing dust/fume/gas/mist/vapors/spray; P271—use only outdoors or in a well-ventilated area; P304 + P340—if inhaled, remove victim to fresh air and instruct the victim to rest in a position comfortable for breathing; P331—do not induce vomiting; P405—store locked up; P305 + P351 + P338—if in the eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing; P337 + P313—if eye irritation persists, get medical advice/attention; P321—specific treatment (see . . . on the label); P332 + P313—if skin irritation occurs, get medical advice/attention; P362—take off contaminated clothing and wash before reuse; P272—contaminated work clothing should not be allowed out of the workplace; P280—wear protective gloves/protective clothing/eye protection/face protection; P333 + P313—if skin irritation or rash occurs, get medical advice/attention; P321—specific treatment (see . . . on the label); P273—avoid release to the environment; P391—collect spillage.

Risk phrases: R11—highly flammable; R20/21/22—harmful by inhalation, in contact with the skin, and if swallowed; R36/38—irritating to the eyes and skin; R43—may cause sensitization by skin contact; R51/53—toxic to aquatic organisms, may cause long-term adverse effects in the aquatic environment.

Safety phrases: S16—keep away from sources of ignition . . . no smoking; S2—keep out of the reach of children;

S36/37—wear suitable protective clothing and gloves; S46—if swallowed, seek medical advice immediately and show this container or label; S61—avoid release to the environment. Refer to special instructions/safety data sheets; S62—if swallowed, do not induce vomiting: seek medical advice immediately and show this container or label.

BACKGROUND AND USES

The use of turpentine (CASRN 8006-64-2) for suicidal and homicidal purposes has become quite infrequent with the increased availability of pesticides and other toxic substances (Pande et al., 1994). Available literature contains few case reports of turpentine poisoning. Turpentine has been nearly eliminated from formulas of ready-made interior oil-based paints, but it is used in shoe polishes and as a raw material in the manufacture of synthetic camphor and terpin hydrate.

HEALTH EFFECTS

Filipsson (1996) described the toxicokinetics, pulmonary effects, and subjective rating of discomfort for turpentine vapor (a mixture of monoterpenes). The subjects experienced discomfort in the throat and airway during an exposure to turpentine, and airway resistance was increased at the end of exposure.

Distilled or wood turpentine contains methyl alcohol, formaldehyde, phenols, and pyridine. Some of these compounds are irritating to the skin, and the use of this kind of turpentine has been followed by outbreaks of dermatitis in the United States, Britain, and Italy (McCord, 1926).

Chapman (1941) reported a careful review of the effect of paint on the kidneys, with particular reference to the role of turpentine. His interest was aroused by two cases, both fatal, of extensive glomerulonephritis. The changing use of turpentine in recent years may account for the absence of current reports of kidney damage associated with its use.

HISTOPATHOLOGY

Pleural effusions were produced by intrapleural turpentine instillation in mice. The fine structure of the inflammatory cells obtained from the effusions was normal except for lipid inclusions (Nielsen et al., 1992). The same type of inclusion was previously found in neutrophils from pleural effusions in patients with tuberculous infection, rheumatoid disease, or carcinomatosis.

INDUSTRIAL HYGIENE

NIOSH (1994), OSHA, and the ACGIH (1996) have set the REL, PEL, and TLV for turpentine at 100 ppm.

AMINO AND NITRO COMPOUNDS

DAVID Y. LAI AND YIN-TAK WOO

Amino and nitro compounds are important classes of industrial chemicals that contain at least one amino or nitro group attached to an aryl or aliphatic moiety. Since the mid-1800s, they have found numerous uses in various industries that manufacture dyes and pigments, rubber, polymers, agricultural chemicals, pharmaceuticals, and photographic chemicals. Hence, occupational exposure to amino and nitro compounds has been widespread. Beyond occupational exposure, public populations may also be exposed to these chemicals. For instance, the ingredients of typical permanent and semi-permanent hair colorants are primarily aromatic amines, aminophenols, nitro-substituted aromatic amines, aminoanthraquinones, and azodyes. Some commonly used pharmaceuticals also are aromatic amines and nitro compounds.

Epidemiologic evidence has indicated that exposures to aromatic amines such as benzidine and 2-naphthylamine are linked to increased incidences of cancers in exposed workers in dyes industry. Experimental studies have shown that many other amino and nitro compounds are carcinogens, mutagens, skin sensitizers, and hematotoxicants capable of inducing methemoglobinemia. Aromatic nitro compounds share many toxicological effects with aromatic amines since their nitro groups can readily be reduced to become amines. Considerable information suggests that the aromatic amines require metabolic activation to yield reactive intermediates for their toxicity and carcinogenicity, and the mechanism of activation of aromatic amines is now known in considerable detail (Woo and Lai, 2012; Lai et al., 1996; Woo et al., 1988). The first stage of metabolic activation involves *N*-hydroxylation and/or *N*-acetylation by the mixed-function oxidase system in the liver to yield the respective *N*-hydroxylated and/or

N-acetylated derivatives. The second stage involves further activation by *N,O*-transacetylation or by *O*-acylation (where the acyl group can be sulfonyl or acetyl) to acyloxyarylamines. Many of the reactive metabolites formed appear to be responsible for their toxic activity. For instance, the acyloxyarylamines are highly reactive and generate, upon departure of the acyloxy anion, electrophilic arylamidonium/arylnitrenium ions, which may readily bind covalently to cellular nucleophiles such as DNA to initiate mutagenesis and carcinogenesis. Ortho-substitution with methyl/methoxy group to unsubstituted aromatic amine or nitrobenzene can substantially enhance carcinogenic potential. *o*-Toluidine and *o*-anisidine are known to be more carcinogenic than aniline. Likewise, *o*-nitrotoluene and *o*-nitroanisole are more carcinogenic than nitrobenzene. The higher carcinogenic potency of the *o*-isomer as compared to other isomers (*m*- and *p*-) or to the unsubstituted aromatic amine or nitrobenzene is likely due to differences in binding capability of the compounds to the metabolic activation enzymes (Woo and Lai, 2012).

After peaking, during the past few decades, United States production of many hazardous amino and nitro compounds has declined or even ceased. Recent worldwide production and sales volume, however, is still growing at steady rate, and the supply of many of these compounds is shifting from the United States to East Asian countries along with textile and dye production. In this chapter, the production, exposure, toxicology, pathology, and regulations of three amino and three nitro aromatic compounds with high production volumes will be reviewed. Related information on other amine and amino compounds can be found in another review by the authors (Woo and Lai, 2012).

ANILINE

Occupational exposure limits: 19 mg/m³ (OSHA PEL); 7.6 mg/m³ (ACGIH TLV); derived no effect level (DNEL); DNEL inhalation, systemic effects, long term: 7.7 mg/m³; DNEL inhalation, systemic effects, short term: 15.4 mg/m³; DNEL dermal, systemic effects, long term: 2 mg/kg/bw/day; DNEL dermal, systemic effects, short term: 4 mg/kg/bw/day

Reference values: 0.001 mg/m³ (IRIS RfC)

Hazard statements: H400—very toxic to aquatic life; H410—very toxic to aquatic life with long lasting effects; H301—toxic if swallowed; H311—toxic if contact with skin; H331—toxic if inhaled; H318—causes serious eye damage; H317—may cause an allergic skin reaction; H341—suspected of causing genetic defects; H351—suspected of causing cancer; H372—causes damage to blood and hematopoietic system through prolonged or repeated exposure

Precautionary statements: P273—avoid release to the environment; P280—wear protective gloves/protective clothing/eye protection/face protection; P301 + P310—if swallowed, immediately call a poison center or doctor/physician; P302 + P352—if on skin, wash with plenty of soap and water; P304 + P340—if inhaled, remove victim to fresh air and keep at rest in a position comfortable for breathing; P305 + P351 + P338—if in eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing

Risk phrases: R23/24/25—toxic by inhalation, in contact with skin and if swallowed; R41—risk of serious damage to eyes; R43—may cause sensitization by skin contact; R48/23/24/25—toxic: danger of serious damage to health by prolonged exposure through inhalation, in contact with skin, and if swallowed; R68—possible risk of irreversible effects; R40—limited evidence of a carcinogenic effect; R50—very toxic to aquatic organisms

Safety phrases: S1/2—keep locked up and out of reach of children; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S27—take off immediately all contaminated clothing, wash with water and soap; S36/37/39—wear suitable protective clothing, gloves, and eye/face protection; S46—if swallowed, seek medical advice immediately and show this container or label; S61—avoid release to the environment; refer to special instructions/safety data sheets; S63—in case of accidental inhalation: remove casualty to fresh air and keep at rest

BACKGROUND AND USES

Aniline (CASRN 62-53-3) is the simplest of the aromatic amines with an amino group attached to a benzene. It has

been produced commercially for decades in the manufacture of a wide variety of products such as dyestuffs, dye-stuff intermediates, rubber accelerators, and polyurethane foams. The largest users of aniline are companies that make isocyanates, especially methyl diphenyl diisocyanate. Other companies use aniline to make pesticides, dyes, and rubber. Companies also use smaller amounts of aniline to make drugs, photographic chemicals, varnishes, and explosives.

From 1969 to 1988, aniline production in the United States grew at an average annual rate of 6%; total production of aniline by eight U.S. companies amounted to 467 million kg in 1988. From 1990 to 2002, U.S. annual production of aniline had been more than 1 billion pounds (U.S. EPA, 2004). Current production figures were not available but aniline demand in the United States was expected to grow at an average annual rate of 4–6% per year (Amini, 1992). In 1979, aniline productions in Japan and Western Europe were estimated to be between 79 and 500 million kg, respectively (IARC, 1982).

Aniline derivatives such as nitro, chloro, chloronitro, *N*-alkyl, and *N,N*-dialkylaniline are also widely used in industry as intermediates in chemical synthesis. Aniline and many of its derivatives have a similar pattern of toxicity. They are all hematotoxic and have been shown to cause methemoglobinemia. *m*-Nitro, *o*-chloro, *m*-chloro, and 2,4-dichloroanilines are irritants to the skin and mucous membrane. Several dichloroanilines have been demonstrated to be skin sensitizers. Aniline and its monochloro derivatives are also nephrotoxic and hepatotoxic. Although there is limited or equivocal evidence of carcinogenicity in rodent studies, they are considered as suspect human carcinogens. In general, alkyl derivatives of aniline are less toxic.

However, addition of chloro or nitro groups on the phenyl ring increases the toxicity of aniline; the ortho-substitution produces the greatest enhancement. More information can be found in several toxicological reviews on aniline (U.S. EPA, 2012a, 1994; ASTDR, 2011; IARC, 1987, 1982) and its derivatives (Woo and Lai, 2012).

PHYSICAL AND CHEMICAL PROPERTIES

Aniline (C₆H₇N), also called aminobenzene, is the prototypical aromatic amine consisting of a phenyl group attached to an amino group. It is a colorless to brown oily liquid with a characteristic aromatic or fishy odor and is flammable. It has a molecular weight of 93.13, a density of 1.002, a melting point of −6.2 °C, a boiling point of 184–186 °C, a vapor density of 3.22 (air = 1), a vapor pressure of 15 mm Hg (77 °C), and a refractive index of 1.5863 (20 °C). Aniline is slightly soluble in water and is miscible with most organic solvents (Budavari et al., 1996; Woo and Lai, 2012).

MAMMALIAN TOXICOLOGY

Acute Effects

Aniline can be absorbed from the skin, lungs, and gastrointestinal tract. Contact with aniline liquid or vapor may cause mild irritation to skin or eyes. Ingestion or inhalation of aniline can lead rapidly to severe systemic toxicity. The major acute toxic effects of aniline in experimental animals are methemoglobinemia and hemolysis. An acute oral LD₅₀ for rats has been reported as 440 mg/kg bw. The dermal LD₅₀ on intact skin was 1320 mg/kg bw. in guinea pigs, and the 4-h LC₅₀ for rats was 250 ppm (950 mg/m³) (Woo and Lai, 2012).

In humans, the first sign of aniline poisoning is cyanosis, caused by conversion of the blood hemoglobin to met-hemoglobin. Other symptoms of aniline exposure include headaches, nausea and vomiting, paresthesias, tremor, colicky pain, narcosis/coma, and cardiac arrhythmia. Volunteers tolerated 1-h exposures ranging from 100 to 160 ppm with only moderate adverse health effects (von Oettingen, 1941). It has also been reported that 100–160 ppm is the maximum concentration that can be inhaled for 1 h without serious consequence (Henderson and Haggard, 1943) and that 50–100 ppm can probably be tolerated for 60 min (AIHA, 1955). Exposure to 7–53 ppm aniline vapor after several hours causes slight symptoms, and concentrations >100–160 ppm cause serious disturbances. Acute aniline exposure can cause acute kidney failure with decreased urinary output, painful urination, and blood, hemoglobin, or methemoglobin in the urine. In addition, bladder-wall irritation, kidney ulceration, and tissue death can also occur (Woo and Lai, 1994; Kimbrough et al., 1989). As little as 1 g of ingested aniline can be fatal to humans; the mean lethal dose is 5–30 g, and the minimum lethal dose for a 150 lb human is about 10 g (HSDB, 2011).

Chronic Effects

Methemoglobin formation, splenic pathology, and hemosiderosis are the principal nonneoplastic lesions reported in inhalation subchronic and chronic toxicity studies in experimental animals on aniline.

In a subchronic inhalation study (DuPont, 1982), groups of 16 male Crl:CD rats were exposed (head-only) to 0 (air-exposed controls), 17 vppm (64.7 mg/m³), 45 ppm (171.4 mg/m³), or 87 ppm (331.3 mg/m³) aniline vapors, 6 h/day, 5 days/week, for 2 weeks. Significantly elevated levels in met-hemoglobin were observed in rats at the 45 ppm (2.2–5.4%) and at 87 ppm (4.2–23%) groups as compared to the controls (0–2.9%), but not at the 7 ppm group. This increase was accompanied by clinical symptoms as the animals exposed to 87 ppm were cyanotic. Furthermore, the animals exposed to 87 or 45 ppm aniline vapors were anemic and accompanying increases in mean relative spleen weight. There were also exposure-dependent increases in erythropoietin foci,

reticuloendothelial cell hypertrophy, and hemosiderin deposition within the spleen of the high dosed (87 ppm) rats, and slight splenic histopathology was noted in the low dose (17 ppm) group. Based on the methemoglobin and splenic effects, a LOAEL of 17 ppm was established in rats.

Oberst et al. (1956) exposed (whole body) 9 male Wistar rats to 5 ppm (19 mg/m³; duration-adjusted value of 3.4 mg/m³) of aniline vapor for 6 h/day, 5 days/week for 26 weeks. Blood analysis indicated a slight increase (0.6%) in met-hemoglobin in rats. Based on the increase of methemoglobin, the no observed adverse effect level (NOAEL) appeared to be 5 ppm (3.4 mg/m³).

Aniline was not teratogenic to F344 rats, even at maternally toxic doses of 10, 30, or 100 mg/kg. However, met-hemoglobinemia, increased relative spleen weight, and decreased red blood cell count were noted in 20 dams (Price et al., 1985; CIIT, 1981). In a reproductive/developmental toxicity study, groups of 24–27 Fischer 344 rats were exposed to 10, 30, and 100 mg/kg/day aniline HCl by gavage on gestational days 7–20. A significant increase in met-hemoglobin (13.7% vs. 3.5% in controls) and altered hematological parameters (e.g., decrease in RBCs) were observed in the dams of the 100 mg/kg group. In addition, a dose-dependent increase in the relative spleen weight was observed in the dams of all treatment groups as compared with controls. However, there were no treatment-related alterations on various reproductive parameters examined. The methemoglobin levels in the fetuses were not significantly different from those of the controls and there was no embryotoxicity or teratogenicity observed at levels of aniline that caused maternal toxicity. Based on the increases in methemoglobin formation, a NOAEL of 30 mg/kg/day was established for maternal effects, with a NOAEL of 100 mg/kg/day for fetal effects.

Carcinogenicity studies of aniline have shown that aniline was carcinogenic in rats (CIIT, 1982). An increased incidence of primary splenic sarcomas was observed in male rats in the high dose group when aniline hydrochloride was administered in the diet for 2 years to CD-F rats (130 rats/sex/group) at levels of 0, 200, 600, and 2000 ppm. Stromal hyperplasia and fibrosis of the splenic red pulp, which may represent a precursor lesion of sarcoma, was also observed in the high dose males and, to a lesser degree, in the female rats.

In another carcinogenesis study, dietary aniline hydrochloride was administered to groups of 50 male and 50 female Fischer 344 rats at 0, 3000, or 6000 ppm and to 50 male and 50 female B6C3F1 mice at 0, 6000, or 12,000 ppm for 103 weeks (NCI, 1978). No increased tumor incidences were observed in both sexes of mice. However, the incidence of hemangiosarcomas of the spleen, and the combined incidences of fibrosarcomas and sarcoma of the spleen were statistically significantly increased in the male rats as compared to the controls. In addition, the number of female rats having fibrosarcomas of the spleen was also significantly increased (Goodman et al., 1984; NCI, 1978).

MECHANISM(S) OF ACTION

Aniline is rapidly absorbed by the skin, lungs, and the gastrointestinal tract of experimental animals. After intravenous injection of radiolabeled aniline to rats, radioactivity is distributed throughout the body; highest concentrations were found in blood, liver, kidney, urinary bladder, and the gastrointestinal tract. The major urinary metabolites in various animal species tested are *o*-, *p*-aminophenol, and their conjugates. *p*-Aminophenyl- and *p*-acetylaminophenylmercapturic acids are also excreted in rats and rabbits. *N*-Hydroxylation of aniline by liver microsomes from several species has been observed *in vitro*. Many of the adverse health effects of aniline are due in part to the formation of methemoglobinemia. Aniline converts the Fe⁺² in hemoglobin to Fe⁺³ which impair its oxygen transport capacity leading to symptoms of oxygen deficiency.

Considerable information suggests that the aromatic amino and nitro compounds require metabolic activation to yield active methemoglobin-producing reactive intermediates. The formation of phenylhydroxylamine from aniline appears to be the reactive metabolite responsible for its toxic activity (IARC, 1982). Cardiac effects of acute aniline exposure, such as irregular heart rhythm, heart block, and acute congestive heart failure, may be caused by decreased oxygen delivery to the tissues. Death can result from progressive acidosis, ischemia, and cardiovascular collapse.

Humans appear to be more sensitive than rats to aniline exposure in regard to formation of methemoglobin. It was noted that after oral administration of aniline to volunteers and rats, the dose that produced increased levels of methemoglobin was 12- to 90-folds lower for humans than for rats Jenkins et al. (1972). The reason for this increased sensitivity in humans is unknown and does not appear to be related to the half-life of methemoglobin in the serum, which is three times longer in rats than in humans.

Carcinogenicity studies of aniline have shown that aniline was carcinogenic in rats, inducing sarcomas in the spleen. The genotoxicity of aniline has been extensively studied in various short-term assay systems but produced generally negative results in reverse mutation assays in *Salmonella typhimurium* except in strain TA98 of *S. typhimurium* in the presence of norharman and S-9. Aniline showed positive responses in a mouse lymphoma assay, in SCE assays in cultured mammalian cells, and in cell transformation assay in mouse Balb/3T3 cell line. DNA adduct formation has also been reported when TA98 *S. typhimurium* was treated with aniline and the co-mutagen norharman. DNA damage assays in *E. coli* and *B. subtilis*, however, were negative (U.S. EPA, 2012a).

Evaluation of the pathogenesis of the splenic lesions and characterization of the disposition of radiolabeled aniline in animals suggests that the spleen tumors may be a secondary response resulting from chemically-mediated erythrocyte toxicity. It was proposed that compound-derived toxicity

to erythrocytes results in scavenging of damaged red blood cells by the spleen, initiating a series of events which may contribute to the development of spleen tumors. These events potentially include (i) specific accumulation of the parent compound or toxic metabolite(s) carried to the spleen by erythrocytes; (ii) deposition of erythrocytic debris, particularly iron, which may catalyse tissue-damaging free-radical reactions; and (iii) induction of splenic hyperplasia resulting from erythrocyte overload. Linkage of the splenic tumorigenicity of aniline to hematotoxicity suggests that the carcinogenicity of aniline may be determined by a definable threshold dose, i.e., the events leading to the carcinogenicity are not initiated until the capacity of the red blood cell to cope with the toxic insult is exceeded (Goodman et al., 1984).

The molecular mechanisms of splenocarcinogenic action of aniline are not clearly understood but may involve upregulation of cytokine genes (IL-1 α , IL-6, and TNF- α) that contribute to induction/initiation of fibrogenic response, activation of transcription factor NF- κ B as a direct signaling molecule in oxidative stress, and oxidative DNA damage as shown by biomarker 8-hydroxy-2'-deoxyguanosine (8-OHdG) (Ma et al., 2008). Along with increased oxidative stress, however, several repair enzymes of the base excision repair pathway (BER) are upregulated; these include: 1. 8-oxoguanine glycosylase 1 (OGG1), a specific DNA glycosylase involved in the removal of 8-hydroxy-2'-deoxyguanosine (8-OHdG) adducts, and 2. Niel-1 and Niel-2 DNA glycosylases (Ma et al., 2008, 2011). It is possible that the repair capacity needs to be exceeded before significant splenocarcinogenic activities can be manifested.

CHEMICAL PATHOLOGY

Aniline is irritating to the skin, eyes, and respiratory tract. All routes of aniline exposure can induce methemoglobinemia in both adults and children, impairing the delivery of oxygen to tissues. The effect is depending on how much aniline is exposed and the length and frequency of exposure. Lack of oxygen causes effects ranging from headache and light headedness to disorientation, coma, tremor, parathesis, pain, narcosis, anemia, and cardiac arrhythmia. When methemoglobin levels are 15–30%, the skin, lips, and ears of patients will become bluish in color due to the dark color of methemoglobin. Headache, dizziness, ataxia, weakness, rapid heart rate and mild shortness of breath will occur when methemoglobin levels are 30–50%. When methemoglobin levels reach 50–70%, stupor, tachycardia, dyspnea, and severe cyanosis will follow. Death can ensue when methemoglobin levels exceed 70% if untreated.

The fetal liver can also *N*-oxygenate aniline to form phenylhydroxylamine which has a high potency for methemoglobin production. Because fetal hemoglobin is more

easily oxidized to methemoglobin than is adult hemoglobin and is less easily reduced back to normal hemoglobin, methemoglobin is likely to be at higher levels in fetuses than in exposed mothers.

Aniline exposure may also cause the destruction of red blood cells, which manifests as acute or delayed hemolytic anemia. Persons with glucose-6-phosphate dehydrogenase (G6PD) deficiency or alcoholism are at higher risk of aniline-induced hemolysis. Spleen, kidney, liver, and heart damage may occur as secondary effects of hemolysis.

Aniline can cross the placental barrier. Limited evidence suggests that aniline may also cause adverse reproductive effects in humans. A high incidence of gynecological disorders and excess frequency of spontaneous abortions have been reported in chemically exposed women. However, aniline is not a developmental toxicant or teratogen.

Bladder cancer was once referred to as "aniline tumor" because of case reports of workers in the aniline dye industries. However, because convincing evidence could not be established for aniline primarily as a result of mixed exposures to a multiplicity of compounds and dyestuff intermediates within the same work area, the International Agency for Research on Cancer (IARC) classified aniline as a Group 3 carcinogen, that is, not classifiable as to its carcinogenicity (IARC, 1987). Based on sufficient evidence of carcinogenicity in animals, the U.S. EPA classified aniline as a B2, probably human carcinogen (U.S. EPA, 2012a). The National Institute for Occupational Safety and Health (NIOSH) has considered aniline as a potential occupational carcinogen. In a more recent epidemiology study, excess bladder cancers were reported in workers exposed to *o*-toluidine and aniline; the authors stated that *o*-toluidine is an animal carcinogen, more potent than aniline and is most likely responsible, although aniline may have played a role (Ward et al., 1996).

SOURCES OF EXPOSURE

Occupational

The greatest potential for human exposure to aniline is through inhalation and dermal contact in the workplace. A specific method of measuring hemoglobin adducts of aniline has been used to biomonitor occupational exposure of workers (Ward et al., 1996). NIOSH Analytical Method 2002 is recommended for determining workplace exposures to aniline and aniline homologs (IARC, 1982). A national occupational exposure survey conducted in the U.S. from 1981 to 1983 has estimated that 41,988 workers were potentially exposed to aniline (NIOSH, 2010). Aniline was reported in the urine of workers at a chemical manufacturing plant in Niagara Falls, NY at mean concentrations of 3.9–29.8 ug/l. These workers also had blood hemoglobin levels of aniline of 3163–17,441 pg/g (Ward et al., 1996).

Environmental

The general population may be exposed to aniline by using various products such as paints, varnishes, marking inks, and shoe polishes. Exposure to aniline can occur in the environment following releases to air, water, land, or groundwater. U.S. EPA's Toxics Release Inventory reported total on- and off-site releases of aniline in 2012 as 1,731,134 pounds (U.S. EPA, 2012). Most releases of aniline in U.S. are to underground injection sites and to air. Because it is a liquid that does not bind well to soil, aniline that makes its way into the ground can move through the ground and enter groundwater. Microorganisms that live in water and in soil can also break down aniline. In air, aniline breaks down to other chemicals. Sunlight also breaks down aniline in surface water and in soil. Plants and animals are not likely to store aniline. Toxic effects appear unlikely to occur at levels of aniline that are normally found in the environment. However, aquatic toxicity studies by the aniline industry submitted to U.S. EPA show that aniline is highly toxic to aquatic life (U.S. EPA, 1994).

INDUSTRIAL HYGIENE

The OSHA-permissible exposure limit (PEL) is 5 ppm (19 mg/m³) TWA (NIOSH, 2013). The NIOSH Immediately Dangerous to Life or Health Concentration (IDLH) is 100 ppm (NIOSH, 1994; U.S. EPA, 1994). NIOSH has recommended OSHA to require labeling aniline as a potential occupational carcinogen, and that occupational exposure is limited to lowest feasible concentration. The ACGIH TLV is 2 ppm (7.6 mg/m³) TWA (ACGIH, 2013; U.S. EPA, 1994). The acute exposure guideline levels (AEGLs) for aniline ranges from 1 ppm (for 8 h AEGL-1, marginal) to 40 ppm (for 30 min AEGL-3, life-threatening) (U.S. EPA, 2012c).

The U.S. EPA has developed the inhalation reference concentration (RfC) is 1×10^{-3} mg/m³ based on the NOAEL of 19 mg/m³ (5 ppm) in a 20–26 week inhalation study in the rat. Using tumor data in the male rats of the NCI carcinogenesis bioassay (NCI, 1978), an oral slope factor of 5.7×10^{-3} /mg/kg/day, and a drinking water unit risk of 1.6×10^{-7} /µg/l were derived (U.S. EPA, 2012a).

MEDICAL MANAGEMENT

Prompt and proper treatment can usually reverse the non-lethal acute effects of aniline. If patients can walk, lead them out of the hot zone to the decontamination zone immediately and allow access for a patent airway. Patient exertion should be minimized as exposure to aniline can produce hypoxia (due to methemoglobinemia) which can be exacerbated by physical activities. Patients, who are unable to walk and if trauma is suspected, maintain cervical immobilization

manually and apply a cervical collar and a backboard when feasible. Ensure adequate respiration and pulse, administer supplemental oxygen, establish intravenous access, and place on a cardiac monitor if necessary.

Because aniline is absorbed through the skin, it is important to remove wet clothing quickly. Flush exposed skin and hair with water for 2–3 min, and then wash thoroughly with mild soap. Rinse thoroughly with water. Irrigate exposed or irritated eyes with tepid water for 15 min. In cases of ingestion, do not induce emesis. Consider gastric lavage with a small nasogastric tube if a large dose has been ingested. If the patient is alert and asymptomatic, administer a slurry of activated charcoal at 1 gm/kg, usual adult dose 60–90 g, child dose 25–50 g.

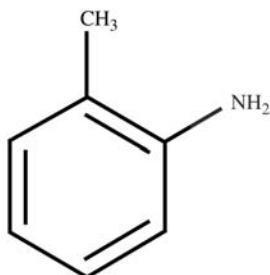

Administer methylene blue antidote to patients who have signs and symptoms of hypoxia (other than cyanosis) or for patients who have methemoglobin levels >30%. The standard intravenous dose is 1–2 mg of methylene blue per kg of body weight (0.1–0.2 ml/kg of a 1% solution) over 5–10 min. Consider hyperbaric oxygen therapy in patients who are refractory to methylene blue therapy. Consider racemic epinephrine aerosol for children who develop stridor. Dose 0.25–0.75 ml of 2.25% racemic epinephrine solution in water; repeat every 20 min as needed cautioning for myocardial variability (ASTDR, 2011).

o-TOLUIDINE

Occupational exposure limits: 5 ppm (OSHA PEL); 2 ppm (ACGIH TLV with skin notation)

Reference values: None

Hazard statements: H301—toxic if swallowed; H315—causes skin irritation; H317—may cause an allergic skin reaction; H319—causes serious eye irritation; H331—toxic if inhaled; H341—suspected of causing genetic defects; H350—may cause cancer; H400—very toxic to aquatic life; H411—toxic to aquatic life with long lasting effects

Precautionary statements: P201—obtain special instructions before use; P280—wear protective gloves/protective clothing/eye protection/face protection; P309+P311—if exposed or if you feel unwell, call a poison center or doctor/physician; P273—avoid release to the environment

Risk phrases: R45—may cause cancer; R23/25—toxic by inhalation and if swallowed; R36—irritating to eyes; R50—very toxic to aquatic organisms

Safety phrases: S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible); S53—avoid exposure; obtain special instructions before use; S61—avoid release to the environment; refer to special instructions/safety data sheets

BACKGROUND AND USES

o-Toluidine, is a methemoglobin-inducing chemical and a human carcinogen. Commercial production of *o*-toluidine was first reported in the United States in 1922. *o*-Toluidine and its hydrochloride salt are used primarily as intermediates in the manufacture of dyes and pigments for printing textiles, in color photography, and as biologic stains. In addition, *o*-toluidine is used as an intermediate for rubber vulcanizing chemicals, pharmaceuticals, and pesticides. Other minor uses include intermediate for organic synthesis and clinical laboratory reagent for glucose analysis (IARC, 2000, 2010; Woo and Lai, 2012).

In the late 1970s, annual production of *o*-toluidine in the United States was estimated to be 1.1–11 million pounds (IARC, 2000). The estimated annual aggregate production/import volumes were 10–50 million pounds in 1986 and 1994, peaked to 50–100 million pounds in 1998 and declined back to 10–50 million pounds in 2002 (U.S. EPA, 2004). In 1983, 34 companies were identified as suppliers. In 1990, two suppliers of *o*-toluidine and 10 suppliers of *o*-toluidine hydrochloride were identified (NTP, 2011). In Europe, *o*-toluidine is a high production volume chemical (HPVC); the estimated annual production volume is 10000–100000 tonnes (ECHA, 2014). Other countries reported to produce or supply *o*-toluidine include Canada, India, Italy, Japan, Mexico, the Netherlands, China, South Africa, and Switzerland (IARC, 2000, 2012). In 2001, the worldwide production volume of *o*-toluidine is estimated to be 59000 tonnes by 11 producers (OECD, 2004).

PHYSICAL AND CHEMICAL PROPERTIES

o-Toluidine (or *o*-methylaniline, 2-aminotoluene), is an alkyl aniline with a methyl group *ortho* to the amino group. It is a light yellow to reddish-brown liquid. It has a molecular weight of 107.15, a density of 0.9984, a melting point of –14.7°C, a boiling point of 200.2 °C, a refractive index of 1.57276 (20°C), a flash point of 86 °C (closed cup), and an octanol/water partition coefficient (Log P) of 1.29–1.32. *o*-Toluidine is slightly soluble in water and soluble in alcohol and ether (IARC, 2010, 2012).

MAMMALIAN TOXICOLOGY

Acute Effects

o-Toluidine can cause skin and eye irritation and is of moderate to low acute toxicity. Acute oral, dermal, or inhalation exposure to *o*-toluidine can result in methemoglobinemia, reticulocytosis, and hematuria. In rats, the LC₅₀ of *o*-toluidine is 852 ppm/4 h (*ca.* 3827 mg/m³/4 h), and the oral LD₅₀ is 750–940 mg/kg bw (OECD, 2004; Woo and Lai, 2012).

Chronic Effects

Repeated-dose studies in rats show that *o*-toluidine is hematotoxic and can cause methemoglobinemia. In a 14-day feeding study in male and female Fischer rats, statistically significant increase in methemoglobin was observed in all animals. No NOAEL could be derived, and based on increases in methemoglobin formation, the LOAEL was 500 ppm (*ca.* 23.7 mg/kg bw/day and 25.5 mg/kg bw/day for males and females, respectively). In another subchronic study, hemolytic anemia was found in Wistar rats receiving daily dose of 80 mg/kg bw *o*-toluidine by gavage; toxicity of the kidney and liver was also noted at 400 mg/kg bw (HSDB, 2012). *o*-Toluidine hydrochloride caused increased incidences of hematopoiesis, hemosiderin accumulation, and capsular fibrosis in the spleen when administered to F344/N rats in feed at daily doses of 5000 ppm (*ca.* 237 mg/kg bw) for 13 or 26 weeks (NTP, 2000).

There is sufficient evidence for the carcinogenicity of *o*-toluidine in experimental animals. Chronic exposure of *o*-toluidine hydrochloride induced multiple-sites tumors in rats and mice. In a 2-year carcinogenesis bioassay (NCI, 1979), groups of 50 F344 rats of each sex and 50 B6C3 F₁ mice of each sex were given diets containing *o*-toluidine hydrochloride (3000 or 6000 ppm for rats and 1000 or 3000 ppm for the mice) for 101–104 weeks. In rats, it induced several types of sarcomas of the spleen and other organs in both sexes, mesotheliomas of the abdominal cavity or scrotum, fibromas of the subcutaneous tissue in males, and transitional-cell carcinomas of the urinary bladder, fibroadenomas, or

adenomas of the mammary gland in females. In mice, it caused blood-vessel tumors (hemangioma and hemangiosarcoma) in both sexes and benign and malignant liver tumors (hepatocellular adenoma and carcinoma) in females. Similar tumors were induced in other strains of rat and mouse (e.g., Wistar rats, CD-1 mice) after chronic exposures to *o*-toluidine (HSDB, 2012). Interestingly, while *o*-toluidine induced leukemia and tumors of the lung, kidney, and mammary gland in rodents, urinary bladder tumors developed in two dogs after 9 and 10 years, respectively, of exposure to *o*-toluidine (Pliss, 2004).

A number of epidemiological studies have found increased incidences of urinary bladder cancer among workers exposed to mixtures of aromatic amines including *o*-toluidine in the dyestuffs and rubber industries. Carcinogenic potential of *o*-toluidine specifically cannot be definitively determined by earlier studies because of small cohorts and confounding exposures to other chemicals. In more recent follow-up studies, bladder cancer incidence remains elevated in the cohorts and despite other concurrent chemical exposures, *o*-toluidine was considered most likely responsible for the excess bladder cancer incidence (Markowitz and Levin, 2004; Baan et al., 2008; Sorahan, 2008; Carreón et al., 2010, 2014).

Mechanism of Action(s)

The metabolism and mode of action of *o*-toluidine has not yet been fully elucidated. Like other aromatic amines, *o*-toluidine is expected to be oxidized to a *N*-hydroxy and/or a *N*-O-acetylated derivative, which interacts with the hem group of hemoglobin resulting in the formation of methaemoglobin. Studies in rats and mice have demonstrated *o*-toluidine (or its metabolites) binds to hemoglobin and that a linear dose relationship exists for hemoglobin (DeBord et al., 1992). The extent of hemoglobin binding in rats correlated well with the concentrations of methemoglobin (Birner and Neuman, 1988). There was a correlation between urinary *o*-toluidine levels and hemoglobin adduct in exposed and unexposed workers (HSDB, 2012). Prilocaine, a widely used local anesthetic, is metabolized to *o*-toluidine. Prilocaine anesthesia has resulted in a significant increase of hemoglobin adducts of *o*-toluidine in blood samples of the patients (Gaber et al., 2007).

On the basis of the *in vitro* and *in vivo* genotoxicity and DNA damages observed in various assay systems, *o*-toluidine appears to be acting as a genotoxic carcinogen. *o*-Toluidine was tested positive in a variety of *in vitro* genotoxicity assay systems that included Ames *Salmonella*, chromosome aberration, sister chromatid exchange (SCE), mouse lymphoma cell mutation, cell transformation, and unscheduled DNA synthesis tests. It was also positive in somatic mutation in *Drosophila* and *in vivo* micronucleus test in rat peripheral blood (Woo and Lai, 2012; Maire et al., 2012; HSDB, 2012; Suzuki et al., 2005). DNA adducts of *o*-toluidine have been detected in the liver and nasal mucosa

of rats given prilocaine, a local anesthetic that is metabolized to *o*-toluidine (Duan et al., 2008).

It is well documented that aromatic amines require metabolic activation for their carcinogenic activities. The mechanism of activation, which involves many competing pathways in a two-stage metabolic activation, has been reviewed (Woo and Lai, 2012). 4-Amino-3-methylphenol, a major metabolite, caused DNA damage in the presence of Cu(II). *o*-Nitrosotoluene, a minor metabolite, induced DNA damage after addition of NADH. Metal-mediated DNA damage by *o*-toluidine metabolites through H₂O₂ and free radicals formation has been suggested to be responsible for the carcinogenicity of *o*-toluidine in rats and mice (Ohkuma et al., 1999). Electrophilic arylamidonium or arylnitrenium ions generated in rodents at the second stage of metabolic activation can also bind covalently to cellular nucleophiles such as DNA to initiate carcinogenesis. Competing against the second-stage activation are two other pathways involving glutathione conjugation and glucuronidation that represent detoxification pathways in rodents. However, at the acidic pH found in the urinary bladder of dogs and humans, and in the presence of urinary β-glucuronidase, they are cleaved to give the electrophilic arylnitrenium ion, which interacts with cellular macromolecules such as DNA to induce urinary bladder tumors. The differences in metabolic activation mechanism between rodents and dogs or humans are consistent with the findings that *o*-toluidine induced leukemia and tumors of the lung, kidney, and mammary gland in rodents, but urinary bladder tumors in dogs (Pliss, 2004), and support the increased risks of urinary bladder cancer observed in workers exposed to *o*-toluidine (Markowitz and Levin, 2004; Baan et al., 2008; Sorahan, 2008; Carreón et al., 2010; Carreon et al., 2014).

Chemical Pathology

o-Toluidine is readily absorbed by inhalation or through the skin and gastrointestinal tract. It can cause skin and eye irritation. The major clinical toxicity following acute and chronic/subchronic exposure to *o*-toluidine are met-hemoglobinemia and related effects on the blood and spleen. Exposure to high concentrations may result in damage to kidneys and bladder. Early symptoms typical of met-hemoglobinemia such as headache, nausea, vomiting, diarrhea, and cyanosis may begin to appear at 6 ppm after several hours, or at 100 ppm after an hour. Continued exposure may lead to difficult breathing, dizziness, stupor, unconsciousness, and death. Ingestion of about 2 oz by a 150 lb person may also result in death (HSDB, 2012).

o-Toluidine induced multisites tumors in rats and mice and is a human carcinogen; an excess of bladder tumors has been found in workers exposed to dyestuffs and chemical mixtures containing *o*-toluidine (Markowitz and Levin,

2004; Baan et al., 2008; Sorahan, 2008; Carreón et al., 2010; Carreon et al., 2014).

SOURCES OF EXPOSURE

Occupational

Occupational exposure to *o*-toluidine and its hydrochloride salt can occur to workers in many industries; among them the greatest potential for exposure are workers in dyes and pigment industries through inhalation and dermal contact. According to a survey conducted in the United States from 1972 to 1974, 13053 workers were potentially exposed to *o*-toluidine. In another U.S. survey conducted from 1981 to 1983, 30,000 workers, including 15,500 women, were estimated to expose to *o*-toluidine (NTP, 2011). There is also evidence of dermal absorption of *o*-toluidine in workers of rubber industry (Korinth et al., 2007; Wellner et al., 2008).

Air and urine samples from automobile workers involved in rubber vulcanization have been measured. Concentrations of *o*-toluidine ranging from 26.63 to 93.93 µg/m³ in air and from 54.65 to 242.88 µg/l in urine were found (Riedel et al., 2006). There was a correlation between air concentrations and urinary *o*-toluidine or hemoglobin adduct levels in blood in studies on exposed and nonexposed workers (OECD, 2004).

Environmental

The general population may be exposed to low concentrations of *o*-toluidine in ambient air or by dermal contact with commercial dyes used on textiles (IARC, 2000). Between 1988 and 2009, environmental releases of *o*-toluidine in the United States ranged from 10,800 to 55,000 pounds, whereas releases of *o*-toluidine hydrochloride ranged from 0 to 265 pounds. In 2007, 16,348 pounds of *o*-toluidine were released from 12 facilities (U.S. EPA, 2009). *o*-Toluidine has been detected in effluents from refineries and production facilities and in river water, process water, and groundwater (IARC, 2000). In 1979, it was measured in the Rhine River at concentrations of 0.03–1.8 µg/l and in Japan at concentrations of up to 20 µg/l (IPCS, 1998).

o-Toluidine is present in cigarette smoke at a concentration of up to 144 ng per cigarette (Stabbert et al., 2003). Hemoglobin adduct levels of *o*-toluidine were significantly higher in children in Germany who were exposed to environmental tobacco smoke than those who were not (Richter et al., 2001). *o*-Toluidine has also been detected in blood and breast milk (Gazarian et al., 1995) and was measured in the urine of individuals with no known exposure at a median concentration of 0.12 µg/l (Weiss and Angerer, 2002). Patients treated with prilocaine, a local anesthetic that is metabolized to *o*-toluidine, have been shown to have substantially elevated hemoglobin adducts of *o*-toluidine (Gaber et al., 2007).

INDUSTRIAL HYGIENE

The time-weighted average TLV-TWA for *o*-toluidine adopted by American Conference of Governmental Industrial Hygienists (ACGIH) is 2 ppm with skin notation. The OSHA Permissible exposure limit (PEL) is 5 ppm. The National Institute for Occupational Safety and Health (NIOSH) immediately dangerous to life or health concentration (IDLH) is 50 ppm (NTP, 2011).

o-Toluidine and *o*-toluidine hydrochloride have been changed from “reasonably anticipated to be human carcinogens” to “known to be human carcinogens” in Report on Carcinogens (NTP, 2014). The International Agency for Research on Cancer has also re-classified *o*-toluidine as a Group 1 “known human carcinogen” from Group 2A “probable human carcinogen” on the basis of increased risk of urinary-bladder cancer reported in these follow-up cohort studies of workers exposed to *o*-toluidine (IARC, 2010). NIOSH considers this compound to be an occupational carcinogen and recommends appropriate worker protection.

Standards	Values
NIOSH REL	None established; NIOSH considers <i>o</i> -toluidine to be an occupational carcinogen
OSHA PEL	5 ppm TWA
ACGIH TLV	2 ppm TWA,
IDLH	50 ppm

MEDICAL MANAGEMENT

As *o*-toluidine can be absorbed by the skin, it is important to remove all contaminated clothing immediately if splashed with *o*-toluidine. The level of methemoglobinemia needs to be consistently monitored. Administer oxygen when met-hemoglobinemia is above 30%. Further administer intravenously a 5% glucose solution containing ascorbic acid when methemoglobinemia is above 50%. If met-hemoglobinemia is above 60% methemoglobinemia, administer intravenously 10–20 cm³ of a 1% solution of methylene blue. If there is no response to treatment with methylene blue, then perform hemodialysis or exchange transfusion (IPCS, 1998).

o-ANISIDINE

Occupational exposure limits: 0.5 mg/m³ (OSHA PEL, NIOSH REL, ACGIH TLV)

Reference values: None

Hazard statements: H350—may cause cancer; H341—suspected of causing genetic defects; H331—toxic if inhaled; H311—toxic if contact with skin; H301—toxic if swallowed.

Precautionary statements: P201—obtain special instructions before use; P273—avoid release to the environment; P280—wear protective gloves/protective clothing/eye protection/face protection; P361—remove/take off immediately all contaminated clothing; P309 + P311—if exposed or if you feel unwell, call a poison center or doctor/physician; P404—store in a closed container.

Risk phrases: R45—may cause cancer; R68—possible risk of irreversible effects; R23/24/25—toxic by inhalation, in contact with skin and if swallowed.

Safety phrases: S53—avoid exposure—obtain special instructions before use; S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible).

BACKGROUND AND USES

Similar to other aromatic amines, *o*-anisidine (CASRN 90-04-0) may cause methemoglobinemia and cancer in humans. It is used mainly as an intermediate for the production of azo dyes and pigments. Other industrial uses of *o*-anisidine include synthesis of other dyes and pharmaceuticals, as a corrosion inhibitor for steel, and as an antioxidant for polymercaptopan resins (IARC, 1999; HSDB, 2012).

o-Anisidine was first produced commercially in the U.S. in 1922, and in 1977, one of the three U.S. companies reported production of 4.5–45.4 thousand kg (IARC, 1982). U.S. production plus imports of *o*-anisidine totaled 500,000–1 million pounds in 1986, 1990, and 2006; 1–10 million pounds in 1998; and 10,000–500,000 pounds in 2002 (U.S. EPA, 2004, 2010). In 1995, worldwide *o*-anisidine production was estimated to be 15,000 tonnes/

year, from which China alone produced about 7000 tonnes/year. In 1997, five producing and processing companies of *o*-anisidine were identified in Western Europe, but the total amounts were <1000 tonnes/year (EU, 2002).

PHYSICAL AND CHEMICAL PROPERTIES

o-Anisidine (or *o*-methoxyaniline) is an aromatic amine with a methoxyl group ortho to the amino group of aniline. It is a colorless to yellowish, pink, or reddish liquid. It has a molecular weight of 123.2, a density of 1.0923 g/cm³ at (20 °C), a melting point of 5 °C, a boiling point of 225 °C, a vapor pressure of 0.08 mm Hg (25 °C), and an octanol/water partition coefficient (Log P) of 1.18. *o*-Anisidine is soluble in water and mineral oils, and miscible with alcohol, benzene, acetone, and diethylether. *o*-Anisidine hydrochloride, a salt of *o*-anisidine, is a grayish crystalline solid or powder at room temperature and is soluble in water (NTP, 2011).

MAMMALIAN TOXICOLOGY

Acute Effects

Acute dermal irritation/corrosion study and acute eye irritation/corrosion study of *o*-anisidine in rabbits were negative (EU, 2002). More recent human data, however, showed that it was very irritating to skin, eyes, and mucous membranes (HSDB, 2012). *o*-Anisidine was reported to be a weak sensitizer in the guinea pig. However, there are uncertainties about the adequacy of the study due to insufficient documentation. The oral LD₅₀ of *o*-anisidine was 1890–2020 mg/kg bw in rats, 1410 mg/kg bw in mice, and 870 mg/kg bw in rabbits. Clinical signs and some hematological changes, anemia and nephrotoxicity were only seen in the high dosed animals. The dermal LD₅₀ for Wistar rats was >2000 mg/kg bw. In an acute inhalation study, no mortality and no signs of toxicity were found in rats at the highest technically feasible aerosol concentration of 3.87 mg/l *o*-anisidine; the 4-h LC₅₀ was determined to be >3.87 mg/l (EU, 2002).

Similar to other aromatic amines, *o*-anisidine induces methemoglobin formation in animals. Significantly elevated methemoglobin levels were observed in rats and mice within 3–48 h after a single oral application via gavage of 690 mg/kg bw *o*-anisidine. In cats, a species with comparable methaemoglobin forming capacity to humans, a single intravenous injection of 7.7 mg/kg bw *o*-anisidine resulted in up to 15% increase of methemoglobin level within 1–5 h (EU, 2002).

Chronic Effects

From a 28-day oral study in Wistar rats, a lowest observed adverse effect level (LOAEL) of 80 mg/kg bw was derived based on hemolytic anemia, spleen toxicity, and increased liver

and spleen weights. The effects observed were considered secondary to the acute methemoglobin formation. The NOAEL was 16 mg/kg bw (EU, 2002).

Except for some complaints of headache and vertigo, increased methemoglobin and sulfhemoglobin, and frequent occurrence of erythrocytic inclusion bodies (Heinz bodies), workers exposed to an air concentration of 0.4 ppm *o*-anisidine 3.5 h/day for 6 months developed no anemia or chronic toxicity (HSDB, 2012).

o-Anisidine hydrochloride was carcinogenic in rats and mice. Dietary administration of *o*-anisidine hydrochloride (at doses of 0, 5000, or 10,000 ppm) caused increased incidences of urinary bladder tumors in rats of both sexes. In male rats, it also induced transitional cell carcinomas of the kidney and follicular cell tumors of the thyroid. A significantly increased incidence of the urinary bladder tumors occurred in the high dose (5000 ppm) mice (NCI, 1978).

There are no epidemiological studies that evaluated the relationship between human cancer and exposure specifically to *o*-anisidine or *o*-anisidine hydrochloride.

Mechanism(s) of Action

The mechanisms of toxicity/carcinogenicity of *o*-anisidine have not been fully elucidated. As with other aromatic amines, it is likely that *o*-anisidine is oxidized to a *N*-hydroxy or *N*-*O*-acetyl derivative, which interacts with the hem group of hemoglobin to cause methemoglobin formation.

o-Anisidine has been tested for genotoxicity in a variety of *in vitro* and *in vivo* assay systems. It was negative in several reverse mutation assays in *Salmonella typhimurium* and *Escherichia coli* with or without metabolic activation. *N*-acetylation appears to play a role in the metabolic activation of *o*-anisidine since mutagenic activity was detected in *Salmonella typhimurium* strain YG1029 containing elevated levels of *N*-acetyltransferase activity (IARC, 1999). In mammalian systems, *o*-anisidine was positive in a chromosome aberration assay and a sister chromatids exchange assay with CHO cells, and in a mouse lymphoma assay (Thompson et al., 1992; EU, 2002).

In most of the *in vivo* test systems, however, *o*-anisidine was negative (EU, 2002; IARC, 1999). Stiborová et al. (2002, 2005, 2009) showed that the genotoxic mechanisms of *o*-anisidine involve metabolic activation by *N*-hydroxylase to the proximate carcinogenic metabolite, *N*-(2-methoxyphenyl) hydroxylamine, which spontaneously decomposes to nitrenium and/or carbonium ions responsible for the deoxyguanosine adducts formation observed in DNA incubated with *o*-anisidine and human microsomes *in vitro*. The same adducts were detected in urinary bladder, the target organ, and to a lesser extent, in liver, kidney, and spleen of rats treated with *o*-anisidine (Stiborova et al., 2005). Furthermore, an extended *in vivo* study by Naiman et al. (2012) showed that the DNA adducts in the urinary bladder were substantially more

persistent than those in all the other organs. Over 39% of the adducts remained in the bladder 36 weeks after the treatment whereas no adducts could be detected in other organs. The negative *in vivo* genotoxic responses may be due to the detoxification of reactive metabolites by cytochrome P450 enzymes (e.g., CYP3A4, 2E1, and 2C) in the liver back to *o*-anisidine (Naiman et al., 2011; Dracínska et al., 2006).

Peroxidases also play a role in the metabolic activation of aromatic amines (Stiborova et al., 2002; Woo and Lai, 2012). Results of *in vitro* studies have suggested a possible role for peroxidation enzymes in the metabolic activation of *o*-anisidine (Martinkova et al., 2012). Several reactive intermediates including electrophilic diimine and quinoneimine metabolites were formed when studied of *o*-anisidine with prostaglandin H synthase, a peroxidation enzyme (Thompson et al., 1992). Formation of these reactive intermediates from *o*-anisidine and covalently binding to nucleic acids, and protein have been demonstrated using horseradish peroxidase (Thompson and Eling, 1991). Metabolic activation of *o*-anisidine by prostaglandin H synthase may play a role in the carcinogenesis of urinary bladder observed in rats and mice as prostaglandin H synthase is broadly distributed in mammalian tissues, including the urinary bladder.

In an *in vitro* study, *o*-anisidine was shown to be a strong inhibitor of thyroid peroxidase (Freyberger, 1994). The persistent thyroid peroxidase inhibition with concomitantly decreased thyroid hormone formation is a key event in thyroid tumorigenesis; the increased incidence of thyroid tumors observed in male rats in the 2-year bioassay may be resulted from thyroid peroxidase inhibition by *o*-anisidine.

Chemical Pathology

o-Anisidine is expected to be absorbed through the skin, in the gastrointestinal and the respiratory tract. Contact with *o*-anisidine may irritate the eyes, skin, and respiratory tract. Overall acute toxicity of *o*-anisidine appears to be low by all routes of exposure.

There are limited data on effects in humans after repeated exposure. Significant increased levels of methemoglobin were not seen in workers exposed to an air concentration of 0.4 ppm *o*-anisidine 3.5 h/day for 6 months (EU, 2002). However, based on acute and subchronic toxicity studies in rodents and in cats, a species with comparable methaemoglobin forming capacity to humans, chronic exposures to higher levels of *o*-anisidine may cause headache, dizziness, vertigo, cyanosis, difficulty in breathing, anemia, organs damage, and death due to methemoglobinemia (HSDB, 2012).

o-Anisidine is *reasonably anticipated to be a human carcinogen* based on sufficient evidence of carcinogenicity in experimental animals (NTP, 2011). As with other aromatic amines, urinary bladder is the main target organ of cancer development in humans. Interindividual differences in susceptibility may occur due to different activities of *N*-

hydroxylases and *N*-acetyltransferases, and other metabolic activation/detoxification enzyme activities for *o*-anisidine.

SOURCES OF EXPOSURE

Occupational

Occupational exposure to *o*-anisidine may occur at workplace through inhalation and dermal contact during its production or processing (IARC, 1999). The National Occupational Exposure Survey conducted from 1981 to 1983 in the U.S. estimated that 705 workers were potentially exposed to *o*-anisidine and 1108 workers were potentially exposed to *o*-anisidine hydrochloride (NIOSH, 2010). According to the survey data in 2006, 1–99 people were likely to be exposed in industrial manufacturing, processing, and use of *o*-anisidine; the data may be greatly underestimated (U.S. EPA, 2010). During the processing of *o*-anisidine, 0.05–0.15 mg/m³ were detected from personal air sampling of some German processing companies between 1990 and 1995 (EU, 2002).

Environmental

o-Anisidine can occur as an environmental pollutant in wastewater from oil refineries and chemical plants (IARC, 1982, 1999). According to EPA's Toxics Release Inventory, about 10,000 pounds of *o*-anisidine were released annually from 1989 to 1992, mostly to air. From 1993 to 2007, releases were much lower; in 2007, total releases were down to 638 pounds (U.S. EPA, 2009). In air, *o*-anisidine is expected to be degraded by reaction with hydroxyl radicals with a half-life of 6 h. In soil, it will be subjected to rapid biodegradation under aerobic conditions. In surface water, it is expected to bind to sediment or suspended solids with high organic matter content and to volatilize from water with an estimated half-life of 31 days from streams and 350 days from lakes. *o*-Anisidine is not expected to bioaccumulate in aquatic organisms (EU, 2002; HSDB, 2012).

The general population may come into contact with *o*-anisidine during the use of consumer products such as textiles and printed packings colored with pigments or dyes based on the compound. In addition, *o*-anisidine occurs in cigarette smoke; the mean concentrations of *o*-anisidine in smoke were reported to range from <0.2 to 5.12 ng per cigarette (Stabbert et al. (2003). *o*-Anisidine was detected at concentrations ranging from <0.05 to 4.2 µg/l (median = 0.22 µg/l) in 20 urine samples from the general population in Germany (Weiss and Angerer, 2002).

INDUSTRIAL HYGIENE

The time-weighted average TLV-TWA for *o*-anisidine adopted by American Conference of Governmental

Industrial Hygienists (ACGIH) is 0.1 ppm (0.5 mg/m³). The OSHA PEL is 0.1 ppm (0.5 mg/m³). The NIOSH recommended exposure limit (REL) is 0.1 ppm (0.5 mg/m³) and the IDLH is 10 ppm (50 mg/m³) (NTP, 2011). The occupational exposure limits for *o*-anisidine in other OECD countries are similar to those of the U.S. (EU, 2002).

o-Anisidine and *o*-Anisidine hydrochloride have been listed in Report on Carcinogens (NTP, 2011) as “reasonably anticipated to be human carcinogens”. The International Agency for Research (IARC) on Cancer has classified *o*-anisidine as a Group 2B “possibly carcinogenic to humans” based on sufficient evidence for carcinogenicity in experimental animals and inadequate evidence for carcinogenicity in humans (IARC, 1999). NIOSH considers this compound to be an occupational carcinogen and recommends appropriate worker protection.

MEDICAL MANAGEMENT

Decontamination, symptomatic, and supportive measures are crucial for medical management of *o*-anisidine poisoning. Victims should be removed from the area of exposure immediately and if splashed with *o*-anisidine, all contaminated clothing should be removed. Early signs and symptoms of methemoglobinemia should be monitored, and appropriate treatments for methemoglobinemia such as administration of oxygen, ascorbic acid, or methylene blue should be used when needed (Dutta et al., 2008).

***o*-NITROTOLUENE**

Occupational exposure limits: 5 ppm (OSHA PEL); 2 ppm (NIOSH REL); 2 ppm (ACGIH TLV with skin notation)

Reference values: None

Hazard statements: H302—harmful if swallowed; H340—may cause genetic defects; H350—may cause cancer; H361—suspected of damaging fertility or the unborn child; H411—toxic to aquatic life with long-lasting effects

Precautionary statements: P201—obtain special instructions before use; P301 + P310—if swallowed, immediately call a poison center or doctor/physician; P273—avoid release to the environment

Risk phrases: R45—may cause cancer; R46—may cause heritable genetic damage; R62—possible risk of impaired fertility; R22—harmful if swallowed; R51/53—toxic to aquatic organisms, may cause long-term adverse effects in the aquatic environment

Safety phrases: S53—avoid exposure—obtain special instructions before use; S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible); S61—avoid release to the environment; refer to special instructions/safety data sheets

BACKGROUND AND USES

o-Nitrotoluene (CASRN 88-72-2) is a high production volume chemical used primarily in the production of *o*-toluidine, 2,4-dinitrotoluene, isocyanate, and other chemicals that are intermediates for synthesizing colorants such as magenta and various azo and sulfur dyes for cotton, wool, silk, leather, and paper. In addition, it is used as an intermediate in the synthesis of agricultural chemicals, pharmaceuticals and rubber chemicals (IARC, 1996; NTP, 2011).

U.S. production of *o*-nitrotoluene was reported to be around 29 million pounds in 1981 and 35.5 million pounds in 1993 (NTP, 2011). Reports filed in 2006 under EPA's Toxic Substances Control Act Inventory Update Rule indicated that U.S. production plus imports of *o*-nitrotoluene totaled 10–50 million pounds (U.S. EPA, 2010). Since 1996, the principal producers and/or processors of *o*-nitrotoluene in Europe are located in Germany (34,400 metric tons in 2000),

the United Kingdom (3740 metric tons in 2003, imported) and Italy (49,200 metric tons in 2002) (EU, 2008).

PHYSICAL AND CHEMICAL PROPERTIES

o-Nitrotoluene (also known as 2-nitrotoluene) is a methylated nitroaromatic compound that has a methyl group ortho to the nitro group. At room temperature, it is a pale yellowish liquid which can crystallize to two solid forms (α -, and β -) at lower temperatures. It has a molecular weight of 137.15, a density of 1.1629, a melting point of -9.5°C (needles, α -form) to -2.5°C (crystal, β -form), a boiling point of 221.7°C , a vapor pressure of 0.1 mm Hg at 20°C , and an octanol/water partition coefficient (Log P) of 2.3. It is slightly soluble in water (0.54 g/l at 20°C) and soluble in benzene, alcohol, ether, and petroleum ether (IARC, 1996; NTP, 2011).

MAMMALIAN TOXICOLOGY

Acute Effects

Acute toxicity studies in animals showed that *o*-nitrotoluene is only slightly toxic. At vapor concentrations of 191 ppm (1.1 mg/l) for 8 h or 320 ppm (1.8 mg/l) for 4 h in rats, and at 354 ppm (2 mg/l) for 4 h in mice, *o*-nitrotoluene did not produce mortalities, toxicity, and gross lesions within 14-day observation period. In dermal exposure studies, there were no mortality and clinical signs in rats at 5000 mg/kg bw, or in rabbits at 20,000 mg/kg bw. The oral LD₅₀ values ranged from 890 to 2546 mg/kg bw. in rats, 970 to 2462 mg/kg bw. in mice and 1750 mg/kg bw. in rabbit. Clinical signs of toxicity observed in animals were related with methemoglobin formation. There are limited acute toxicity data in humans but effects due to methemoglobin formation can occur in humans exposed to *o*-nitrotoluene by various routes (EU, 2008).

Chronic Effects

In a repeated-dose toxicity study, *o*-nitrotoluene was administered in the feed to groups of male and female in F344 rats and B6C3F1 mice at concentrations ranging from 388 to 20,000 ppm for 14 days. There were no effects on survival or clinical signs of toxicity, although animals at the higher doses showed decreases in body weight gains relative to controls (Dunnick, 1993).

Comparative toxicity studies of *o*-, *m*-, or *p*-nitrotoluene showed that all three chemicals caused toxicity in the liver, spleen, and kidney in rats administered the test compounds in the feed at doses ranging from 625 to 10,000 ppm for 13 weeks. The most toxic effects occurred at or >2500 ppm and the toxicity was most pronounced in rats receiving *o*-nitrotoluene (Dunnick et al., 1993, 1994).

o-Nitrotoluene was clearly shown to be a multi-target carcinogen in 2-year chronic studies of rats and mice. In rats, oral exposure of *o*-nitrotoluene in the feed (approximately 0, 25, 50, or 90 mg/kg per day in males, and approximately 0, 30, 60, or 100 mg/kg per day in females) caused 1. subcutaneous skin tumors and mammary gland tumors (fibroadenoma) in both sexes, 2. malignant mesothelioma and benign or malignant tumors of the liver (hepatocellular adenoma or carcinoma, or cholangiocarcinoma) and lung (alveolar/bronchiolar adenoma or carcinoma) in males, and 3. benign liver tumors (hepatocellular adenoma) in females. In mice given *o*-nitrotoluene in the feed at approximately 0, 150, 320, or 700 mg/kg per day developed malignant blood-vessel tumors (hemangiosarcoma) in both sexes; malignant tumors of the large intestine (cecal carcinoma) in males, and benign or malignant liver tumors (hepatocellular adenoma or carcinoma) in females (NTP, 2002). Under similar conditions, the *p*-isomer was either noncarcinogenic or equivocal (Dunnick et al., 2003).

o-Nitrotoluene has also been shown to be a potent carcinogen with short tumor latency. Mesotheliomas, skin, liver, mammary gland, and liver tumors were induced in male rats administered with *o*-nitrotoluene in their feed at 125 or 315 mg/kg per day for as short as 13 weeks (NTP, 1992; Dunnick et al., 2003). Under the similar conditions the *p*- and *m*-isomers did not display any carcinogenic potential (NTP, 1992). Bile duct cancer (cholangiocarcinoma) was observed in rats exposed to *o*-nitrotoluene for 26 weeks as well as in rats exposed for 13 weeks and then observed for 13 more weeks without exposure (NTP, 1996). A concurrent comparative study showed that *o*-nitrotoluene was a more potent carcinogen than its nitroreductase-reduced metabolite, *o*-toluidine (NTP, 1996).

There are no studies on the relationship between human cancer and specific exposure to *o*-nitrotoluene. However, *o*-nitrotoluene is used to manufacture magenta and reviews of magenta manufacturing in 1987 and 1993 by the IARC working group concluded that there is sufficient evidence in humans that the manufacture of magenta entails exposures that are carcinogenic (IARC, 1996). Their assessment was based on two cohort studies and a case-control study, all of which reported an excess risk of bladder cancer, and one study specifically mentioned that the workers were exposed to *o*-nitrotoluene as a part of the magenta manufacturing process.

o-Nitrotoluene is a reproductive and developmental toxicant in rats. In a nonstandard reproductive toxicity study in rats, *o*-nitrotoluene administered in feed at 5000 ppm for 13 weeks caused damage to the testes and the epididymis with a simultaneous reduction in the sperm count and the motility, and a prolongation of the menstrual cycle among the females. Reduced sperm motility was also observed at 10,000 ppm for the mouse. The NOAEL for impaired fertility was considered to be 2500 ppm (179 mg/kg bw) in male rats.

In a developmental toxicity study in which male and female CD rats received *o*-nitrotoluene at daily doses of 0, 50, 150, or 450 mg/kg/day over a total period of approximately 10 weeks, the only effect considered as indicative of developmental toxicity was the retardation in pup growth. The LOAEL was considered to be 50 mg/kg/day (EU, 2008; Dunnick, 1994).

Mechanism of Action

o-Nitrotoluene is absorbed rapidly into the blood after oral administration to rats and mice. In the rat liver, *o*-nitrotoluene is metabolized to *o*-nitrobenzyl alcohol which can undergo several pathways: (1) glucuronidation (2) sulfation and subsequent reaction with glutathione and acetylcysteine, or (3) nitroreduction to *o*-aminobenzyl alcohol followed by oxidation to *o*-aminobenzoic acid. Most of the metabolites are eliminated primarily in the urine (NTP, 2002). The glucuronide of *o*-nitrobenzyl alcohol, via the bile, can also be excreted into the small intestine where bacteria can deconjugate and reduce the nitro group to form aminobenzyl alcohol. The aminobenzyl alcohol reabsorbed from the intestine can be further metabolized by the liver to reactive compounds (carbonium and nitrenium ions) that can covalently bind to DNA or proteins (Chism and Rickert, 1985; NTP, 2002, 2008). Thus, microbial metabolism in the intestine appears to be an important step in the carcinogenicity of *o*-nitrotoluene. The higher carcinogenic potency of the *o*-isomer as compared to *m*- and *p*-isomers is likely due to difference in metabolic activation of the isomers.

NTP studies (NTP, 2002; Dunnick, 1993) consistently showed that *o*-nitrotoluene did not cause mutations in *S.typhimurium* with and without S9. However, a study by Salamanca-Pinzon et al. (2006) showed positive results for nitroaromatic compounds using nitroreductase proficient bacteria. Mixed results were observed from assays using cultured mammalian cells. *o*-nitrotoluene caused (1) sister chromatids exchange in Chinese hamster ovary (CHO) cells, (2) chromosomal aberrations in Chinese hamster lung (CHL) cells and human peripheral lymphocytes but not in CHO cells, (3) micronucleus formation in CHL cells but not in CHO-K1 cells, and (4) DNA damage in L5178Y mouse lymphoma cells but no induction of DNA repair in rat or human hepatocytes (NTP, 2008). In rats and mice exposed *in vivo*, *o*-nitrotoluene caused a slight increase in micronucleus formation in peripheral normochromatic erythrocytes in male mice at a high dose level but this finding was not considered conclusive. *o*-Nitrotoluene did not induce micronucleus formation in peripheral normochromatic erythrocytes in female mice or in polychromatic erythrocytes in the bone marrow of male rats or mice (NTP, 2002). Following *in vivo* exposure of rats to *o*-nitrotoluene, DNA repair was increased in liver cells isolated from males, but not from females or germ-free males. These results suggest that

activation of *o*-nitrotoluene to become genotoxic may be sex-specific and depends on both mammalian metabolism and metabolism by intestinal bacteria (Doolittle et al., 1983).

There is evidence that mutations of some oncogenes and tumor suppressor genes may play a role in the molecular pathogenesis of *o*-nitrotoluene-induced. Mutations in the p53 and β -catenin genes and production of these proteins in mice were detected in *o*-nitrotoluene-induced hemangiosarcomas and colon tumors from mice (Hong et al., 2003); K-ras gene mutations and cyclin D1 protein production also were detected in the colon tumors (Sills et al., 2004). Mutations in p53, β -catenin, and K-ras genes may be a result of the genotoxic effects of *o*-nitrotoluene, and these alterations probably contributed to the pathogenesis of the hemangiosarcomas and large intestinal carcinomas in mice induced by *o*-nitrotoluene. Studies in rats have also provided evidence that cellular and molecular events involved in the induction of mesotheliomas are similar in both experimental animals (rats exposed to *o*-nitrotoluene) and humans. Microarray analysis of peritoneal mesotheliomas from F344 rats treated with *o*-nitrotoluene identified the following carcinogenic pathways: insulin-like growth factor 1 (IGF-1), p38 MAPK, Wnt/ β -catenin, and integrin signaling pathways (Kim et al., 2006).

o-Nitrotoluene and its metabolite, *o*-nitrosotoluene have recently been shown to cause estrogen-disrupting effects in a number of bioassays by Watanabe et al. (2010). An E-screen assay using the human breast cancer cell line MCF-7 revealed that *o*-nitrotoluene can induce estrogen-dependent cell proliferation. On the other hand, *o*-nitrosotoluene decreased the cell number and suppressed 17 β -estradiol-induced cell proliferation. These disruptive effects may play a role in the reproductive toxicity of *o*-nitrotoluene.

Chemical Pathology

o-Nitrotoluene, as an aromatic, nitrogen-containing compound, is capable of forming methemoglobin. Exposures to 1 ppm (5.7 mg/m³) or lower is not expected to show any toxic effects, and 40 ppm (228 mg/m³) is considered as a no tolerated concentration because exposure to that level may lead to symptoms of illness. Exposure to 200 ppm (1140 mg/m³) or higher may cause severe toxic effects (EU, 2008).

It is a fast-acting, potent carcinogen that induces tumors in multiple targets in rodents with a latency as short as 13 weeks. Although there are no studies on the relationship between human cancer and specific exposure to *o*-nitrotoluene, an excess risk of bladder cancer has been shown in workers exposed to *o*-nitrotoluene as a part of the magenta manufacturing process (NTP, 2011). There is evidence of mutations of some tumor suppressor genes and oncogenes (e.g., p53, β -catenin, and K-ras genes) in tumors induced by *o*-nitrotoluene. These alterations may be a result of the

genotoxic effects of *o*-nitrotoluene and probably play a role in the molecular pathogenesis of *o*-nitrotoluene in rodents and in humans (Hong et al., 2004; Sills et al., 2004; Kim et al., 2006).

There are some evidences that *o*-nitrotoluene is a reproductive and developmental toxicant in rats; estrogen disruptive effects have been suggested to play a role in the reproductive toxicity of *o*-nitrotoluene (Watanabe et al., 2010).

SOURCES OF EXPOSURE

Occupational

In factory workers exposed to *o*-nitrotoluene, *o*-nitrotoluene–hemoglobin adducts were detected in the blood (Jones et al., 2005a), and *o*-nitrobenzoic acid and *o*-nitrobenzyl alcohol were detected in the urine (Jones et al., 2005b), providing evidence that human exposure to *o*-nitrotoluene results in production of a reactive metabolite(s). In addition, adducts between hemoglobin and 2-methylaniline (a metabolite of *o*-nitrotoluene) were identified in both exposed workers and exposed rats, and the level of 2-methylaniline–hemoglobin adducts in the blood of rats was proportional to the level of 2-methylaniline–DNA adducts in the livers of rats (Jones and Sabbioni, 2003; Jones et al., 2003).

o-Nitrotoluene was detected at a concentration of 47 ng/m³ in ambient air at a chemical manufacturing plant in New Jersey (IARC, 1996) and at air concentrations of up to 2.0 mg/m³ in the nitrotoluene production area of a Swedish plant producing pharmaceuticals and explosives (Ahlborg et al., 1985). The highest measured value of occupational exposure in an Italian manufacturer of *o*-nitrotoluene was reported to be 0.280 mg/m³, whereas the values based on the estimation and assessment of substance exposure (EASE) model were 0.35–0.7 mg/m³ (EU, 2008).

Environmental

o-Nitrotoluene may enter the environment via the air and waste water during its production and/or use in the manufacture of other products. In West Europe, the major manufacturers and/or processors of *o*-nitrotoluene settled in Germany, the United Kingdom, and Italy (EU, 2008). The U.S. has one plant in Pascagoula, Mississippi (U.S. EPA, 2010).

Environmental surveys have demonstrated the presence of *o*-nitrotoluene in river and drinking water (IARC, 1996). *o*-Nitrotoluene was detected in ground water that was contaminated by munitions arsenal; the average concentrations reported in 2001 was 42.6 mg/l (42,600 μ g/l) (NTP, 2011). There were some reports of detection of *o*-nitrotoluene in the smog in China (Wu et al., 2006).

INDUSTRIAL HYGIENE

The time-weighted average TLV-TWA for *o*-nitrotoluene adopted by American Conference of Governmental Industrial Hygienists (ACGIH) is 2 ppm with skin notation. The OSHA PEL is 5 ppm. The NIOSH recommended exposure limit is 2 ppm and IDLH is 200 ppm (HSBD, 2011). *o*-Nitrotoluene is considered by ACGIH to be an inducer of methemoglobin and recommends that methemoglobin in blood be used as a biological exposure index for *o*-nitrotoluene (ACGIH, 2009). It is designated as a hazardous substance under the Federal Water Pollution Control Act and further regulated by the Clean Water Act Amendments of 1977 and 1978 (HSDB, 2011).

o-Nitrotoluene has been listed in Report on Carcinogens (NTP, 2011) as “reasonably anticipated to be human carcinogens” based on of sufficient evidence of carcinogenicity from studies in experimental animals and supporting data on mechanisms of carcinogenesis. The IARC (IARC, 1996) has classified *o*-nitrotoluene as a Group 2B “possible human carcinogen” based on sufficient animal data but inadequate human data.

MEDICAL MANAGEMENT

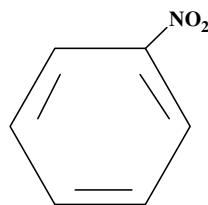

Appropriate treatments for methemoglobinemia such as administration of oxygen, ascorbic acid or methylene blue should be performed as described (Dutta et al., 2008) if overexposure of *o*-nitrotoluene is suspected and signs of cyanosis (at the lips, tongue, and nail beds) and symptoms of methemoglobinemia occur.

NITROBENZENE

BACKGROUND AND USES

Nitrobenzene is a synthetic, volatile compound produced primarily for use to manufacture aniline. It is also used as a solvent in refining petroleum and lubricating oils, and in production of dyes, synthetic rubber, pesticides, and drugs including acetaminophen and metoclopramide. Small amounts of nitrobenzene are used as a flavoring agent for soaps and as a solvent for shoe dyes (HSDB, 2009; IARC, 1996). Dinitrobenzene isomers (1, 2-, 1, 3-, and 1, 4-) are used in organic synthesis of dyes, pesticides, and industrial solvents. 1,3-Dinitrobenzene and 1,3,5-trinitrobenzene are chemicals found in the production of explosives.

The U.S. production volume of nitrobenzene has increased from 73,000 metric tons in 1960 to 435,000 metric tons in 1986, and from 533,000 metric tons in 1990 to 740,000 metric tons in 1994 that was about one-third of the worldwide production of 2,133,800 metric tons (IARC, 1996; IPCS, 2003). Since 1990, U.S. annual production of nitrobenzene

has been more than one billion pounds (U.S. EPA, 2004). In 2009, there were 5 U.S. producers and 20 U.S. suppliers of nitrobenzene (NTP, 2011).

Nitrobenzene and all isomers (1,2-, 1,3-, and 1,4-) of dinitrobenzene can be absorbed by all routes of exposures and may cause irritation in the respiratory tract and skin. 1,3-Dinitrobenzene and 1,3,5-trinitrobenzene are of severe explosive hazard. Toxicity studies on nitrobenzene, di- and trinitrobenzenes in experimental animals have revealed a similar spectrum of toxicological effects. Nitrobenzene was the subject of several toxicological reviews (ATSDR, 1990; IARC, 1996; IPCS, 2003; U.S. EPA, 2009).

PHYSICAL AND CHEMICAL PROPERTIES

Nitrobenzene has a single nitro group attached to a benzene ring. It is an oily yellow liquid with an almond-like odor. It has a molecular weight of 123.11, a density of 1.204, a melting point of 5.8 °C, a boiling point of 210.8 °C, and a vapor pressure of 0.15 mm Hg (20 °C). It is moderately soluble in water (1.9 g/l at 20 °C) and is soluble in alcohol, acetone, ether, and benzene (IARC, 1996). It has a flash point of 88 °C and an explosive limit of 1.8% by volume in air, representing a fire hazard. Its log P (octanol/water partition coefficient) is 1.85.

MAMMALIAN TOXICOLOGY

Acute Effects

Nitrobenzene can be absorbed by all routes of exposure. It is moderately irritating to the respiratory tract and skin. A 40% rate of mortality in Sprague-Dawley (CD) rats was reported after they were exposed to 125 ppm nitrobenzene by inhalation (Medinsky and Irons, 1985). After two or three dermal applications of nitrobenzene (dosage not reported) to mice resulted in 80% deaths of the animals. Most animals were in partial collapse within 15 min and were dead within the first day. Slight swelling of the glomeruli and tubular epithelium were observed upon histological examination (Shimkin, 1939). Single acute oral exposure of Fischer 344 rats to 200 mg/kg or higher nitrobenzene resulted in over 20% increase in methemoglobin (Goldstein et al., 1984). Testicular degeneration and transiently decreased sperm production were observed in rats following a single oral dose of 300 mg/kg (Levin et al., 1988). Brain damages have also been reported after a single oral administration of nitrobenzene at 550 mg/kg to rats (Morgan et al., 1985). An oral LD₅₀ was estimated to be 600 mg/kg in rats (Smyth et al., 1969).

Chronic Effects

The major toxic effect of chronic and subchronic exposures to nitrobenzene is methemoglobinemia. Elevated levels of

blood methemoglobin have been reported in rats exposed to nitrobenzene by inhalation at levels as low as 10 ppm for two weeks (Medinsky and Irons, 1985) or 5 ppm for 90 days or longer (CIIT, 1984, 1993; Cattley et al., 1994). In addition, dose-related lesions of the liver, kidney, spleen, brain, and lung occurred in rats and mice after exposure to 5–125 ppm nitrobenzene vapor in repeated-dose studies (Medinsky and Irons, 1985; CIIT, 1984, 1993; Cattley et al., 1994). A number of repeated dose studies by the oral route have also reported induction of methemoglobinemia with dose-related changes in the levels of hematologic parameters and histopathologic effects on various organs including spleen, liver, kidney, thymus, and the brain in rats at doses of 60–300 mg/kg bw/day nitrobenzene (Bond et al., 1981; NTP, 1983; Mitsumori et al., 1994). Differences in species, strain and sex susceptibility to the toxic effects of nitrobenzene exposure were noted. For example, despite the mice were treated with higher doses, nitrobenzene-induced pathological changes were much less pronounced in mice than in rats, suggesting that the mice were more resistant to nitrobenzene toxicity. On the basis of increases in absolute and relative organ weights and the dose-dependent increases in methemoglobin and reticulocyte count in F344 rats, a LOAEL of 9.38 mg/kg-day was determined for the subchronic oral effects of nitrobenzene (NTP, 1983).

There is strong evidence that nitrobenzene is a male reproductive toxicant. Testicular atrophy, bilateral degeneration of the seminiferous tubules, and a reduction in or absence of mature sperm in the epididymis were noted in both F-344 and Sprague-Dawley (CD) rats exposed to nitrobenzene vapor at 50 ppm for 90 days (Hamm, 1984). Dodd et al. (1987) reported a decrease in fertility indices in a two-generation inhalation study in rats exposed to 40 ppm nitrobenzene for 10 weeks resulting from atrophy of seminiferous tubules, spermatocyte degeneration and reduced testicular, and epididymal weights. Following a single oral dose of 300 mg/kg of nitrobenzene, lesions in the seminiferous tubules of the testicles, with marked necrosis of primary and secondary spermatocytes were observed in male F344 rats (Bond et al., 1981). A significant effect on testis weight in rats was seen at 75 and 150 mg/kg-day and in male mice at 300 mg/kg-day in a 90-day gavage study. In addition, sperm motility of exposed rats was adversely affected, and the incidence of abnormal sperm was increased (NTP, 1983; Morrissey et al., 1988). A dose-related increase in the incidence of sperm abnormality was seen in mice exposed to a mixture of three metabolites of nitrobenzene (Wang et al., 2011).

Several reproductive/developmental toxicity studies in Sprague-Dawley rats administered nitrobenzene by gavage have also shown significant reductions in testicular and epididymal weights, sperm count, and motility, sperm viability, atrophy of the seminiferous tubules, hyperplasia of Leydig cells, loss of intraluminal sperm in the epididymides, and fertility index in animals receiving 60 to 100 mg/

kg-day of nitrobenzene (Mitsumori et al., 1994; Kawashima et al., 1995). However, studies in Sprague-Dawley rats indicate that inhalation exposure to nitrobenzene does not result in fetotoxic, embryotoxic, or teratogenic effects at concentration (40 ppm) that is maternally toxic (Tyl et al., 1987).

Nitrobenzene is carcinogenic in rats and mice, inducing multiple-sites tumors in both species. In a 2-year inhalation cancer bioassay, groups of male rats of two strains (F344/N and Sprague-Dawley), female rats of one strain (F344/N), and male and female mice (B6C3F1) were administered nitrobenzene for 6 h/day, 5 days/week for 104 weeks at concentrations of 0, 1, 5, or 25 ppm (rats) and 0, 5, 25, or 50 ppm (mice). Exposure to nitrobenzene caused liver tumors in male rats of both F344/N and Sprague-Dawley strains, kidney tumors and thyroid tumors in male F344/N rats, and endometrial polyps in female F344/N rats. In addition, positive dose-response trends in the incidences of liver tumors were observed in female F344/N rats. Exposure to nitrobenzene caused lung and thyroid tumors in male B6C3F1 mice and liver and mammary gland tumors in female B6C3F1 (CIIT, 1993; Cattley et al., 1994).

There is one case-control study describing cancer effects from exposure to nitrobenzene. Paternal exposure to nitrobenzene was associated with a statistically nonsignificant increase in the risk of childhood brain cancer, based on a small number of cancer patients whose fathers had been exposed to nitrobenzene (Wilkins and Sinks, 1990). A recent epidemiological study reported significantly increased bladder cancer incidence among workers coexposed to *o*-toluidine, aniline, and nitrobenzene at a rubber chemical manufacturing plant (Carreón et al., 2013).

MECHANISM(S) OF ACTION

Nitrobenzene is readily absorbed by animals and humans via inhalation, and dermal and oral routes of exposure. Metabolism studies in mammals showed that it can be reduced to aniline by intestinal microflora and hepatic microsomes. In addition, nitrobenzene can be oxidized by hepatic microsomes to *o*-, *m*-, and *p*-nitrophenol. Metabolism of nitrobenzene in mammals displays animal species and strain specificity, and toxicokinetics data in rats and mice after oral administration indicate that various amounts of metabolites are distributed to the blood, liver, brain, kidney, and lung. Species and/or strain differences in toxicity of nitrobenzene are likely due to the difference in oxidative and reductive metabolism of nitrobenzene to its toxic metabolites (Reddy et al., 1976; Levin and Dent, 1982; Goldstein et al., 1984). There is ample evidence that methemoglobinemia is caused by the interaction of Hb with the metabolic intermediates of nitrobenzene reduction including nitrosobenzene, phenylhydroxylamine, and aniline.

The mechanism of nitrobenzene carcinogenesis is not clearly understood. Nitrobenzene showed negative responses in most genotoxicity tests. Except in strain TA 98 in the presence of S9 and the comutagen, norharman, nitrobenzene was negative in all standard Ames assays in various strains of *Salmonella typhimurium*. It was weakly positive for the induction of chromosome aberrations in cultured human peripheral lymphocytes but negative in human spermatozoa. It failed to induce unscheduled DNA synthesis or cell transformation *in vitro*. Cytogenetic analyses of lymphocytes in the peripheral blood or in splenic blood of rats exposed to nitrobenzene did not reveal an increase in sister chromatid exchange (SCE), chromosomal aberrations or unscheduled DNA synthesis (IARC, 1996). However, a more recent study has reported DNA damages and induction of micronuclei in rat and human kidney cells by nitrobenzene (Robbiani et al., 2004). A dose-related increase in the incidence of micronucleus was seen in mice exposed to three metabolites mixture of nitrobenzene (Wang et al., 2011). It has been speculated that tumors may arise from oxidative stress resulting from oxidative and reductive metabolism of nitrobenzene and generation of free radicals (e.g., nitro anion and superoxide anion, hydronitroxide) (Hsu et al., 2007; Holder, 1999; Gutteridge, 1995). Possible events by which reactive free radicals could cause tumor formation include direct DNA oxidative damage, lipid peroxidation, damage to DNA repair enzymes, or modulation of DNA methylation (Halliwell, 2007).

CHEMICAL PATHOLOGY

Methemoglobinemia is the major adverse effect of nitrobenzene in humans. The condition arises when the rate of methemoglobin (metHb) formation exceeds the rate of reduction of oxidized heme iron from the ferrous (Fe^{2+}) state to the ferric (Fe^{3+}) state, and when a metHb concentration exceeding 2–3% of total methemoglobin (Hb) (Denshaw-Burke, 2013). Nitrobenzene and some aromatic amines can cause methemoglobinemia by accelerating the oxidation of Hb to metHb, which loses its ability to combine reversibly with and to transport oxygen (Percy et al., 2005). Following such an exposure, the skin may turn bluish in color and this may be accompanied by nausea, vomiting, and shortness of breath. Effects such as headache, irritability, dizziness, weakness, and dyspnoea may also occur. If the exposure level is extremely high, nitrobenzene can cause coma and possibly death unless prompt medical treatment is received. The lethal dose is reported to range from 1 g to 10 g (Chongtham et al., 1997).

Acute intoxication is usually asymptomatic up to the level of 10–15% of methemoglobin, showing only cyanosis. Beyond 20%, headache, dyspnea, chest pain, tachypnea, and tachycardia develop. At 40–50%, confusion, lethargy,

and metabolic acidosis occur leading to coma, seizures, bradycardia, ventricular dysrhythmia, and hypertension. Fractions around 70% are fatal. Anemic or G6PD-deficient patients suffer more severe symptoms. Leukocytosis has been reported, with relative lymphopenia. Other effects include hepatosplenomegaly, altered liver functions, and Heinz body haemolytic anemia (Dutta et al., 2008). The findings of damage to the testicles and decreased levels of sperm in animals exposed to nitrobenzene is a concern to humans.

Some workers in plants producing nitrobenzene with air concentrations averaging 6 ppm (30 mg/m³) experienced headache and vertigo with low concentrations of met-hemoglobin. Poisoning was reported to start at air concentrations of about 40 ppm (200 mg/m³). A man ingested about 7 g nitrobenzene was reported to have developed severe methemoglobinemia (78% methemoglobin) (IARC, 1996). Severe methemoglobinemia (70% methemoglobin) was also observed in an 82-year-old male who had ingested 250 ml of nitrobenzene; 3.2 µg/ml of nitrobenzene was detected in the blood 48 h after ingestion (Martínez et al., 2003).

SOURCES OF EXPOSURE

Occupational

Occupational exposure is of great concern, since nitrobenzene can be absorbed readily through the skin as well as by inhalation. On the basis of a survey conducted from 1981 to 1983 by the National Institute of Occupational Safety and Health's (NIOSH's), it was estimated that 5080 employees (475 females) potentially were exposed to nitrobenzene (IARC, 1996; HSDB, 2009).

There were no recent data on occupational exposure to nitrobenzene. Direct release of nitrobenzene to air during its manufacture is minimized by passage of contaminated air through activated charcoal, and most (97–98%) of the nitrobenzene produced is retained in closed systems, thus limiting its release into air (ATSDR, 1990).

Environmental

Environmental exposure to nitrobenzene is primarily through inhalation of ambient air, ingestion of water, or dermal exposure to products and water containing nitrobenzene. Although direct release of nitrobenzene to air during its manufacture is minimized by the passage of contaminated air through activated charcoal or retained in closed manufacturing systems, as much as 8.3 million pounds/year were estimated to be released from industrial processes (ATSDR, 1990). Nitrobenzene was found in 7 of the 1177 NPL hazardous waste sites in the United States (ATSDR, 1990); a geometric mean concentration of 1000 µg/kg nitrobenzene was detected in soil/sediment samples at 4 of 862

hazardous waste sites (ATSDR, 1990). Since 1988, trends data have shown annual declines; total air emissions have varied between 25529 and 81297 pounds, with no evident upward. In 2012, EPA's Toxics Release Inventory reported total on- and off-site releases of nitrobenzene as 240,529 pounds (U.S. EPA, 2012).

Use of nitrobenzene in consumer products such as metal and shoe polishes could contribute to environmental releases via fugitive emissions, wastewater, spills, and end-product usage. However, environmental degradations including photolysis and microbial biodegradation occur within a few days after it is released, and air and water in most areas contain no detectable nitrobenzene. Nitrobenzene has been measured in fish samples in Japan (4 of 147 samples) at levels ranging from 11 to 26 µg/kg. It is poorly bioaccumulated and not biomagnified through the food chain (IPCS, 2003).

Standards	Values
NIOSH REL	1 ppm (5 mg/m ³) TWA (skin)
OSHA PEL	1 ppm (5 mg/m ³) TWA (skin)
ACGIH TLV	1 ppm (5 mg/m ³) TWA (skin)
IDLH	200 ppm
RfD	2×10^{-3} mg/kg-day
RfC	9×10^{-3} mg/m ³
Cancer unit risk (inhalation)	4×10^{-5} per µg/m ³

INDUSTRIAL HYGIENE

The American Conference of Governmental Industrial Hygienists (ACGIH, 2013) has established a threshold limit value (TLV) for nitrobenzene of 1 ppm (5 mg/m³), with a skin notation, indicating potential absorption through skin. The Occupational Safety and Health Administration (NIOSH, 2011) has established a permissible exposure level (PEL) of 1 ppm (5 mg/m³) as an 8-h time-weighted average (TWA) for nitrobenzene and all isomers of dinitrobenzene. According to the National Institute for Occupational Safety and Health (NIOSH) "immediately dangerous to life or health" (IDLH) concentration for nitrobenzene is 200 ppm. Nitrobenzene is grouped as 2B "Possibly carcinogenic to humans" in IARC (1996), and is listed as "Reasonably Anticipated to be a Human Carcinogen" by the National Toxicology Program (NTP, 2011).

The U.S. Environmental Protection Agency (EPA) regulates nitrobenzene under the Clean Air Act (CAA), the Clean Water Act (CWA), the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and the Resource Conservation and Recovery Act (RCRA). Under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), any release in excess of 1,000 pounds (454 kg) should be reported. Based on the toxicological data of nitrobenzene, EPA has established an oral RfD of 2×10^{-3} mg/kg-day, an inhalation RfC of 9×10^{-3} mg/m³

and an inhalation unit cancer risk of 4×10^{-5} per µg/m³ (U.S. EPA, 2009).

MEDICAL MANAGEMENT

A severe case of acute poisoning of a 16-year-old female with nitrobenzene was reported by Saxena and Saxena (2010). After clinical evaluation, treatment based on the principles of decontamination and symptomatic, and supportive management, a life was saved with repeated intravenous methylene blue and other treatments. Methylene blue is an exogenous cofactor, which greatly accelerates the NADPH-dependant methemoglobin reductase system, and is the antidote of choice for the acquired (toxic) methemoglobinemia. It is administered intravenously at 1–2 mg/kg as a 1% solution over 5 min. In this case, repeated low dose of methylene blue was administered which helped in tiding over the fluctuating symptoms due to the release of nitrobenzene from the body stores, without exceeding the maximum dose. Being an oxidant, methylene blue may cause methemoglobinemia in susceptible patients at levels of more than 7 mg/kg. Fresh blood transfusion was given which improved the oxygen carrying capacity and hemoglobin content, thus improving the patient symptomatically. Oral charcoal and purgation up to 5 days were administered to eliminate the body stores of nitrobenzene and prevent secondary deterioration in the patient, as reported in other cases (Dutta et al., 2008). Forced diuresis led to a rapid fall in methemoglobin levels and improved discoloration. Ascorbic acid supplements were prescribed for follow-up management of methaemoglobinaemia (Kaushik et al., 2004).

It is noteworthy that methylene blue is contraindicated in patients with G6PD deficiency, because it can lead to severe hemolysis. Ascorbic acid is an antioxidant and may be administered in such patients especially when methemoglobin levels were more than 30%. Hyperbaric oxygen is reserved only for those patients who have a methemoglobin level more than 50% or those who do not respond to standard treatment (Dutta et al., 2008). It is important to take care of nutrition, adequate urine output, and hepatoprotection to prevent possible late effects of kidney and liver failure.

2-NITROPROPANE

BACKGROUND AND USES

Several nitroalkanes, including nitromethane, nitroethane, 1-nitropropane (1-NP), and 2-nitropropane (2-NP) have been commercially available since 1940. By virtue of their unusual spectrum of industrially desirable properties, their

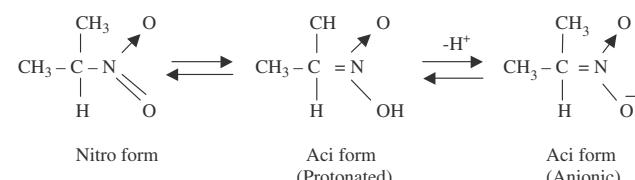

production has rapidly increased for many applications. 2-NP is used widely as a specialty solvent for coatings, printing inks, paints, varnishes, and adhesives. It has also been used as an intermediate in the synthesis of dyes, pesticides, textile chemicals, and pharmaceuticals, and an additive in explosives, propellants, and fuels. In 1977, it was estimated that about 30 million pounds of 2-NP were produced by a U.S. producer annually, and as many as 185,000 workers were exposed to 2-NP during its production and use (Bingham and Robbins, 1980). Between 1986 and 2002, U.S. production plus imports of 2-NP were reported to be about 10–50 million pounds (U.S. EPA, 2004). 2-NP is also manufactured by companies in France and other countries. The current worldwide production of 2-NP is unknown.

2-NP is a minor component of tobacco smoke and is present in smoke from other types of nitrate-rich organic matter. Residues in food products containing fatty acids separated with 2-NP and in beverage can linings and other coatings may represent additional sources of exposure to low amounts of 2-NP. Emerging evidence on carcinogenicity in experimental animals, along with various other toxic effects observed in animals and workers exposed to 2-NP, has attracted the attention of various U.S. and international regulatory agencies to the potential hazards of 2-NP and other nitroalkanes. As a result, 2-NP has been the subject of several toxicological reviews (U.S. EPA, 1991; IARC, 1999; IPCS, 1992; Woo et al., 1985).

PHYSICAL AND CHEMICAL PROPERTIES

The physicochemical properties of nitroalkanes have been extensively reviewed (Woo et al., 1985). 2-NP is an aliphatic nitro compound. It is a colorless, oily, and flammable liquid with a mild fruity odor. It has a molecular weight of 89.10, a boiling point of 120 °C, a melting point of –91.3 °C, a vapor pressure of 13 torr at 20 °C, and a flash point of 39.4 °C. It is slightly soluble in water (1.7 ml/100 ml) and miscible with many organic solvents.

As other nitroalkane, 2-NP exists in tautomeric equilibrium with its nitronic acid isomers (protonated and anionic aci forms):

The aci form is amphotERICALLY reactive, the protonated form being electrophilic and the anionic form being nucleophilic.

MAMMALIAN TOXICOLOGY

Acute Effects

The acute toxicity of 2-NP has mainly been studied in animals by inhalation and oral exposures (IPCS, 1992). The LC₅₀ for rats following a 6-h exposure was 400 ppm (1.5 g/m³) for males and 720 ppm (2.6 g/m³) for females. In mice, the LC₅₀ value was about 560 ppm (2038 mg) for both males and females following a 6-h exposure. Cats appeared more sensitive to acute exposure to 2-NP than other animals; the acute sensitivity of animals to inhaled 2-NP (from high to low) was cat, rat and mouse, rabbit, and guinea pig. Animals exposed to concentrations of 2,300 ppm (8.4 g/m³) for 1 h or longer have been reported to display severe pathological changes including hepatocellular damage, pulmonary edema, and hemorrhage. The 14-day oral LD₅₀ for mice was 0.40 g/kg. The minimal inhalation and oral lethal doses for the rabbit were 0.24 g/kg and 0.50–0.75 g/kg, respectively. In animals, the toxic effects of acute exposure to 2-NP are characterized by hepatotoxicity, methaemoglobin formation, and depression of the central nervous system (Zitting et al., 1981).

2-NP is Irritating to the skin, eyes, and respiratory system. Acute occupational exposures to about 20–45 ppm (73–164 mg/m³) 2-NP caused headache, nausea, vomiting, diarrhea, and anorexia in workers. Several human cases of fatalities have been reported (HSDB, 2011). One construction worker who was exposed to 2-NP while applying epoxy resin coatings died 10 days after exposure from fulminant hepatitis, and had serum concentration of 2-NP at 13 mg/l (Harrison et al., 1987). Exposures to high concentration (about 600 ppm or 2184 mg/m³) of 2-NP have also been reported to be fatal after severe liver and kidney damages and respiratory failure (Hine et al., 1978).

Chronic Effects

A number of repeated-dose studies in animals have shown that chronic exposures to 2-NP caused primarily liver toxicity and neoplasms. Increased liver weights and serum enzyme levels (e.g., SGPT), and morphological changes in the liver characterized by cytoplasmic vacuolization of hepatocytes, focal necrosis, and hypertrophic nodules with large vesiculated nuclei have been observed in a series of inhalation exposure studies in Sprague-Dawley rats or Long Evans rats (Angus Chemical Company, 1985a, 1985b; Griffin et al., 1980, 1981). These effects showed a dose–response relationship at 25–200 ppm and exposed for 2–22 months. In addition, male rats were shown to be more sensitive to 2-NP than females. Based on mild hepatic effects, a LOAEL of 25 ppm (78 mg/m³; HEC = 16.3 mg/m³) was determined (Griffin et al., 1981). In addition to hepatic effects, thickening of alveolar septa was noted in all exposed Sprague-Dawley and Long Evans rats who inhaled 200 ppm (624 mg/m³)

2-NP, 7 h/day, 5 days/week for 2–6 months, suggesting possible respiratory toxicity (Angus Chemical Company, 1985a, 1985b; Griffin et al., 1978).

In a study treating rats with oral doses of 0.002, 0.01, 0.05, and 0.25 g/kg, five times per week for 4 weeks by gavage, there was some mortality among male rats, and in both sexes there was decreased growth, anemia, increased liver and heart weights, and severe damage to the liver at 0.25 g/kg. At 0.05 g/kg, the major effect appeared to be anemia. Lower doses (0.01 and 0.002 g/kg) did not produce any toxic effects (Wester et al., 1989).

There is little information on the reproductive or developmental toxicity of 2-NP. No evidence of an increase in dominant lethality or in sperm abnormality was noted in genetic studies (McGregor, 1981). Fetal toxicity (delayed fetal heart development) in Sprague-Dawley rats following i.p. injection of 170 mg/kg 2-NP on days 1–15 of gestation was the only developmental effect reported (Hardin et al., 1981).

Several studies have demonstrated that 2-NP is carcinogenicity in the rat. In one inhalation study, groups of 50 male Sprague-Dawley rats were exposed to 0, 27, and 207 ppm 2-NP vapor 7 h/day, 5 days/week, for 24 weeks/6 months. Rats exposed at 207 ppm (0.75 g/m³) developed various liver changes such as hepatocellular hypertrophy, hyperplasia, and necrosis after 3 months. Liver neoplasms (hepatocellular carcinoma) were found in all surviving 10 rats exposed to 207 ppm 2-NP (Lewis et al., 1979). In a similar study, groups of 10 Sprague-Dawley rats of either sex were exposed to 2-NP vapor at 0, 25, 100, or 200 ppm, 7 h/day, 5 days/week, for up to 6 months. Liver carcinomas were observed in 9 of 10 male rats exposed for 6 months at 200 ppm (0.73 g/m³) and held unexposed for 6 more months. Liver tumors were also found in male rats exposed to 100 ppm (0.36 g/m³) 2-NP. Only hyperplasia and vacuolar degeneration in the livers were noted in female rats exposed to 100 or 200 ppm 2-NP (Griffin & Coulston, 1983; Griffin et al., 1984; Coulston et al., 1985). Oral dosing of male rats with 89 mg/kg (1 mmol/kg) by gavage, three times a week for 16 weeks, also induced hepatocellular carcinomas in all 22 rats sacrificed 40 weeks after the last exposure; no liver carcinoma was found in 29 control rats (Fiala et al., 1987a).

MECHANISM(S) OF ACTION

The mechanisms of liver toxicity and carcinogenicity of 2-NP are not clearly understood. 2-NP has been shown to be mutagenic in a variety of test systems. It is an active genotoxic agent in rat hepatocytes both *in vitro* and *in vivo* (Andrae et al., 1988; Fiala et al., 1989; George et al., 1989; Guo et al., 1990; Conaway et al., 1991a). Studies in various strains of rats have also demonstrated that 2-NP induced nucleic acid damage in the livers but not other organs (Andrae et al., 1988; Guo et al., 1990; Conaway et al., 1991a; Robbiano et al., 1991). Damage

to rat liver nucleic acids was only caused by intraperitoneal injection of secondary nitroalkanes but not with a primary or a tertiary nitroalkane. The greater genotoxicity of the secondary nitroalkanes was speculated to be due to the greater stability of their nitronate/aci forms at physiological pH values (Conaway et al., 1991b). The proportion of the nitronate/aci form present in water at 25 °C has been found to increase with the length of the side chain in the order of: C₃H₇>C₂H₅>CH₃ (Turnbsall and Maron, 1943).

In addition, 2-NP is mutagenic in bacteria both in the presence and absence of exogenous metabolic activation (Fiala et al., 1987b; Conaway et al., 1991a; Kohl et al., 1994). As the mutagenicity of 2-NP does not require metabolic activation and alkylation of DNA occurs after *in vitro* reaction with 2-NP, it has been hypothesized that 2-NP may exert its mutagenic and carcinogenic action via a direct nonenzymatic reaction between the compound and DNA (Speck et al., 1982). The nitronate tautomer of 2-NP is more mutagenic in *S. typhimurium* TA100 and TA102 than the parent compound, suggesting that the electrophilic aci form of 2-NP may be the reactive intermediate responsible for its mutagenic and carcinogenic effects (Fiala et al., 1987b; Kohl et al., 1994).

Nitrite is the major metabolite after oxidative metabolic degradation of 2-NP. There is evidence from *in vitro* studies that 2-NP can undergo denitrification, and conversion of 2-NP into aci tautomer propane 2-nitronate, either chemically or enzymatically, was a prerequisite for rapid denitrification (Kohl et al., 1997). Denitrification has been postulated to be the molecular mechanism involved in toxicity and carcinogenicity of 2-NP (Sakurai et al., 1980; Ullrich et al., 1978). This appears to be consistent with the relative rates of “oxidative denitrification” of nitroalkanes; as the affinity toward the microsomal mixed-function oxidase system decreases with decrease of the chain length, lower nitroalkanes are noncarcinogenic or only weakly carcinogenic as compared with 2-NP. Furthermore, genotoxicity and DNA damages in liver were increased when rats were pretreated with inducers of cytochrome P-450-dependent monooxygenases, and were reduced in rats when pretreated with inhibitors of the enzymes (Robbiano et al., 1991; Roscher et al., 1990).

The formation of 8-aminodeoxyguanosine after reaction of DNA with the nitronate tautomer of 2-NP has led Sodium and coworkers (1993) to speculate that 8-aminodeoxyguanosine may be formed either by base nitrosation followed by reduction, or via an enzyme-mediated conversion of the nitronated anion to hydroxylamine-O-sulfonate or acetate, which yields the highly reactive nitrenium ion NH₂⁺. There is evidence from *in vitro* and *in vivo* studies that sulfotransferases in rat liver are involved in the activation of 2-NP to a reactive species that animates guanosine at the C⁸ position (Sodium et al., 1994). Recent studies have also demonstrated that human sulfotransferases play a role in the bioactivation and genotoxicity of 2-NP (Oda et al., 2012; Deng et al., 2011). Several genes involved in DNA damage, DNA repair, apoptosis, and cell

cycle checkpoint control have been identified in liver of rats exposed to 2-NP for 28 days (Nakayama et al., 2006).

2-NP can induce cell proliferation in rat liver. Significant increases in the frequency of S-phase cells by measuring the incorporation of bromodeoxyuridine into newly synthesized DNA have been found in the liver of rats exposed to daily oral doses of 40 or 80 mg/kg 2-NP by gavage for 10 days. The noncarcinogenic 1-NP did not affect DNA synthesis of liver cells at these dose levels, suggesting that increased cell proliferation may contribute to the hepatocarcinogenicity of 2-NP (Cunningham and Matthews, 1991).

CHEMICAL PATHOLOGY

2-NP can be absorbed via lungs, peritoneal cavity, gastrointestinal tract, and, to a lesser extent, via skin (Nolan et al., 1982; Müller et al., 1983). High concentrations are acutely toxic and several cases of industrial fatalities have been attributed to inhalation of solvent mixtures containing 2-NP for a total of 5–16 h during the course of 1–3 days (Hine et al., 1978; Rondia, 1979; Harrison et al., 1985, 1987). The actual concentrations of 2-NP that caused deaths were not measured. In one case, the concentration of 2-NP that caused deaths was estimated to be about 2.18 g/m³ (600 ppm), as determined by the 2-NP level in the victim’s blood (0.013 g/l) (Harrison et al., 1987). Initial symptoms included headache, nausea, dizziness, anorexia, vomiting, diarrhea, and abdominal pain. Later symptoms included persistent nausea, vomiting, anorexia, jaundice, reduced urine output, diarrhea, bloody stools, and loss of reflexes. In all cases the primary cause of death was acute hepatic failure, with contributing factors such as lung edema, gastrointestinal bleeding, and respiratory and kidney failure. Liver necrosis and in some cases fatty degeneration were revealed at postmortem microscopic examination of the liver.

Exposure to nonlethal concentrations of 2-NP may exhibit symptoms such as headache, nausea, anorexia, vomiting, diarrhea, and abdominal pain (Angus Chemical Co. & Occusafe, Inc., 1986). No signs of toxic effects were noted in workers exposed to 36–109 mg/m³ (10–30 ppm) for less than 4 h/day on not more than 3 days/week (Skinner, 1947). There is inadequate epidemiological evidence that 2-NP induces cancer or other long-term toxic effects in humans (IARC, 1982, 1999).

SOURCES OF EXPOSURE

Occupational

Occupational exposure to 2-NP may occur through inhalation and dermal contact with this compound in many industries including printing (rotogravure and flexographic inks), coatings and adhesives used in industrial construction and

maintenance, highway markings, shipbuilding and maintenance, furniture manufacture, and food packaging. Area monitoring results in 2-NP production plants were ranged from 23 to 120 ppm. Current industrial exposure in the United States or worldwide is unknown. On the basis of a NIOSH survey between 1981 and 1983, as many as 9818 U.S. workers were potentially exposed to 2-NP (HSDB, 2011).

Although manufacture of 2-NP is an enclosed process with little worker exposure, and exposure levels in most operations are generally low, some painting and manufacturing operations have exposed workers to dangerously high concentrations of 2-NP vapors. Concentrations of 2-NP up to 2744 mg/m³ (754 ppm) and up to at least 265 mg/m³ (73 ppm) were exposed by workers in a pigment production and a solvent extraction plant, respectively, and concentrations as high as 6 g/m³ (1640 ppm) in air were recorded in a drum-filling operation (Crawford et al., 1985).

Environmental

Releases of 2-NP to the environment are mainly due to solvent evaporation from coated surfaces such as beverage can coatings, adhesives, and print, and from vegetable oils fractionated with 2-NP. 2-NP is a minor component of tobacco smoke and is present in smoke from other types of nitrate-rich organic matter that may represent additional sources of environmental exposure to low levels of 2-NP. In 1988, environmental releases of 2-NP were estimated to be more than 655,000 lb; releases then steadily declined and in 2007, eight facilities released a total of 28,600 lb (U.S. EPA, 2009).

2-NP is not persistent in the environment. When released to air, it undergoes photodegradation, with a half-life of 9.8 days (HSDB, 2009). When released to soil or water, it will volatilize or be degraded by bacteria. It has low acute toxicity in fish and other aquatic organisms, and it is not expected to bioaccumulate in the food chain. Thus, 2-NP is not considered to pose serious environmental hazards.

INDUSTRIAL HYGIENE

A threshold limit value (TLV) for 2-NP of 10 ppm was established by the American Conference of Governmental Industrial Hygienists (ACGIH) and a permissible exposure level (PEL) of 25 ppm (90 mg/m³) as an 8-h time-weighted average (TWA) was established by the Occupational Safety and Health Administration (OSHA). The National Institute for Occupational Safety and Health (NIOSH) "immediately dangerous to life or health" (IDLH) concentration is 100 ppm. These occupational exposure limits have been proposed to be reduced because 2-NP was found to be a potent carcinogen in rats and strong recommendations have been issued on minimizing all worker contact with 2-NP and its fumes (IRPTC, 1986; U.S. EPA, 1986; NIOSH, 1997).

NIOSH has listed 2-NP as a potential occupational carcinogen, and has issued guidelines for handling 2-NP in the workplace as if it were a human carcinogen (Finklea, 1977). 2-NP has been listed as "reasonably anticipated to be carcinogenic to humans" by the U.S. National Cancer Institute/National Toxicology Program (NTP, 2011) and classified as a group 2B, "possibly carcinogenic to humans" by the International Agency for Research on Cancer (IARC, 1999) based on sufficient evidence of carcinogenicity in rats.

The U.S. Environmental Protection Agency (EPA) regulates 2-NP under the Clean Air Act (CAA), the Emergency Planning and Community Right-To-Know Act, and the Resource Conservation and Recovery Act (RCRA). Under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), 2-NP has a reportable quantity of 10 pounds (4.54 kg) (NTP, 2011). On the basis of the toxicological data of 2-NP, EPA has established an inhalation RfC of 2E-2 mg/m³ (U.S. EPA, 1991) and a provisional inhalation cancer unit-risk factor of 27E-4 µg/m³ (U.S. EPA, 1997).

Standards	Values
NIOSH REL	None established; NIOSH considers 2-NP to be a potential occupational carcinogen
OSHA PEL	25 ppm (90 mg/m ³) TWA
ACGIH TLV	10 ppm (36 mg/m ³) TWA
IDLH	100 ppm
RfC	2E-2 mg/m ³
Cancer unit risk (inhalation)	27E-4 µg/m ³

Occupational exposure limits in the air vary among other countries and range from a TWA of 3.6 mg/m³ (1 ppm) to a short-term exposure limit (STEL) of 146 mg/m³ (40 ppm) (IPCS, 1992). The Joint FAO/WHO Expert Committee on Food Additives (JECFA) recommended that 2-NP should not be used as a solvent in food processing or as a fractionating solvent in the production of fats and oils (FAO/WHO, 1990a, 1990b; FAO/WHO, 1984).

MEDICAL MANAGEMENT

Individuals who have been exposed to high concentrations of vapors from solvent mixtures and exhibit symptoms such as headache, nausea, dizziness, drowsiness, weakness, anorexia, vomiting, diarrhea, and abdominal pain may have been exposed to 2-NP and should be hospitalized immediately. 2-NP exposures may produce a daily cycle in symptoms and improvement of initial symptoms may be temporary (Skinner, 1947). Serum enzyme levels indicative of liver toxicity, lung edema, gastrointestinal bleeding, and respiratory, and kidney functions should be continuously monitored until full recovery.

METHYL TERT-BUTYL ETHER (MTBE)

JANICE S. LEE AND ROBYN BLAIN

First aid: Eye: Irrigate immediately; skin: water flush promptly; breathing: respiratory support; swallow: seek medical attention immediately

Target organ(s): Skin, eyes, CNS, liver, kidney, blood

Occupational exposure limits: ACGIH TLV: TWA 50 ppm (mg/m³)

Reference values: EPA RfC = 3 mg/m³

Risk phrases: 11-38

Highly flammable. Irritating to the skin

Safety phrases: 2-9-16-24-33-37

Keep out of the reach of children. Keep container in a well-ventilated place. Keep away from sources of ignition—no smoking. Avoid contact with the skin. Take precautionary measures against static discharges. Wear suitable gloves

BACKGROUND AND USES

Methyl tert-butyl ether (MTBE) (CASRN 1624-04-4) is a synthetic chemical with synonyms methyl tertiary-butyl ether, tert-butyl methyl ether, tertiary-butyl methyl ether, methyl-1,1-dimethylethyl ether, 2-methoxy-2-methylpropane, 2-methyl-2-methoxypropane, methyl t-butyl ether, and MTBE. It was primarily used as a gasoline additive in unleaded gasoline in the United States prior to 2005, in the manufacture of isobutene, and as a chromatographic eluent especially in high pressure liquid chromatography (ATSDR, 1996; HSDB, 2012). It is also a pharmaceutical agent and can be injected into the gallbladder to dissolve gallstones (ATSDR, 1996). As a

result of its manufacture and use, MTBE may be released into the environment through various waste streams directly (IPCS, 1998; HSDB, 2012).

It is manufactured by the chemical reaction of methanol and isobutylene, from methanol and tert-butyl alcohol, and from tert-butyl alcohol and diazomethane (Merck, 2006). The predominant use for MTBE in the United States was as an oxygenate in unleaded gasoline promoting more complete burning of gasoline. Reformulated fuel with MTBE was widely used in the United States between 1992 and 2005 to meet the 1990 Clean Air Act Amendments (CAA) requirements for reducing carbon monoxide (CO) and ozone (O₃) levels. In 1992, 9.1 billion pounds of MTBE were produced in the United States, and the capacity was estimated at 11.6 billion pounds (U.S. EPA, 1994a). The oxygenate requirement for reformulated gasoline was removed in 2005 by the Energy Policy Act. Subsequently, refiners made a wholesale switch removing MTBE and blending fuel with ethanol. It has not been used in the United States in significant quantities in reformulated gasoline or conventional gasoline since 2005.

PHYSICAL AND CHEMICAL PROPERTIES

Methyl tert-butyl ether, a colorless liquid, is an aliphatic ether and volatile organic compound (VOC). It is moderately soluble in water and very soluble in some organic solvents such as alcohol and diethylether (ATSDR, 1996). It is a flammable liquid with a characteristic odor. Selected chemical and physical properties of MTBE are presented in Table 62.1.

TABLE 62.1 Chemical and Physical Properties of MTBE

Characteristic	Information
Chemical name	Methyl tert-butyl ether
Synonyms/trade names	Methyl tertiary-butyl ether; tert-butyl methyl ether; tertiary-butyl methyl ether; methyl-1,1-dimethylethyl ether; 2-methoxy-2-methylpropane; 2-methyl-2-methoxypropane; methyl t-butyl ether; MTBE
Chemical formula	C ₅ H ₁₂ O or (CH ₃) ₃ C(OCH ₃)
CASRN	1634-04-4
Molecular weight	88.15
Melting point	-109 °C
Boiling point	53.6–55.2 °C
Vapor pressure	245–251 mmHg at 25 °C
Density/specific gravity	0.7404–0.7578
Flashpoint	28 °C (closed cup)
Water solubility at 25 °C	51.26 g/l
Explosion limits	1.65–8.4%
Octanol/water partition coefficient (log K _{ow})	1.24
Henry's law constant	5.5 × 10 ⁻⁴ atm·m ³ /mole at 25 °C
Odor threshold	0.32–0.47 mg/m ³
Conversion factors	1 ppm = 3.61 mg/m ³ 1 mg/m ³ = 0.28 ppm

ENVIRONMENTAL FATE AND BIOACCUMULATION

It can be released during manufacturing or blending with gasoline; during the storage, distribution, and transfer of MTBE-blended gasoline; and from spills or leaks or fugitive emissions at automotive service stations (U.S. EPA, 1994a). In 1992, 3 million pounds of MTBE were released to the environment with 2.8 million pounds to the air, 100 thousand pounds to surface water, 68 thousand pounds to underground injection sites, and 288 pounds to land (U.S. EPA, 1994b). Vapor emissions from MTBE-blended gasoline may also contribute to atmospheric levels (U.S. EPA, 1988). It is not expected to persist in the atmosphere because it undergoes destruction from reactions with hydroxyl radicals. A total atmospheric lifetime for MTBE of approximately 3 and 6.1 days has been reported in polluted urban air and in non-polluted rural air, respectively (U.S. EPA, 1993a). Based upon its vapor pressure and Henry's law constant, MTBE is highly volatile and would be expected to evaporate rapidly from soil surfaces or water. It may be fairly persistent when introduced into subsurface soils or to groundwater since volatilization to the atmosphere is reduced or eliminated. It does not readily degrade in surface waters due to hydrolysis or other abiotic processes. It is also resistant to biodegradation (U.S. EPA, 1993a). It is usually removed from surface waters very rapidly because of its high volatility. If released as part of a gasoline mixture from leaking

underground storage tanks, its relatively high water solubility combined with little tendency to sorb to soil particles encourages migration to local groundwater supplies (U.S. EPA, 1993a).

The bioconcentration potential for MTBE appears to be very minor and can be considered insignificant (ATSDR, 1996).

ECOTOXICOLOGY

Aquatic toxicity data show relatively low toxicity to MTBE in freshwater and marine organisms, with lethal concentrations generally >100 mg/l (U.S. EPA, 1994a). The toxicity of MTBE has been studied in two species of freshwater algae (green algae), with 96-h EC₅₀ values ranging from 184 to 492 mg/l (BenKinney et al., 1994; Mancini et al., 1999). Acute studies in invertebrates (water flea, water snail, mayfly, amphipod, and midge) indicate MTBE to be of low toxicity with EC₅₀ values well above 100 mg/l (BenKinney et al., 1994; Mancini et al., 1999). A chronic study in the water flea reported a no observed effect concentration (NOEC) of 51 mg/l and an IC₂₀ of 42 mg/l for a 21-day test (Mancini et al., 1999). The toxicity of MTBE in freshwater fish has been evaluated, and all studies indicate MTBE to be of low acute toxicity with reported LC₅₀ values well above 250 mg/l (BenKinney et al., 1994; Geiger et al., 1988; Veith et al., 1983). The effect of MTBE on survival and development of tadpoles was evaluated and an LC₅₀ of >2500 mg/l was derived (Paulov, 1987).

Similar to freshwater algae, an EC₅₀ of 185 mg/l in marine algae also suggests low toxicity to MTBE (Mancini et al., 1999). Acute studies in marine invertebrates (copepod, mysid shrimp, grass shrimp, blue crab, mussel, and amphipod) reported LC₅₀ values ranging from 136 to >1000 mg/l (BenKinney et al., 1994; Bengtsson and Tarkpea, 1983; Mancini et al., 1999). In a 28 day chronic test with mysid shrimp, an IC₂₀ of 36 mg/l and a NOEC of 26 mg/l were reported (Mancini et al., 1999). Toxicity studies conducted in marine fish (bleak, inland silverside, sheepshead minnow) reported LC₅₀ values well above 500 mg/l (Bengtsson and Tarkpea, 1983; BenKinney et al., 1994; Mancini et al., 1999).

MAMMALIAN TOXICOLOGY

Acute Effects

The National Institute of Occupational Safety and Health (NIOSH) considers MTBE to be a skin and eye irritant (IPCS, 1998). However, in acute testing studies, results indicated that MTBE was not a skin sensitizer or primary skin irritant and eye irritation to be transient (Duffy et al., 1992). It does cause sensory and respiratory irritation with

1-h inhalation exposure to mice that increased with dose (Tepper et al., 1994). The NIOSH also reports acute inhalation exposures to MTBE to potentially cause other symptoms, including drowsiness, dizziness, headache, weakness, and unconsciousness (IPCS, 1998). Acute ingestion exposures to MTBE may cause abdominal pain, nausea, and vomiting (IPCS, 1998). However, acute toxicity studies in rodents have found MTBE to have low to very low acute toxicity after oral ($LD_{50} = 3\text{--}3.8\text{ g/kg}$), dermal ($>10\text{ g/kg}$), or inhalation (23,630–33,000 parts per million (ppm)) exposures (Duffy et al., 1992).

Humans are also acutely exposed to MTBE as part of a medical treatment to dissolve cholesterol gallstones (Thistle, 1992). Injecting the gallbladder with high doses of MTBE can result in nausea, vomiting, sleepiness, and minor transient mucosal damage in the gallbladder (U.S. EPA, 1993b).

A couple of epidemiology (cross-sectional and ecological) studies have been conducted to evaluate the health effects of individuals exposed to oxygenated gasoline or reformulated fuels (Mohr et al., 1994; Joseph and Weiner, 2002). Symptoms potentially associated with MTBE exposure included coughing, burning sensations of the nose and throat, headache, allergic rhinitis, nausea, dizziness, wheezing, and other nonspecific symptoms. Since the workers were also exposed to other gasoline components and/or combustion products of MTBE, the specific role of MTBE is unknown. Individuals exposed to concentrations of MTBE up to 50 ppm for up to 2 h with or without light physical work did not report any difference in symptoms, showed no difference in neurobehavioral battery tests, indicators of upper airway inflammation, or indication of eye inflammation compared to exposure to clean air (Prah et al., 1994; Cain et al., 1996; Johanson et al., 1995; Nihlén et al., 1998).

In an effort to further explore whether MTBE may cause adverse health effects from short-term exposure, controlled exposures to MTBE have been used to study sensory, symptomatic, cellular, and eye responses in healthy humans. Potential MTBE-related responses have also been studied in subjects with reported past exposures, but most have been conducted on small numbers of healthy adults and not on people who may be especially sensitive to MTBE exposure. Humans exposed to 11% MTBE (110,000 ppm) in gasoline for 15 min did not show any increase in symptoms compared to subjects that were exposed to clean air or gasoline alone (Fiedler et al., 2000). However, subjects exposed to 15% MTBE (150,000) in gasoline for 15 min and those who were self-reported sensitive to MTBE had a greater total number of symptoms compared to all other groups (Fiedler et al., 2000). Transient (1 h after exposure only) central nervous system (CNS) depression (as measured by functional observational battery tests) was observed in rats after a 6-h inhalation exposure to 4000 and 8000 ppm, which did not cause mortality or any overt signs of toxicity (Daughtrey et al., 1997). No such effects were noted at 800 ppm. These effects were

not persistent with subchronic exposures lasting up to 13 weeks (Daughtrey et al., 1997).

Chronic Effects

The National Health and Nutritional Survey (NHANES) collected data on MTBE exposure using personal monitors on more than 500 participants and measured several serum enzymes associated with liver function (i.e., albumin, alkaline phosphatase [ALP], γ -glutamyl transferase [GGT], total bilirubin, alanine aminotransferase [ALT], aspartate aminotransferase [AST], and lactic dehydrogenase [LDH]) (Liu et al., 2009). Methyl tert-butyl ether was associated with increases in serum levels of albumin, ALP, and GGT. Chronic rodent studies have evaluated that all major organ systems, including the reproductive system and other systems, are affected during development. The liver and kidney appear to be the most sensitive to short- and long-term exposures to MTBE. In experimental animals, chronic MTBE exposure has the potential to induce transient neurotoxicity (Bird et al., 1997; Clary, 1997; Duffy et al., 1992), liver toxicity (Bird et al., 1997), kidney toxicity (Bird et al., 1997; Bermudez et al., 2012; Dodd et al., 2013), endocrine (de Peyster et al., 2003) and developmental toxicity in the presence of maternal toxicity (Bevan et al., 1997a, 1997b). Two-generation reproductive studies have not observed effects on reproduction (Duffy et al., 1992), but effects on the male reproductive system have been observed in male rats, including effects on spermatogenesis (Li et al., 2008). No such effects have been observed in male mice (de Peyster et al., 2008).

Longer-term exposure to MTBE induces several forms of cancer in rodents. Significant increases in hepatocellular tumors in both male and female mice, renal tubule tumors in male rats, lymphohematopoietic cancer in female rats, and Leydig cell tumors in male rats have been observed (Bird et al., 1997; Belpoggi et al., 1995, 1997, 1998). However, a meta-analysis of the literature evaluating non-Hodgkins lymphoma in workers involved in the production, distribution, or use of gasoline did not find any increase in risk (Kane and Newton, 2010). A marginal increase in brain tumors was observed in a drinking water study in male rats, which the study authors considered within the historical control and not related to MTBE treatment (Dodd et al., 2013).

Chemical Pathology

Progressive nephropathy is the main pathology associated with chronic MTBE exposure in rats (Bird et al., 1997; Bermudez et al., 2012). Although chronic progressive nephropathy is observed in both sexes, it occurs earlier in males. The same is not observed after 13 weeks of exposure (Lington et al., 1997; Bermudez et al., 2012). Oral exposures in rats have been associated with lymphoma, leukemia, and

haemolymphoreticular dysplasias in female rats and interstitial cell hyperplasia and adenomas (Leydig cell tumors) accompanied by testicular degeneration, atrophy, and mineralization in male rats (Belpoggi et al., 1995, 1997, 1998). An inhalation exposure has been associated with hepatocellular tumors in both male and female mice and renal tubule tumors in male rats (Bird et al., 1997).

Hypothesized Modes of Action

There is no definitive mode of action (MOA) for MTBE-induced toxicity, but a few MOAs have been suggested. A suggested MOA for kidney toxicity in male rats, including the kidney tumors observed, has been associated with the binding of MTBE to a α_{2u} -globulin, which then accumulates in the kidney of male rats only (U.S. EPA, 1991). Kidney effects related to α_{2u} -globulin would not be relevant in humans as this MOA is not operative in humans. The presence of α_{2u} -globulin in male rats has been observed in several studies after MTBE inhalation (Bird et al., 1997; Prescott-Mathews et al., 1997, 1999; Bermudez et al., 2012). The establishment of α_{2u} -globulin as the MOA for kidney tumors is controversial with differences in opinion (Burns and Melnick, 2012; Prescott-Mathews et al., 1997). The MOA for MTBE-induced liver toxicity, including liver tumors in mice, is unknown, but MTBE has not been found to induce hepatocyte unscheduled DNA synthesis or long-term hepatocyte proliferation (Bird et al., 1997), increase nonfocal hepatocyte DNA synthesis (Moser et al. 1996), show tumor-promoting ability (Moser et al., 1996), or cause hepatic oxidative stress (de Peyster et al., 2008). Although there is no proposed MOA for the development of testicular (Leydig cell) adenoma in rats, hormonal imbalances, including reduced serum estradiol levels, decreased prolactin secretion (Cook et al., 1999), and decreased serum testosterone levels (Williams et al., 2000; de Peyster et al., 2003; Li et al., 2008) have been suggested to be involved. Others have suggested a potential role for inhibition of 5α -reductase. The combined data suggest a disruption in hormone signaling, but the data are insufficient to draw any conclusions on the specific MOA.

Methyl tert-butyl ether is metabolized to tertiary butyl alcohol (TBA), formaldehyde, 2-methyl-1,2-propanediol (MPD), and α -hydroxy isobutyric acid (HBA) (Phillips et al., 2008). Formaldehyde and TBA are the only metabolites studied in enough detail to compare to MTBE toxicity and carcinogenicity. Tertiary butyl alcohol and MTBE exposure have some similarities in their effects on rat kidney, as well as liver toxicity. However, TBA has not been found to induce liver or Leydig cell tumors (NTP, 1995). In addition, TBA exposure also has been associated with some kidney, bladder, and thyroid effects in rodents that have not been observed with MTBE exposure (NTP, 1995). In tissues exposed to exogenous formaldehyde, there is evidence for

genotoxicity observed *in vitro* in many systems with multiple end points and carcinogenesis observed in occupationally exposed humans (IARC, 2012; NTP, 2011). Methyl tert-butyl ether induces tumors in rodents, but the evidence for genotoxicity is not as clear. Genotoxicity studies have found MTBE to be nonmutagenic in Ames assays even using a sensitive strain (TA 102) of bacteria (Kado et al., 1998; McGregor et al., 2005; Vosahlikova et al., 2006), but one study found that MTBE was weakly mutagenic in the absence of S9 and moderately mutagenic in the presence of S9 using TA102, a strain proficient in excision repair (Williams-Hill et al., 1999). It has also been negative in inducing micronuclei in mouse bone marrow (McKee et al. 1997; Kado et al., 1998), Drosophila sex-linked recessive-lethal test, and rat bone marrow cytogenetics test (McKee et al., 1997). However, MTBE has been found to induce DNA double-strand breaks and DNA adducts (Du et al., 2005; Yuan et al., 2007; Chen et al., 2008; Sgambato et al., 2009), but it does not appear to affect DNA repair mechanisms (Sgambato et al., 2009).

SOURCES OF EXPOSURE

Methyl tert-butyl ether has primarily been used as a gasoline additive in unleaded gasoline, in the manufacture of isobutene, as a chromatographic eluent, and as a pharmaceutical agent. Exposure to MTBE in humans can occur through inhalation, ingestion, and eye or skin contact (IPCS, 1998).

Occupational

An occupational exposure may occur through inhalation and dermal contact at workplaces where MTBE is produced or used. This includes operations outside of the United States that manufacture or blend gasoline with MTBE, as well as operations that produce isobutene and chromatographic eluents containing MTBE. It has not been used as a fuel additive in the United States since 2005. However, the National Occupational Exposure Survey (NOES), conducted from 1981–1983 by NIOSH, statistically estimated that 4213 male workers and 1783 female workers were potentially exposed to MTBE in the United States prior to the phase out of MTBE (NIOSH, 2010). Mean concentrations ($\mu\text{g}/\text{m}^3$) of MTBE in air were 1500 for manufacturing workers; 5000 for blending workers; 14,000 for transportation workers; 2600 for distribution workers; 5200 for gasoline station workers; 660 for mechanics; and 61 for professional drivers (Brown, 1997).

Environmental

The general population in the United States may have been exposed to MTBE via inhalation of ambient air, especially during refueling operations prior to 2005, ingestion of

contaminated groundwater, and dermal contact with consumer products containing MTBE (HSDB, 2012). Mean concentrations ($\mu\text{g}/\text{m}^3$) of MTBE in air were 61 for commuters; 30 for other drivers; 390 for gasoline station customers; 4 for manufacturing and blending neighbors; 66 for gasoline station neighbors; and 2.6 for the general public (Brown, 1997). As the use of MTBE in gasoline has been phased out, drinking water contamination is the most likely source of exposure for the general population. Methyl tert-butyl ether can contaminate water through leaking underground gas storage tanks and pipelines, as well as from gasoline spilled on the ground. Older boat engines may also contribute small amounts of MTBE to water sources.

INDUSTRIAL HYGIENE

There is no Occupational Safety and Health Administration (OSHA) or NIOSH standard for MTBE. The American Conference of Governmental Industrial Hygienists (ACGIH) has assigned MTBE a threshold limit value (TLV) of 50 ppm as an 8-h time-weighted average (TWA) concentration based on its carcinogenicity (A3: confirmed animal carcinogen with unknown relevance to humans) (ACGIH, 2010). The ACGIH (2010) recommends excursions in worker exposure levels may exceed three times the TLV-TWA for no more than a total of 30 min during a work day, and under no circumstances should they exceed five times the TLV-TWA, provided that the TLV-TWA is not exceeded.

RISK ASSESSMENTS

The regulatory levels as well as the recommended values determined for MTBE by various government agencies and organizations are listed below.

U.S. EPA

The reference concentration (RfC) for MTBE is $3 \text{ mg}/\text{m}^3$ (0.774 ppm), and this is based on increased absolute and relative liver and kidney weights and increased severity of spontaneous renal lesions (females), increased prostration (females), and swollen periocular tissues (males and females) in a 24-month inhalation rat study (U.S. EPA, 1993b). The Environmental Protection Agency (EPA) has identified MTBE as a possible human carcinogen, Class C (U.S. EPA, 1995).

ATSDR

The toxicological profile for MTBE was released in August 1996 (ATSDR, 1996). Cancer-effect levels of MTBE were identified for inhalation and oral routes of exposure using animal studies.

WHO

The World Health Organization (WHO) concluded that MTBE should be considered a rodent carcinogen, but the data are insufficient to reach any conclusions about its potential to cause cancer in humans (IPCS, 1998). Therefore, the available data on MTBE are inconclusive and limited in their use for human carcinogenic risk assessment (IPCS, 1998). The International Agency for Research on Cancer (IARC) (IARC, 1999) has classified MTBE in Group 3, not classifiable as to its carcinogenicity to humans, based on limited evidence in experimental animals and inadequate evidence in humans.

NTP

Methyl tert-butyl ether is not included in the National Toxicology Program's (NTP) 12th report on carcinogens (NTP, 2011).

ETHYL TERTIARY BUTYL ETHER (ETBE)

KEITH D. SALAZAR

First aid: Respiratory: Seek fresh air and medical attention, if necessary; eyes: flush with water; skin: rinse with water and remove clothing; ingestion: rinse mouth and seek medical attention

Target organ(s): Kidney, liver, skin, lungs, eyes

Occupational exposure limits: ACGIH TLV: 5 ppm (20.9 mg/m³)

Reference values: RIVM TDI: 0.25 mg/kg/day; RIVM TCA: 1.9 mg/m³

Risk phrases: 11-20-36/37-38-67

Highly flammable; harmful by inhalation; irritating to the eyes and respiratory system; irritating to the skin; vapors may cause drowsiness and dizziness

Safety phrases: 16-23-29-33

Keep away from sources of ignition. No smoking. Do not breathe gas/fumes/vapor/spray. Do not empty into drains. Take precautionary measures against static discharges

BACKGROUND AND USES

Ethyl tertiary butyl ether (CASRN 637-92-3) is a colorless liquid also referred to by the synonyms ethyl tert-butyl ether, ethyl tert-butyl oxide, methyl-2-ethoxypropane, tert-butyl ethyl ether, 2-ethoxy-2-methylpropane, or 2-methyl-2-ethoxypropane; and the acronym ETBE. Ethyl tertiary butyl ether is synthesized from ethanol and isobutene and is used primarily as an oxygenate that is added to gasoline to improve the automobile exhaust quality by reducing the ozone and carbon monoxide emissions (HSDB, 2012). Ethyl tertiary butyl ether has similar utility compared to another

widely used oxygenate, methyl tertiary butyl ether (MTBE), and thus is a potential replacement for MTBE. Usage of ETBE as a fuel additive has halted in the United States, falling from 2 to 4 million barrels per month in 2005 to 0 barrels in 2006 (DOE, 2007). Ethyl tertiary butyl ether continues to be used widely in Europe (EFOA, 2010). Since ETBE is used almost exclusively in fuels, contamination of groundwater as a result of spillage or leakage of the underground storage tanks is a major source of environmental release.

PHYSICAL AND CHEMICAL PROPERTIES

Ethyl tertiary butyl ether is a liquid at a temperature range of -94 to 72.6 °C. It is soluble in ethanol, ethyl ether, and water. Ethyl tertiary butyl ether has a strong, highly objectionable odor and taste at relatively low concentrations. This chemical is highly flammable and reacts with strong oxidizing agents. Ethyl tertiary butyl ether is stable when stored at room temperature in tightly closed containers. Table 63.1 includes other additional physiochemical properties.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Due to the usage of ETBE as a fuel additive, ETBE may be released into air, soil, and water. Ethyl tertiary butyl ether will exist as a vapor at 25 °C due to its vapor pressure of 124 mmHg and is estimated to have a half-life of 2 days. Upon release into the soil, ETBE is anticipated to have a high mobility based on the high soil organic carbon–water partitioning coefficient of 9–160. Once in the water, ETBE is not

TABLE 63.1 Chemical and Physical Properties of Ethyl Tertiary Butyl Ether

Characteristic	Property
Chemical name	Ethyl tertiary butyl ether
Synonyms	Ethyl tert-butyl ether, ethyl tert-butyl oxide, methyl-2-ethoxypropane, tert-butyl ethyl ether, ETBE
CASRN	637-92-3
Chemical formula	C ₆ H ₁₄ O
Molecular weight	102.17
Melting point	-94 °C
Boiling point	72.6 °C
Vapor pressure	124 mmHg at the rate 25 °C
Density	0.73–0.74 g/cm ³ at the rate 25 °C
Water solubility	12,000 mg/l at the rate 20 °C
Octanol/water partition coefficient (log k _{ow})	1.92
Henry's law constant	2.7 × 10 ⁻³ atm·m ³ /mol at the rate 25 °C
Odor detection threshold	0.013 ppm (0.054 mg/m ³)
Taste detection threshold (in water)	0.047 ppm (47 µg/l)
Conversion factors	1 ppm = 4.18 mg/m ³ 1 mg/m ³ = 0.24 ppm 1 mg/m ³ = 102,180 mmol/l

predicted to adsorb onto suspended particles and is likely to resist biodegradation (Deeb et al., 2001). Based on the Henry's law constant, ETBE is likely to be volatized from the surface of the water (HSDB, 2012). A volatilization half-life of 3 h to 4 days is anticipated from water solutions. A bioconcentration factor (BCF) of 9 was estimated for ETBE to accumulate in fish, suggesting a relatively low propensity for aquatic bioaccumulation (HSDB, 2012).

ECOTOXICOLOGY

Few data are available that examine the effects of ETBE on wildlife. One study in sheepshead minnow determined that the LC₅₀ following a 96-h exposure is >2500 mg/l (Boeri et al., 1994a). Another study in the shrimp species *Mysidopsis bahia* demonstrated an EC₅₀ of 37 mg/l after a 96-h exposure (Boeri et al., 1994b). As mentioned above, ETBE has a low bioaccumulation potential. Altogether, the limited available data do not suggest that ETBE has high toxicity for aquatic organisms.

MAMMALIAN TOXICOLOGY

Acute Effects

Marsh and Leake (1950) reported that the AC₅₀ for anesthetizing half of the white mice within 30 min was 0.7 mmol/l,

and the median lethal concentration was 1.2 mmol/l. In CD rats, no rats died after nose-only exposure at 5.88 mg/l (IIT research, 1989). When rats were treated by single-dose gavage, no mortality or abnormal physical signs were observed at concentrations up to 5000 mg/kg (MB Research, 1988a). Dermal exposure studies in rabbits did not report any lethality at concentrations up to 2 g/kg but irritation, edema, erythema, and eschar formation were observed at the application site (MB research, 1988b; IIT research, 1989). Finally, acute ocular exposure in New Zealand rabbits induced conjunctival irritation, which subsided after 7 days (MB research, 1988c); washing the eye for 20–30 s after exposure greatly reduced the iritis and conjunctival irritation. These data suggest potential irritating effects following acute dermal and ocular exposure.

Chronic Effects

Toxicity has not been assessed in humans chronically or occupationally exposed to ETBE. Three separate studies have been performed in rats to identify potential adverse effects following chronic exposure to ETBE.

Oral Exposure A single published study examined the effects of chronic drinking water exposure to ETBE (Suzuki et al., 2012). Male and female F334/N rats were exposed to ETBE in drinking water for 2 years at daily concentrations of 0, 28, 121, and 542 mg/kg in males, and 0, 46, 171, and 506 mg/kg in females. Clinical signs were monitored daily, and upon termination of the study, blood biochemistry, histopathology, and organ weights were examined. No treatment-related mortality was observed.

Both relative and absolute kidney weights were increased in males and females after 2 years; however, weights were increased to a greater extent in females than males. Relative liver weights were dose-responsively increased in males but unaffected in females. Urinalysis and blood biochemistry did not demonstrate any dose-responsive changes associated with the altered organ weights. Body weights were dose-responsively reduced in both males and females by as much as 17% in females and 10% in males at the highest dose. Water consumption was reduced in males and females throughout the experiment. Overall, water consumption was reduced more in females with the largest reduction (22%) occurring at the highest dose.

The carcinogenicity of ETBE following oral exposure has produced differing results depending on the method of exposure. No treatment-related neoplasms were observed following a 2-year drinking water study (Suzuki et al., 2012). In contrast, a 2-year oral gavage study in male and female Sprague Dawley rats to daily ETBE concentrations of 0, 250, and 1000 mg/kg significantly increased the mouth epithelium tumors at high dose in males and uterine malignancies at only the low dose in females (Maltoni et al., 1999).

Inhalation Exposure Inhalation studies elicit similar effects as observed in the oral exposures; however, data for comparison are available from a single unpublished study (Saito et al., 2013). Male and female Sprague Dawley rats were inhalationally exposed to 2090, 6270, and 20,900 mg/m³ for 6 h/day, 5 days/week for 2 years. Clinical signs were monitored daily and identical analyses were performed as by Suzuki et al. (2012). After 2 years, survival was significantly reduced in females from 76% in controls to 60% in the two highest dose groups (Saito et al., 2013). Male survival was similarly reduced from 88% in controls compared to 60% at the highest exposure concentration.

Organ weights were increased to a greater extent in the inhalational study compared to the oral exposure. The largest organ weight changes occurred in the kidneys and liver. Relative kidney weight was dose-dependently increased in males up to 66% at the highest dose and 51% in females. Dose-responsive increases in the relative liver weights were observed in males (49% at 20,900 mg/m³) and in females (30% at 20,900 mg/m³). Finally, body weights were significantly reduced at all exposure concentrations with maximal reductions occurring at the highest doses in males (−26% of control) and in females (−23% of control).

Statistically significant carcinogenic effects were only observed in males. One hepatocellular carcinoma and nine hepatocellular adenomas were observed in the highest dose; statistically significant compared to controls. No additional carcinogenic effects were observed in any other organs.

Chemical Pathology

Pathological exposure data for ETBE are restricted to animal studies, specifically rats and mice. Treatment-related non-neoplastic lesions were most prominent in the kidneys and livers of males following both oral and inhalation exposures. Ethyl tertiary butyl ether exposure induced similar, but smaller, effects in females. Inhalation exposure elicited more adverse pathology than oral exposures; however, there are no published data comparing the calculated internal dose of ETBE between oral and inhalation exposures.

Following inhalation exposure, a number of pathologies related to chronic progressive nephropathy were observed with the most severe nephropathy occurring in males. A 2-year exposure increased the severity of nephropathy in both male and female rats (Saito et al., 2013). The observed nephropathy was characterized by glomeruli sclerosis, tubular basement membrane thickening, hyaline casts, tubular regeneration, and interstitial fibrosis. Shorter 13-week exposure data are supportive of the 2-year findings. The incidence and severity of hyaline droplets was increased in males but not in females (Medinsky et al., 1999; JPEC, 2008a). Proximal tubular proliferation and the incidence of papilla mineralization were also only observed in males (Saito et al., 2013; Medinsky et al., 1999). Bone marrow congestion was

increased without corresponding changes in hematopoietic cell populations in one 90-day study and was not concluded to be clinically relevant (Medinsky et al., 1999); however, this result was not observed by other researchers (JPEC, 2008a).

Oral exposure induced fewer nephropathies as compared with inhalation studies. A 2-year exposure did not affect the incidence or severity of nephropathy in either males or female rats. A shorter 26-week gavage exposure increased the incidence of hyaline droplets (JPEC, 2008b) and papillary mineralization was induced following a 2-year drinking water exposure (Suzuki et al., 2012); however, these effects were only observed in males.

Liver pathologies were confined to two primary effects: centrilobular hypertrophy and acidophilic and basophilic foci. Centrilobular hypertrophy incidence was increased in males and females after a 26-week gavage exposure (JPEC, 2008b) but was not observed in a longer 2-year exposure (Suzuki et al., 2012). Similarly, a shorter 13-week inhalation exposure also increased centrilobular hypertrophy in male and female mice (Medinsky et al., 1999; Weng et al., 2012) and rats (JPEC, 2008a), but a 2-year inhalation exposure did not induce hypertrophy (Saito et al., 2013). In addition, only the inhalation exposure increased the preneoplastic lesions in the liver by increasing the incidence of acidophilic and basophilic foci in male rats (Saito et al., 2013).

Mode of Action

Available *in vivo* and *in vitro* mutagenicity studies do not provide evidence that ETBE is genotoxic (JPEC, 2007a, 2007b, 2007c, 2007d; Zeiger et al., 1992; Vergnes, 1995; Vergnes and Kubena, 1995).

Kidney Chronic progressive nephropathy, which was observed in female rats, has an unknown etiology; however, several studies have examined the possible mode of action underlying the nephropathy in male rats. Alpha_{2u}-globulin is derived from the hepatic synthesis and can be chemically induced in males to accumulate in the proximal tubule as a result of impaired renal catabolism. This accumulation leads to chronic proliferation of the renal tubule epithelium and nephrotoxicity (Hard et al., 2009). The accumulation of α_{2u}-globulin in hyaline droplets following ETBE exposure was examined in several studies.

Hyaline droplets were increased following oral and inhalation exposure in males only (JPEC, 2008a, 2008b). In addition, α_{2u}-globulin was confirmed in the hyaline droplets from multiple studies following both oral gavage and inhalational exposure (JPEC, 2008a, 2008b; Medinsky et al., 1999). Finally, mineralization of the renal papilla and urothelial hyperplasia of the renal pelvis was noted in the male rats (Suzuki et al., 2012; Saito et al., 2013). Although these data are suggestive for α_{2u}-globulin mode of action for

nephropathy, several additional data could strengthen this hypothesized mechanism. For instance, examining the affinity of ETBE to bind to α_2 u-globulin, identifying hyperplasia foci in the proximal tubules, and establishing the evidence of necrosis in the tubules could all serve to bolster the hypothesis. It should also be noted that a primary metabolite of ETBE in animals is tertiary butyl alcohol (TBA) (Dekant et al., 2001). Although TBA is known to exert kidney effects similar to ETBE, the relative contribution of ETBE and TBA in the overall toxicity observed following ETBE exposure has not been determined.

Liver Only a single study has examined the putative mode of action for the increase in centrilobular hypertrophy and adenomas in male rats. Oral ETBE exposure increased a number of CAR and PXR nuclear receptors that are upstream of *peroxisome proliferator-activated receptors* (PPAR) activation, which is a possible mechanism for liver tumor and hepatocyte proliferation (JPEC, 2012). However, no direct measurement of PPAR activation or specific manipulation of the pathway has been performed for a definitive correlation of ETBE-induced PPAR activation.

SOURCES OF EXPOSURE

Exposure to ETBE occurs through oral, inhalation, or dermal routes. Although ETBE production has essentially ceased in the United States, ETBE is presently used as a fuel additive in Europe and Japan (Eitaki et al., 2011).

Occupational

Exposure to ETBE can occur in occupational settings that either manufacture or use ETBE. A study monitoring the exposure in gasoline tanker truck drivers and fueling-station employees whose primary route of exposure is inhalation, measured a time-weighted average (TWA) of 0.08 parts per million (ppm) in the gas station attendees and 0.04 ppm in the tanker drivers (Eitaki et al., 2011). Airborne concentrations of ETBE around the fueling pumps were 4.12 ppm (Eitaki et al., 2011).

Environmental

Groundwater contamination represents the most likely situation for the widespread oral exposure. Analysis of an aquifer beneath a gas station in the Rhone area of France found concentrations as high as 300 mg/l of ETBE in the water (Fayolle-Guichard et al., 2012). The distribution of the ETBE plume was much larger than other volatile organic compounds found in the spill, likely due to ETBE's high solubility in water and lower biodegradation (Fayolle-Guichard et al., 2012). No data are available on vapor

intrusion from the contaminated groundwater. It should be noted that ETBE has taste and odor detection thresholds in water of 47 µg/l and 49 µg/l, respectively, which would make drinking water unpalatable to humans at these concentrations (Vetranio, 1993).

INDUSTRIAL HYGIENE

The American Conference of Governmental Industrial Hygienists (ACGIH) lists the occupational exposure limit for ETBE to have a threshold limit value (TLV) of 5 ppm as a TWA (ACGIH, 2001). No other exposure limits have been issued by National Institute for Occupational Safety and Health (NIOSH) or Occupational Safety and Health Administration (OSHA). The International Programme on Chemical Safety (IPCS) recommends using protective gloves, eye protection, and breathing protection when handling ETBE to minimize the eye, skin, and inhalation exposures. In the case of eye or skin exposure, the affected area should be flushed with water and the contaminated clothing should be removed. If drowsiness, coughing, or unconsciousness occurs, it is recommended to seek fresh air. Since ETBE is highly flammable, maintain caution when handling and do not expose the working area to ignition sources.

RISK ASSESSMENTS

The National Institute for Public Health and the Environment (RIVM) of the Netherlands has derived noncancer values for oral and inhalation exposures. The oral noncancer tolerable daily intake (TDI) of 0.25 mg/kg/day is based on the decreased body weight, from a 2-generation rat study (Baars, 2009). The noncancer inhalation tolerable concentration in air (TCA) is 1.9 mg/m³ (0.45 ppm) based on the increased liver and kidney weights and bone marrow congestion. The RIVM determined that there were insufficient data to evaluate the carcinogenicity of ETBE.

In 2001, the aforementioned ACGIH recommended a TLV-TWA for ETBE of 5 ppm (21 mg/m³) based on the no-observed adverse effect levels (NOAELs) derived from short-term exposures in rodents and a 2-h human toxicokinetic study (ACGIH, 2001). No other government or independently peer-reviewed assessments for ETBE have been conducted.

***tert*-BUTYL ALCOHOL**

JANICE S. LEE

First aid: Eye: Irrigate immediately; skin: flush with water promptly; breathing: respiratory support; swallow: medical attention immediately

Target organ(s): Eyes, skin, respiratory system, central nervous system

Occupational exposure limits: OSHA PEL: TWA 100 ppm (300 mg/m³), STEL 150 ppm (450 mg/m³); NIOSH REL: TWA 100 ppm (300 mg/m³), STEL 150 ppm (450 mg/m³); and ACGIH TLV: TWA 100 (303 mg/m³), STEL 150 ppm (455 mg/m³)

Reference values: Not available

Risk phrases: 11-20-36/37

Highly flammable

Harmful by inhalation

Irritating to eyes and respiratory system

Safety phrases: 9-16-46

Keep the container in a well-ventilated place. Keep away from sources of ignition—no smoking. If swallowed, seek medical advice immediately and show the container or label

BACKGROUND AND USES

tert-Butyl alcohol (CASRN 75-65-0; NCI-C55367) is a branched-chain alcohol having the following synonyms: *tert*-butanol, *tertiary*-butanol; *t*- or *tertiary* butyl alcohol; *t*-butyl hydroxide; 2-methyl-2-propanol; 1,1-dimethyl ethanol; trimethyl methanol, trimethyl carbinol, and TBA. *tert*-Butyl alcohol is used as a solvent (e.g., for paints, lacquers, and varnishes); as a denaturant for ethanol and several other

alcohols; as an octane booster in gasoline; as a dehydrating agent; as a chemical intermediate in the manufacturing of methyl methacrylate; and in the manufacturing of flotation agents, fruit essences, and perfumes. As a result of its manufacture and use, *tert*-butyl alcohol may be released into the environment through various waste streams directly (IPCS, 1987a; NIOSH, 1992; HSDB, 2007).

Several production methods exist for *tert*-butyl alcohol (HSDB, 2007). *tert*-Butyl alcohol has been prepared from the reaction of acetyl chloride with dimethylzinc, by the catalytic hydration of isobutylene, by the reduction of *tert*-butyl hydroperoxide, by the absorption of isobutene, from cracking petroleum or natural gas, and from sulfuric acid with subsequent hydrolysis by steam (Chen, 2005). It is usually purified by distillation. *tert*-Butyl alcohol is produced as a by-product from the isobutane oxidation process for producing propylene oxide and from the oxirane process for manufacturing propylene oxide. *tert*-Butyl alcohol is also a likely degradation product of methyl *tert*-butyl ether (MTBE) and has been detected in MTBE-contaminated wells (HSDB, 2007).

PHYSICAL AND CHEMICAL PROPERTIES

tert-Butyl alcohol is a white crystalline solid or colorless liquid (above 77 °F) with a camphor-like odor (IPCS, 1987a; NIOSH, 2005). It is soluble in water and miscible with alcohol, ether, and other organic solvents (IPCS, 1987a). It is highly flammable and easily ignited by heat, sparks, or flames; vapors may form explosive mixtures with air. Fire and explosion may result from contact with oxidizing agents, strong mineral acids, or strong hydrochloric acid (NIOSH,

TABLE 64.1 Chemical and Physical Properties of *tert*-Butyl Alcohol

Characteristic	Information
Chemical name	<i>tert</i> -Butyl Alcohol
Synonyms/trade names	<i>tert</i> -butanol, tertiary-butanol; t-, or tertiary butyl alcohol; t-butyl hydroxide; 2-methyl-2-propanol; 1,1-dimethylethanol; trimethyl methanol; trimethyl carbinol; TBA; NCI-C55367
Chemical formula	C ₄ H ₁₀ O
CASRN	75-65-0
Molecular weight	74.12
Melting point	25.7 °C
Boiling point	82.41 °C
Vapor pressure	40.7 mmHg at 25 °C
Density/specific gravity	0.78581
Flashpoint	11 °C (closed cup)
Water solubility at 25 °C	1 × 10 ⁶ mg/l
Explosion limits	2.4–8%
Octanol/water partition coefficient (log K _{ow})	0.35
Henry's law constant	9.05 × 10 ⁻⁶ atm·m ³ /mole
Odor threshold	219 mg/m ³
Conversion factors	1 ppm = 3.082 mg/m ³ 1 mg/m ³ = 0.324 ppm

1992). Selected chemical and physical properties of *tert*-butyl alcohol are presented in Table 64.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Based upon its log K_{ow}, *tert*-butyl alcohol is expected to have very high mobility if released into the soil. If released to air, its vapor pressure indicates that it exists solely as a vapor in the ambient atmosphere. If released into water, it is not expected to adsorb to suspended solids and sediment in water. Volatilization from moist soil surfaces and water surfaces is expected to be an important environmental fate process based upon Henry's law constant. Biodegradation is expected to occur at a slower rate for *tert*-butyl alcohol than for primary or secondary alcohols; furthermore, it does not bioaccumulate (IPCS, 1987a).

ECOTOXICOLOGY

Quantitative information on *tert*-butyl alcohol levels in the environment is not available. As *tert*-butyl alcohol is biodegradable, its substantial concentrations are only likely to occur locally when there is a major spill. *tert*-Butyl alcohol does not bioaccumulate and is not known to be toxic to ecosystems.

MAMMALIAN TOXICOLOGY

Acute Effects

The National Institute of Occupational Safety and Health (NIOSH) considers *tert*-butyl alcohol to be a skin irritant; slight skin irritation has been reported in humans following acute dermal exposure (IPCS, 1987a; NIOSH, 1992; ACGIH, 2001). In addition, NIOSH reports acute exposure to *tert*-butyl alcohol to potentially cause other symptoms, including ocular, nasal, and throat irritation; headache; nausea; fatigue; and dizziness (NIOSH, 1992).

Chronic Effects

No published data are available regarding the health effects of *tert*-butyl alcohol on humans exposed orally or by inhalation for chronic durations. However, there are chronic animal studies for oral exposures to *tert*-butyl alcohol.

Chronic Oral Exposure Studies The National Toxicology Program (NTP) (Cirvello et al., 1995; NTP, 1995) conducted a 2-year drinking water study of chronic toxicity and carcinogenesis in F344/N rats and B6C3F1 mice (60/sex/species/group) exposed to *tert*-butyl alcohol in drinking water. Male rats were exposed to 0, 1.25, 2.5, or 5 mg/ml for approximate doses of 0, 90, 200, or 420 mg/kg/day. Female rats were exposed to 0, 2.5, 5, or 10 mg/ml for approximate doses of 0, 180, 330, or 650 mg/kg/day. Mice were exposed to 0, 5, 10, or 20 mg/ml for approximate doses of 0, 540, 1040, or 2070 mg/kg/day in males and 0, 510, 1020, or 2110 mg/kg/day in females. Animals were observed twice daily. Body weights and clinical observations were recorded weekly for the first 13 weeks and monthly thereafter, as well as at interim evaluation (15 months) and at termination. Water consumption was recorded monthly.

Rats In rats exposed for 2 years, survival was significantly reduced in males at 5 mg/ml ($p = 0.01$) and females at 10 mg/ml ($p = 0.006$) by life table analysis (NTP, 1995). Body weight gain in treated rats was similar to controls during the first year and then declined in high dose groups; terminal body weights were 24% lower than controls in males at 5 mg/ml and 21% lower in females at 10 mg/ml. In males, no adverse effects of treatment were noted for water consumption, clinical signs, urinalysis, or hematology parameters. A dose-related decrease in water consumption was observed in females; during the first year, consumption was reduced by approximately 12 and 20% in the 5 and 10 mg/ml groups, respectively, but the difference from control dropped to approximately 10% in both groups during the second year of the study. Females at 10 mg/ml exhibited an increased incidence of hyperactivity (number affected not reported).

Increases in urine specific gravity (measured at 15 months) in females exposed to 5 and 10 mg/ml were consistent with their reduced water consumption. There were no treatment-related changes in hematology parameters in either sex.

Mice In male mice exposed to *tert*-butyl alcohol in drinking water for 2 years, survival was significantly reduced ($p=0.007$) at 20 mg/ml by life table analysis (NTP, 1995). Mean body weights were 5–10% lower than controls from week 9 to week 91 in male mice exposed to 20 mg/ml; terminal body weights were similar to controls. Body weights of females exposed to 20 mg/ml were 10–15% lower than controls from week 13 through termination, and the terminal weight was 12% lower than controls. In females at lower exposures, there were dose-related decreases in body weight, but the difference was not biologically significant (<10% change from control). Exposure to *tert*-butyl alcohol had no effect on water consumption or the incidences of clinical signs in male or female mice.

Carcinogenicity The 2-year study by NTP (NTP, 1995) concluded that there was some evidence of carcinogenic activity of *tert*-butyl alcohol in male F344/N rats based on increased incidences of renal tubule adenoma and carcinoma (combined), no evidence of carcinogenic activity in female F344/N rats, equivocal evidence of carcinogenic activity in male B6C3F1 mice based on marginally increased incidences of follicular cell adenoma or carcinoma (combined) of the thyroid gland, and some evidence of carcinogenic activity in female B6C3F1 mice based on increased incidences of follicular cell adenoma of the thyroid gland.

Chemical Pathology

No published data are available regarding the chemical pathology of *tert*-butyl alcohol on humans. Potential target organs, as observed from the results of animal studies, include kidney, thyroid gland, urinary bladder, and liver.

Rats At the end of the NTP 2-year drinking water study mentioned above, kidney effects were observed in both sexes in rats (NTP, 1995). Nephropathy was observed in nearly all control and exposed rats; the severity of the lesion was moderate in all male rats, but the severity was significantly increased over controls in all female treatment groups. The incidence and severity of mineralization was dose related in males, and the incidence was significantly elevated at 5 mg/ml. Males exposed to ≥ 1.25 mg/ml exhibited significant dose-related increases in the incidence of a type of mineralization (linear) that is associated with $\alpha 2\mu$ -globulin (NTP, 1995). Normal, moderate-severity mineralization was present in nearly all female rats. Dose-related increases in hyperplasia of transitional epithelium were significant in males at ≥ 2.5 mg/ml

and females at 10 mg/ml. Renal tubule hyperplasia was observed as a minimal-to-moderate lesion in all male groups and as a minimal lesion in one female at 10 mg/ml. The incidence of this lesion was significantly increased in males exposed to 5 mg/ml. The incidence of minimal suppurative inflammation was dose related and significantly increased in females at 5 and 10 mg/ml.

Male rats were observed to have a statistically significant increase ($p \leq 0.01$) in renal tubule adenoma (multiple) and combined renal tubule adenoma or carcinoma at 2.5 mg/ml (NTP, 1995) (The incidence was significantly increased over controls when standard histopathology results were combined with an extended step-sectioning procedure used to enhance tumor detection but was not significantly elevated when evaluated by standard results). No renal tumors were observed in female rats.

Mice In mice, nonneoplastic lesions associated with chronic *tert*-butyl alcohol ingestion involved the thyroid gland, urinary bladder, and liver. Increased incidences of hyperplasia of thyroid follicular cells were statistically significant in males at all exposure levels and in females at ≥ 10 mg/ml. Chronic inflammation of the urinary bladder was significantly increased in incidence and severity in male and female mice at 20 mg/ml. Males exposed to 20 mg/ml also had increased incidences of hyperplasia of the transitional epithelium of the bladder and fatty change of the liver.

The incidence of follicular cell adenoma was non-significantly increased in males at 10 mg/ml but showed a significant ($p=0.011$) dose-related trend in females and a significant increase over controls in females at 20 mg/ml (NTP, 1995). The historical incidence of this tumor in controls in NTP drinking water studies is 8/238 (3.4% \pm 2.2%, range 0–5%; (NTP, 1995)). There were no other increases in neoplasms in mice exposed for 2 years.

The only nonneoplastic effect observed in mice exposed to 5 or 10 mg/ml *tert*-butyl alcohol for 2 years was an increased incidence of thyroid follicular cell hyperplasia in males. The NTP (NTP, 1995) noted that thyroid follicular cell tumorigenesis follows a progression from hyperplasia to adenoma and carcinoma, suggesting that hyperplasia is a preneoplastic lesion in the thyroid. Although neither adenomas nor carcinomas were statistically significantly increased in male mice, NTP noted that the incidence of adenomas in males at 10 mg/ml (7%) exceeded the upper end of the range of historical control incidence (2%). Further, carcinoma was observed in male mice at the highest concentration despite the significant early mortality in this group. Together with the evidence for a significantly increased incidence of thyroid follicular cell adenomas in high dose females, these observations support the finding that the increased hyperplasia in male mice is a preneoplastic effect rather than an adaptive response.

Hypothesized Modes of Action

The available literature indicates that *tert*-butyl alcohol is not mutagenic or genotoxic. *In vitro* studies for gene mutation, sister-chromatid exchange, and chromosomal aberrations in mammalian cells (McGregor et al., 1988; Cirvello et al., 1995), and an *in vivo* study of micronucleus induction (NTP, 1995) did not produce any evidence of mutagenicity or genotoxicity. A comprehensive review of genetic toxicity studies by McGregor (2010) revealed that most *in vitro* and *in vivo* assays for genetic effects conducted with *tert*-butyl alcohol are negative.

Kidney Tumors Two possible modes of action for the induction of renal tubule cell tumors have been suggested: consequences of excessive accumulation of $\alpha 2\mu$ -globulin and the consequences of exacerbation of chronic progressive nephropathy (CPN).

$\alpha 2\mu$ -Globulin is a low molecular weight urinary protein that is synthesized and secreted by the liver of certain strains of male rats. Approximately 50 mg of $\alpha 2\mu$ -globulin is filtered per day with 40% of the filtered protein excreted in the urine and 60% reabsorbed and catabolized (Neuhaus, 1986). Nephropathy is due to the modification of the protein in blood by a chemical ligand so that the complex reabsorbed in the P1 segment of the proximal renal tubules is rendered more resistant to proteolysis and accumulates in the phagolysosomes of the tubule cells (McGregor, 2010). The accumulation, recognized as hyaline droplets, leads to lysosomal overload and the shedding of cells into the lumen, resulting in cell population regeneration and the formation of tumors. The $\alpha 2\mu$ -globulin mode of action is an established cancer mode of action specific to male rats and not considered relevant to human health (NTP, 1995).

A possible alternative to the $\alpha 2\mu$ -globulin-associated nephropathy mode of action is exacerbation of CPN. Chronic progressive nephropathy is becoming more widely recognized as a potential mode of action by which chemicals may influence the incidence of kidney tumors in rats (McGregor, 2010). In contrast to $\alpha 2\mu$ -globulin nephropathy, CPN has no identified biochemical events and the process is not easily investigated by experiments. It must occur in untreated rats with severity increasing with age and exacerbated by exposure to the suspect chemical in comparison with untreated rats (McGregor, 2010).

Thyroid Follicular Cell Tumors There are some data to suggest the possibility of *tert*-butyl alcohol induced-thyroid follicular cell tumors but information is lacking to draw this conclusion. In a chronic drinking water study (Cirvello et al., 1995; NTP, 1995), thyroid effects were noted, including a significant increase in follicular cell hyperplasia of the thyroid gland in both male and female mice. In male mice, the increase occurred at all dose levels, while in females, it was limited to

the two highest doses. The mechanism of formation of these lesions resulting from *tert*-butyl alcohol exposure has not been specifically studied. However, it is known that the metabolism of thyroxine (T4), a major thyroid hormone, involves conjugation with glucuronic acid in the liver and excretion in the bile (NSF International, 2003). *tert*-Butyl alcohol is also eliminated, at least in part, by glucuronides conjugation, which may enhance the elimination of T4 through enzyme induction in the liver. Through a negative feedback loop, the pituitary gland increases or decreases the output of thyroid stimulating hormone (TSH) based on circulating levels of thyroid hormone. Thus, a decrease in circulating T4 may lead to sustained increases in TSH, resulting in an increase in the size of the thyroid gland or an increase in the number of thyroid follicular cells. Sustained thyroid follicular cell proliferation may eventually result in the progression of hyperplasia to adenoma and carcinoma (USEPA, 1998). There are significant differences between humans and rodents in susceptibility to this effect; the serum half-life of T4 in humans is 5–9 days, whereas in rodents, it is only 0.5–1 day. These differences have led to an uncertainty regarding the relevance of rodent thyroid follicular cell effects to human health. There are no data regarding thyroid cell proliferation after exposure to *tert*-butyl alcohol.

SOURCES OF EXPOSURE

Exposure to *tert*-butyl alcohol in humans can occur through inhalation, ingestion, and eye or skin contact (IPCS, 1987b; HSDB, 2007).

Occupational

Occupational exposure may occur through inhalation and dermal contact at workplaces where *tert*-butyl alcohol is produced or used. This includes operations that use *tert*-butyl alcohol as a solvent for paints, lacquers, varnishes, natural and synthetic resins, gums, vegetable oils, dyes, camphor, and alkaloids and as an octane booster in unleaded gasoline (OSHA, 1996). Other routes of exposure can occur through the manufacturing of artificial leather, safety glass, rubber and plastic cement, shellac, raincoats, photographic films, flotation agents, fruit essence, perfumes, cellulose esters, lacquers, paint removers, and plastics (OSHA, 1996). Occupational exposure can also occur when *tert*-butyl alcohol is used as a denaturant for alcohol and as a chemical intermediate in the manufacturing of methyl methacrylate and pharmaceuticals (OSHA, 1996).

Environmental

The general population may be exposed to *tert*-butyl alcohol through the ingestion of drinking water and foods and inhalation of air tainted with *tert*-butyl alcohol (HSDB,

2007). Although not quantified, *tert*-butyl alcohol has been found in drinking water samples from New Orleans, LA (Dowty et al., 1975) and other unspecified locations in the United States (Lucas, 1984). *tert*-Butyl alcohol was also identified, not quantified, in beer (Bavisotto and Heinisch, 1961), chickpeas (Rembold et al., 1989), and mother's milk (Erickson et al., 1980; Pellizzari et al., 1982). Snider (1985) detected *tert*-butyl alcohol in the air of Tucson, AZ at a mean concentration of 3.7 parts per billion (ppb) but not at two rural sites 40 km away.

INDUSTRIAL HYGIENE

The current Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for *tert*-butyl alcohol is 100 parts per million (ppm) (300 mg/m^3) as an 8-h time-weighted average (TWA) concentration and 150 ppm (450 mg/m^3) as a 15-min short-term exposure limit (STEL). NIOSH has not issued a recommended exposure limit (REL) for *tert*-butyl alcohol but has stated that they concur with OSHA's PEL (NIOSH, 1988). The American Conference of Governmental Industrial Hygienists (ACGIH) has assigned *tert*-butyl alcohol a threshold limit value (TLV) of 100 ppm (303 mg/m^3) as an 8-h TWA concentration and 150 ppm (455 mg/m^3) as a 15-min STEL (ACGIH, 2001). Recommendations by NIOSH on respiratory protection for workers exposed to *tert*-butyl alcohol are listed in Table 64.2.

OSHA (1996) recommends the following guidelines regarding respiratory protection and personal protective equipment. Government-approved respirators must be worn if the ambient concentration of *tert*-butyl alcohol exceeds prescribed exposure limits. Protective clothing should be worn to prevent skin contact with *tert*-butyl alcohol. Protective clothing made of butyl rubber has been recommended for use against permeation by *tert*-butyl alcohol and may provide protection for periods of exposure >8 h, while polyethylene ethylene/vinyl alcohol may withstand permeation for more than 4 but < 8 h. Safety glasses, goggles, or face shields should be worn during operations where *tert*-butyl alcohol may come in contact with the eyes. Eyewash fountains and emergency showers should be readily available within the immediate work area. Contact lenses should not be worn if exposure to *tert*-butyl alcohol can occur.

RISK ASSESSMENTS

No chronic reference dose (RfD) or reference concentration (RfC) for *tert*-butyl alcohol is currently available on EPA's Integrated Risk Information System (IRIS), in the Drinking Water Standards and Health Advisories (USEPA, 2006), or in the Health Effects Assessment Summary Tables (HEAST) (USEPA, 2011). The EPA's Chemical Assessments and

TABLE 64.2 NIOSH Recommended Respiratory Protection for Workers Exposed to *tert*-Butyl Alcohol

Condition/airborne concentration of <i>tert</i> -butyl alcohol	Minimum respiratory protection
100–1000 ppm ($10 \times \text{PEL}$)	Any supplied-air respirator equipped with a half mask and operated in a demand (negative-pressure) mode
100–2500 ppm ($25 \times \text{PEL}$)	Any supplied-air respirator equipped with a hood or helmet and operated in a continuous-flow mode
100–5000 ppm ($50 \times \text{PEL}$)	Any supplied-air respirator equipped with a full facepiece and operated in a demand (negative-pressure) mode or Any supplied-air respirator equipped with a tight-fitting facepiece and operated in a continuous-flow mode or Any self-contained respirator equipped with a full facepiece and operated in a demand (negative-pressure) mode or Any supplied-air respirator operated in a pressure-demand or other positive-pressure mode
Entry into unknown concentrations	Any self-contained respirator equipped with a full facepiece and operated in a pressure-demand or other positive-pressure mode or Any supplied-air respirator equipped with a full facepiece and operated in a pressure-demand or other positive-pressure mode in combination with an auxiliary self-contained breathing apparatus operated in a pressure-demand or other positive pressure mode
Firefighting	Any self-contained respirator equipped with a full facepiece and operated in a pressure-demand or other positive-pressure mode
Escape	Any air-purifying, full-facepiece respirator equipped with an organic vapor canister or Any escape-type, self-contained breathing apparatus with a suitable service life (number of minutes required to escape the environment)

Source: Adapted from OSHA Occupational Safety and Health Guideline for *tert*-butyl alcohol (OSHA, 1996)

Related Activities (CARA) list (USEPA, 1994) does not include any documents relating to *tert*-butyl alcohol. ATSDR has not prepared a toxicological profile for *tert*-butyl alcohol. The World Health Organization (WHO) considered the data on *tert*-butyl alcohol to be insufficient to support derivation of an acceptable daily intake (ADI) (IPCS, 1987b). The ACGIH set a TLV of 100 ppm to protect against narcosis and also determined that *tert*-butyl alcohol was not classifiable as a human

carcinogen based on the equivocal evidence from the NTP study (ACGIH, 2001). The International Agency for Research on Cancer (IARC, 1999) has not fully summarized the toxicological data on *tert*-butyl alcohol but has briefly mentioned its toxicity and genotoxicity as a metabolite of MTBE. *tert*-Butyl alcohol is not included in the National Toxicology Program's (NTP) 11th Report on Carcinogens (NTP, 2006). CalEPA and the National Institute of Public Health and the Environment (RIVM) also do not have any health or risk assessment information on *tert*-butyl alcohol.

NAPHTHALENE

LISA A. BAILEY, LAURA E. KERPER, AND LORENZ R. RHOMBERG

Target organ(s): Eye, skin, blood, liver, kidneys, central nervous system, respiratory tract

Occupational exposure limits: 10 ppm (50 mg/m³) OSHA (PEL); 10 ppm (52 mg/m³) ACGIH (TLV); 15 ppm (79 mg/m³) ACGIH (STEL); 10 ppm (50 mg/m³) NIOSH (REL); 250 ppm (1250 mg/m³) NIOSH (IDLH)

Reference values: 0.02 mg/kg/day US EPA (RfD)

Risk/safety phrases: Harmful if swallowed, limited evidence of carcinogenic effect, very toxic to aquatic organisms, may cause long-term effect in the aquatic environment.

BACKGROUND AND USES

Naphthalene occurs naturally in fossil fuels such as coal and petroleum. It is commonly produced from the distillation and fractionation of coal tar. Naphthalene is used as an intermediate in the production of phthalate plasticizers, other plastics and resins, and other products such as dyes, wood preservatives, explosives, lubricants, pharmaceuticals, deodorizers, and insect repellants. Moth balls and other moth repellants, and some solid block deodorizers used for toilets and diaper pails, are made of crystalline naphthalene (ATSDR, 2005).

PHYSICAL AND CHEMICAL PROPERTIES

Naphthalene (CASRN 91-20-3) is a white solid with the chemical formula C₁₀H₈. Its molecular weight is 128.09. It evaporates easily and has a strong odor of tar or mothballs. The melting point of naphthalene is 80.5 °C, its boiling point is 218 °C, and its density is 1.145 g/ml at 20 °C. Solubility in

water is low (31.7 mg/l at 25 °C), and it is soluble in benzene, alcohol, ether, and acetone (ATSDR, 2005).

MAMMALIAN TOXICOLOGY

Acute Effects

Dermal contact with naphthalene may cause skin irritation and an allergic skin reaction (ATSDR, 2005; Acros Organics, 2000). Contact with the eyes may cause conjunctivitis, corneal injury, diminished visual acuity, and cataracts (ATSDR, 2005; Acros Organics, 2000). Naphthalene vapor at concentrations ≥15 parts per million (ppm) may cause eye irritation. When swallowed in large amounts, it may cause liver and kidney damage, methemoglobinemia, cyanosis, convulsions, and death. Digestive tract irritation, abdominal pain, nausea, vomiting, and diarrhea may also occur. Inhalation of naphthalene may cause respiratory tract irritation, and at high concentrations, salivation, headache, confusion, nausea, vomiting, abdominal pain, fever, labored breathing, and death may occur. In individuals who have a glucose-6-phosphate dehydrogenase genetic defect, inhalation or ingestion of or dermal exposure to large amounts of naphthalene may cause hemolytic anemia (ATSDR, 2005).

Chronic Effects

In mice and rats, the target of chronic naphthalene toxicity is the respiratory tract. The National Toxicology Program (NTP) conducted 2-year bioassays in which mice (NTP, 1992; Abdo et al., 1992) or rats (NTP, 2000; Abdo et al., 2001) were exposed by inhalation to ranges of naphthalene concentrations. In mice, females (and not males) exhibited a

significant increase in combined incidence of alveolar/bronchiolar adenomas and carcinomas at the highest dose (30 ppm). Inflammation of lung tissue was observed in both sexes at 10 and 30 ppm. There were no significant increases in lung tissue hyperplasia at any exposure. There was no evidence of nasal tumors in either sex at any exposure; however, all treatment groups exhibited significant increases in nasal inflammation, metaplasia of the olfactory epithelium, and hyperplasia of the respiratory epithelium. Based on the outcome of this assay, NTP concluded, there was no evidence of carcinogenic activity in male mice, and some evidence of carcinogenic activity in female mice (NTP, 1992; Abdo et al., 1992).

In rats, there was a significant increase in neuroblastomas of the olfactory tissue in females in the highest exposure group (60 ppm), and a significant trend with dose in both sexes. Males exhibited a significant increase in adenomas of the nasal respiratory epithelium at all exposure levels. For both sexes, at all exposure levels, there were significant increases in inflammation and hyperplasia in both olfactory and nasal respiratory epithelial tissues. In lung tissue, there was some evidence of hyperplasia in females but not males, and some inflammation in males but not females. No increases in lung tumors were observed. Based on the outcome of this assay, NTP concluded there was clear evidence of carcinogenic activity in male and female rats (NTP, 2000; Abdo et al., 2001).

There is very little information about cancer risk in humans associated with naphthalene exposure. The human data on naphthalene exposure and cancer risk are limited to a few case reports and one nested case-control study of oral/oropharyngeal cancer. Lung cancer has been addressed in several occupational studies of industries where naphthalene exposure may occur, but the interpretation of these is limited due to low or unquantified naphthalene exposures and concurrent exposures to other chemical agents.

Olsson et al. (2010) conducted a case-control study of 433 lung cancer cases and 1253 controls, nested within a cohort of 38,296 asphalt workers. Although naphthalene exposure was not studied specifically, naphthalene may account for up to 90% of occupational inhalation exposure to polycyclic aromatic hydrocarbons (PAHs) for asphalt workers (NIOSH, 2000). The authors found no association between lung cancer and any exposure to asphalt fumes.

Merletti et al. (1991) conducted a population-based, case-control study of 86 oral or oropharyngeal cancer cases and 373 controls in Italy. This group evaluated the risk associated with 40 occupations, 41 industries, and 16 specific chemicals, including naphthalene. Naphthalene was not associated with the risk of oral or oropharyngeal cancer in this study.

Lewis (2012) reviewed several studies of lung cancer risk in connection with industries and occupations in which naphthalene exposure is common, including the petroleum (Wong and Raabe, 2000; Consonni et al., 1999; Lewis et al., 2003;

Rushton, 1993), asphalt (Boffetta et al., 2003a, 2003b; Olsson et al., 2010; Fayerweather, 2007), and creosote industries (Wong and Harris, 2005), as well as jet fuel handlers (D'Mello and Yamane, 2007; Yamane, 2006). No association with lung or nasal cancer was reported in any of the studies.

Mechanisms of Action

The mechanisms of acute naphthalene toxicity are known for hemolytic anemia and cataract formation. For chronic respiratory toxicity, the mechanism of action has not been definitively determined.

Hemolytic Anemia Individuals who are deficient in glucose-6-phosphate dehydrogenase are more susceptible to oxidizing agents such as naphthalene. Naphthalene and other oxidizing agents can oxidize heme iron in red blood cells to the ferric state, and the resulting free radical oxygen acts on membrane lipids to increase fragility and lysis of the red blood cell (ATSDR, 2005).

Cataracts Naphthalene is metabolized by cytochrome P-450 (CYP) enzymes to 1,2-naphthalenediol, which can reach the lens via circulation and subsequently become metabolized to 1,2-naphthoquinone. 1,2-Naphthoquinone is highly reactive and can bind to proteins, amino acids, and glutathione in the lens, affecting its transparency (ATSDR, 2005).

Respiratory Tract Lesions The respiratory toxicity of naphthalene depends on metabolic pathways that are highly specific to species, tissue, and cell type, and differences in toxicity depend on the balance between generation of toxic metabolites and the elimination of those metabolites (Bogen, 2008; Buckpitt et al., 2002). In mouse and rat respiratory tissue, CYP enzymes are largely responsible for naphthalene metabolism to reactive species, namely, CYP2F2 and CYP2A5 in mice (Bogen, 2008; Buckpitt et al., 2002; Li et al., 2011; Hu et al., 2013) and likely CYP2F4—and possibly CYP2E1—in rats (Baldwin et al., 2004; Cruzan et al., 2009). It is generally agreed that human CYP2F1 and CYP2A13 metabolize naphthalene in respiratory tissue but at a much lower rate than either mouse or rat CYP enzymes, suggesting that the highly reactive naphthalene metabolites are generated in smaller amounts with less potential to cause toxicity to human tissues (Buckpitt et al., 2002; Cruzan et al., 2009; Lewis et al., 2009; Fukami et al., 2008; Su et al., 2000). As discussed above, there are no studies that show an association between naphthalene exposure and lung or nasal cancer in humans. In fact, there is very little evidence of any cancer in humans linked to naphthalene exposure.

In the NTP mouse (NTP, 1992) and rat (NTP, 2000) studies, tumor formation was always accompanied by cytotoxicity. Other studies have shown nasal cytotoxicity in rats at lower doses of naphthalene than those associated with

tumors in the NTP studies, or at similar levels but shorter exposure times (Dodd et al., 2010, 2012). These studies also identified a no observed adverse effect level (NOAEL) for cytotoxicity in the rat nose (0.1 ppm). These results suggest that cytotoxicity is an essential component of naphthalene-induced tumorigenesis, but there is a likely threshold below which cytotoxicity does not occur. In mouse nasal tissue, cytotoxicity occurs at sufficiently high doses of naphthalene, but tumor formation does not (NTP, 1992). This suggests that, while it may be necessary, cytotoxicity may not be sufficient for development of tumors, and there may be an additional step that occurs in rat nose and in mouse lung that, together with cytotoxicity, is essential for naphthalene-induced carcinogenicity.

Naphthalene metabolites are highly reactive, and the cytotoxicity observed in the respiratory tract may be due to the formation of metabolite–protein adducts and/or reactive oxygen species (ROS). Protein adducts of naphthalene metabolites have been observed in various cultured cells (Cho et al., 1994), target respiratory tissues in rodents and nonhuman primates (Boland et al., 2004; Cho et al., 1994; Lin et al., 2006; DeStefano-Shields et al., 2010), and cell-free systems (Pham et al., 2012a, 2012b). It is suggested that generation of ROS may occur by redox cycling of naphthoquinone or as a result of cytotoxicity and inflammation at the target site. ROS generation may lead to lipid peroxidation, depletion of reducing equivalents, and DNA oxidation or strand breaks (ATSDR, 2005). Glutathione (GSH) depletion has been observed with high levels of administered naphthalene, such as those that have been associated with tumor formation in mouse lung (Phimister et al., 2004). Glutathione protects cells against reactive species, including reactive metabolites and oxygen radicals that are generated from those metabolites (Bergamini et al., 2004; Phimister et al., 2004). Thus, GSH depletion could lead to cellular injury via naphthalene-metabolite-induced protein adducts and/or oxidative stress, both of which may be precursors to cytotoxicity-induced tumor formation. Several studies (although not in target respiratory tissue) have shown that naphthalene metabolites (naphthalene epoxide, 1,2-naphthoquinone, and 1,4-naphthoquinone) react readily with cellular proteins in rats and mice in a dose-dependent manner (Zheng et al., 1997; Waidyanatha et al., 2002; Waidyanatha and Rappaport, 2008; Buckpitt et al., 2002) and therefore may mediate cytotoxicity well before any 1,2-naphthoquinone is available to undergo redox cycling to generate ROS, which could react with DNA.

Most studies of naphthalene genotoxicity indicate that it occurs secondary to cytotoxicity (Brusick, 2008). Recent *in vitro* and *in vivo* assays provide supporting evidence that cytotoxicity precedes genotoxic responses to naphthalene in human lymphoblasts (Recio et al., 2012), rat nasal tissue (Meng et al., 2011), and mouse lung tissue (Karagiannis et al., 2012). Thus, the available data suggest that any

positive genotoxic results induced by naphthalene are the result of (1) saturation of detoxification mechanisms and generation of downstream genotoxic metabolites (likely to occur only at high concentrations that deplete detoxification mechanisms) and/or (2) secondary genotoxic effects due to cytotoxicity. These results also suggest that there would be a practical threshold for any involvement of genotoxicity in the carcinogenic mode of action, and genotoxicity would not be an initiating event in tumor formation.

The overall weight of evidence suggests that mouse lung and rat nasal tumors following naphthalene exposure are the result of a cytotoxic or dual cytotoxic and genotoxic mode of action, and that formation of cytotoxic amounts of reactive naphthalene metabolites (via CYP enzymes) in mouse lung and rat nasal tissue also causes chronic inflammation and regenerative hyperplasia. The data suggest that genotoxic events following naphthalene treatment are secondary to naphthalene-induced cytotoxicity, or they occur concurrently but as independent events. In either scenario, DNA damage occurs at cytotoxic (or greater than cytotoxic) exposure concentrations. This mode of action, for cancer and non-cancer effects, has little or no relevance to humans at typical environmental exposures because human metabolic activation in respiratory tissue is much lower than those in rats at comparable exposure concentrations (Campbell et al., 2013). Therefore, exposure concentrations much higher than typical exposures in humans are necessary to reach a metabolic activation equivalent to those in rats that cause respiratory cytotoxicity. For some cytotoxic end points, metabolism in humans appears to saturate, reaching a maximum (Campbell et al., 2013) that is below the level needed in rats to produce cytotoxic effects. The weight-of-evidence evaluation and proposed mode of action are summarized in Bailey et al. (2015, submitted).

SOURCES OF EXPOSURE

Occupational

The highest occupational exposure to naphthalene occurs in wood treatment (creosote), coke and coal tar production, mothball production, and jet fuel industries. Exposure in these industries may be in the range of 100–3000 µg/m³ during the course of an 8-h work day (Price and Jaycock, 2008). Lower exposures occur in the petroleum, asphalt, aluminum production, chemical manufacture, tanning, and ink and dye industries. In these occupations, work-day exposures may be in the range of 3–100 µg/m³ (Price and Jaycock, 2008).

Environmental

Because naphthalene occurs naturally in fossil fuels and is used in the production of plasticizers and other products, it

is released to the air in industrial and auto emissions. It is also produced when organic materials, such as wood and tobacco, are burned (ATSDR, 2005). Ambient air levels of naphthalene for urban and suburban areas in the U.S. have been reported to range from 0.4 to 170 µg/m³, with a median of 0.94 µg/m³ (ATSDR, 2005). Concentrations at industrial and hazardous waste sites are typically higher. Sources of exposure to naphthalene in indoor air include cooking, tobacco smoking, and moth repellants. Indoor air levels have been reported to average 1.0 µg/m³ in non-smoking households and 2.2 µg/m³ in households with smokers (ATSDR, 2005). Indoor air levels from mothball use in the home are estimated to range from 1 to 100 µg/m³ for typical use and up to 300 µg/m³ for off-label use (e.g., fumigation) (Griego et al., 2008).

REGULATORY REPORTS ON CARCINOGENESIS

In a 2011 NTP Report on Carcinogens (NTP, 2011), the agency designated naphthalene as “reasonably anticipated to be a human carcinogen.” The NTP determined that the human data on naphthalene were inadequate for an evaluation of carcinogenicity, and the designation was based on the evidence of nasal tumors in rats (NTP, 2000) and lung tumors in mice (NTP, 1992) as described above. NTP noted that naphthalene exhibited genotoxicity in some, but not all test systems and the mode of action for tumor formation was not known, but oxidative damage and DNA breakage may be contributing factors.

The International Agency for Research on Cancer (IARC) (IARC, 2002) designated naphthalene as “possibly carcinogenic to humans” (Group 2B). This designation was based on inadequate human data and sufficient animal data (the NTP rat and mouse studies). The IARC noted that there was little evidence of mutagenicity, and some positive results for genotoxicity. This agency proposed a mode of action for tumor formation that resulted from the generation of cytotoxic metabolites and increased cell turnover.

Based on the likely mode of action and very low metabolic activity of naphthalene in human respiratory tissue identified as part of the PBPK model (including saturation at much lower levels compared to rodents), these classifications may only be relevant to humans at very high exposure levels (e.g., occupational).

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration (OSHA), National Institute for Occupational Safety and Health (NIOSH), and American Conference of Governmental Industrial Hygienists (ACGIH) have set the permissible exposure limit (PEL), recommended exposure limit (REL),

and threshold limit value (TLV), respectively, for naphthalene at 10 ppm (50 mg/m³) (ACGIH, 2013).

Naphthalene can be absorbed through the skin. Workers should wear protective clothing and gloves to prevent skin contact and eye protection to prevent splashing in eyes. Respirators should be worn to prevent inhalation (CDC, 2010). Naphthalene is combustible. Dispersal of dust should be prevented, as explosive vapor/air mixtures may be formed above 80 °C (IPCS and NIOSH, 2005).

MEDICAL MANAGEMENT

In the case of accidental inhalation exposure, the subject should first be removed to an area with fresh air and good ventilation and then referred for medical attention. Skin that has come into contact with naphthalene should be rinsed with soap and plenty of water. In case of eye contact, first rinse eyes with plenty of water (remove contact lenses if easily possible) and then seek medical attention (NIOSH, 2005, 2010). If naphthalene is ingested, do not induce vomiting. Seek immediate medical attention (NIOSH, 2005, 2010; Acros Organics, 2000).

GASOLINE (PETROL, MOTOR SPIRITS, MOTOR FUEL, NATURAL GASOLINE, BENZIN, MOGAS)

RAYMOND D. HARBISON AND DANIEL A. NEWFANG

Note: Gasoline has many different CAS and EINICS registry numbers assigned to it due to the different distillation fractions and/or all of the different process derivatives. To name a few typically seen identifiers: CAS: 8006-61-9 gasoline, natural (EINICS 232-349-2); CAS 86290-81-5 gasoline, refinery grade components (EINICS 289-220-8); CAS 64671-46-4 gasoline, light straight run naphtha (EINICS 265-046-8); CAS 68514-15-8 gasoline, vapor recovery (EINICS 271-025-4) . . . as mentioned there are many more identifying registry numbers for gasoline, its mixtures, grades, distillation fractions, and/or process derivatives.

Target organs: Kidneys, eyes, skin, liver, CNS, respiratory system (*inhalation and aspiration risks*)

Risk/safety phrases: May cause cancer; may cause genetic damage; defects: may cause lung damage if swallowed; may be fatal if swallowed and enters airway; highly flammable

Exposure limits:

OSHA PELs (*There is no PEL for gasoline, the composition of these materials varies greatly. The OSHA recommends that the content of benzene, other aromatics, and additives should be determined individually*)

ACGIH TLVs (adopted 1982): 300 ppm (890 mg/m³) TWA, 500 ppm (1480 mg/m³) STEL, appendix A3 (adopted 1996) confirmed animal carcinogen with unknown relevance to humans. (ACGIH TLV Documentation Gasoline, 2014)

NIOSH RELs: No established limits, potential occupational carcinogen (i.e., “Ca” notation)

International Agency for Research on Cancer (IARC): 2B
possible carcinogenic to humans

MAK (Germany): No established value

ERPG-1 (AIHA 2014): 200 ppm (654 mg/m³) 1-h TWA.
Note: An average molecular weight of 80 g/mole conversion was used to convert mg/m³ to ppm . . . conversion factor of 3.27

ERPG-2 (AIHA 2014): 1000 ppm (3270 mg/m³) 1-h TWA. *Note: An average molecular weight of 80 g/mole conversion was used to convert mg/m³ to ppm . . . conversion factor of 3.27*

ERPG-3 (AIHA 2014): 4000 ppm (13,080 mg/m³) 1-h TWA. *Note: An average molecular weight of 80 g/mole conversion was used to convert mg/m³ to ppm . . . conversion factor of 3.27*

AEGL-1 USEPA (Proposed Limit 2009) (nondisabling): 730 mg/m³ for 10 and 30 min, 1 h, 4- and 8-h timeframes

AEGL-2 USEPA (Proposed Limit 2009) (disabling): 7500 mg/m³ for 10 and 30 min, 1 h, 4- and 8-h timeframes. *Note: The AEGL-2 value is higher than 1/10 of the lower explosive limit (LEL) of gasoline in air (which has an LEL = 14,000 ppm), therefore, safety considerations against hazard of explosion must be taken into account.*

AEGL-3 USEPA: Not determined. *Note: Although a lethal concentration was not attained in the available acute, subchronic and chronic toxicity studies, automotive gasoline vapor may act as a simple asphyxiant in sensitive individuals at 990,000 mg/m³.*

WEEL (AIHA 2013): None established

IDLH: [Ca, potential occupational carcinogen] 1400 ppm: Due to all of the differing blends a specific IDLH has not been established for gasoline. A recommended IDLH of 1400 ppm based strictly on safety considerations (i.e., being 10% of the lower explosive limit of 1.4%).

Odor thresholds and recognition: Ranges from 0.1 to 1.1 ppm. The level of odor awareness (LOA), which is the concentration above which it is predicted that more than half of the exposed population will experience at least a distinct odor intensity and about 10% of the population will experience a strong odor intensity, is 7.4 ppm ($\sim 22 \text{ mg/m}^3$) as a representative value for a gasoline blend comprising summer and winter blends (API, 1994).

Reference values: There is no EPA reference dose (RfD) or reference concentration (RfC) for gasoline.

Typical routes of exposure: Inhalation, skin contact, and ingestion (lesser risk with normally accepted storage and use, although siphoning or accidental ingestion from unlabeled, incorrectly stored containers) (Conservation of Clean Air and Water in Europe, 1992).

BACKGROUND AND USES

Gasoline is a complex, volatile mixture of flammable liquid hydrocarbons derived chiefly from crude petroleum with specific additives such as octane improvers, antioxidants, metal deactivators, corrosion inhibitors, detergents, and demulsifiers to enhance performance characteristics. Typically gasoline contains about 150 different chemicals, including benzene, toluene, ethylbenzene, and xylene, which also are known as the BTEX compounds. Although tetraethyl lead (TEL) (used as an antiknock agent) was removed from the formulations in most industrialized nations by the early 2000s, it is still being used in some areas of the world (Taylor, 2011 and (United Nations Environmental Programme, 2014) UNEP 10th general meeting strategy presentation). Some aviation and racing fuels still contain TEL.

Environmentally, gasoline may be present in the air, groundwater, and soil. Its uses range from ground transport vehicles, aviation, agricultural, gasoline-powered equipment (i.e., lawnmowers) and stationary (i.e., generators and pumps) spark ignited, reciprocating, and Wankel (i.e., rotary) internal combustion engines.

Gasoline is a volatile liquid with characteristic odor properties. As a liquid, gasoline contains about 60–70% alkanes, 25–30% aromatics, and 6–9% alkenes. In the vapor phase, the aromatics are depleted to about 2% aromatics (which can contain up to 0.9% benzene), and the smaller chained hydrocarbons, being more volatile, are enriched to about 90% alkanes (Page and Mehlman, 1989). In many industrialized nations, there are limits on certain component

concentrations specifically for the conventional, reformulated, and oxygenated blends by regulation, such as benzene, ethers (i.e., methyl tertiary butyl ether (MTBE)), and alcohols. The United States Environmental Protection Agency (USEPA) Clean Air Act Amendments of 1990 required reformulated gasoline to contain between 2.0 and 2.7% oxygen additives (i.e., MTBE) and <1% benzene. The Energy Policy Act of 2005 removed the oxygenate requirement, and the industry responded by reducing MTBE due to groundwater impacts with replacement strategies focused on alcohols (i.e., ethanol) (Weaver et al. 2014). Various additives (e.g., lubricants, antirust agents, and anti-icing agents) are blended into gasoline and may influence the properties and toxicity of specific gasoline blends (Gasoline Blending Streams Category Assessment Document, USEPA, 2014).

Oxygenating compounds have been added to the mixture to reduce carbon monoxide and soot, which is created during the burning of the gasoline. Historically, MTBE has been added but has been declining in use in the United States due to groundwater contamination (impacts taste of the water). Ethanol in the United States and ethyl tertiary butyl ether (ETBE, referred to as a bio-ether) in the European Union are now being researched and used as oxygenates (EFOA, 2013).

Holistically, gasoline components have a large boiling point in the range of 20–260 °C (−4–500°F).

Ethanol blends or gasohol (denoted by the letter "E" preceding the percentage of the mixture made up of the ethanol): New formulations of gasoline with blends from 5% ethanol denoted as E5 to 100% ethanol denoted as E100 are being introduced throughout the world. Ethanol is favored as an oxygenate additive to replace MTBE. Methyl tertiary butyl ether was used as a TEL replacement since 1979 in the United States and has been identified as a groundwater contaminant. Ethanol was identified as a renewable fuels oxygenate replacement for MTBE (Note: The addition of an oxygenate allows the fuel to burn more completely and therefore produce cleaner emissions). Some common ethanol blends are as follows:

E10: Mixture containing 10% anhydrous ethanol and 90% gasoline (Note: The anhydrous ethanol has to contain <1% water)

E15: Mixture containing 15% anhydrous ethanol and 85% gasoline

E15: Mixture containing 15% hydrous ethanol and 85% gasoline (NOTE: The hydrous ethanol can contain up to 4.9% water)

E85: Mixture containing 51–85% anhydrous ethanol and 49–15% gasoline, respectively

ED95: Mixture containing 95% hydrous ethanol and 5% additives (there is no gasoline fraction in the ED95 blend . . . refer to ethanol toxicology for assistance to E95 exposures)

E100: 100% anhydrous ethanol (there is no gasoline fraction in the E100 blend . . . refer to ethanol toxicology for assistance to E100 exposures)

Aviation: Aviation gas (or avgas for short) is a lower volatility gasoline that is important for aircraft engines because they regularly operate at high altitudes and have high temperature engines. It is important not to confuse jet fuel with aviation gasoline; they are in no way similar. Jet fuel is similar to kerosene. As of this publishing date, organic lead (i.e., TEL) is still used in some aviation grade gasoline blends. There are two main types of leaded avgas: 100 octane, which can contain up to 4.24 grams of lead per gallon; and 100 octane low lead (100LL), which can contain up to 2.12 grams of lead per gallon. Currently, 100LL is the most commonly available and most commonly used type of avgas. Common avgas grades (current and historical) are as follows:

80/87 (80-87 octane with up to 0.5 ml TEL/US gallon—dyed red, sometimes called Grade 80 Avgas, fuel is obsolete and phased out of production now)

100LL (103-131 octane with up to 2 ml TEL/US gallon of lead—dyed blue, sometimes called Grade 100LL Avgas, the most common aviation gasoline)

100/130 (103-130 octane with up to 4 ml TEL/US gallon—dyed green, sometimes called Grade 100 Avgas, fuel is phased out of production now)

Note 1: Future Development Note, there is a concerted industry effort to phase out the use of lead compounds, which is designated as UL or UnLeaded fuels (such as 82UL, 94UL, Hjelmco 100UL, UL102/100SF-Swift Fuels or G100UL-GAMI 100UL)

Note 2: Historical Note, there have been many different grades of aviation gasoline in general use, e.g., 80/87, 91/96, 100/130, 108/135, and 115/145. With decreasing demand, many blends have become obsolete and Avgas 100/130 (a.k.a. 100LL) is the predominant fuel choice.

Note 3: Nomenclature Note, avgas grades are defined primarily by their octane rating. Two ratings are applied to avgas (the lean mixture rating first and the rich mixture rating second). For example, Avgas 100/130LL (in this case the lean mixture performance rating is 100 octane and the rich mixture rating is 130 octane). In an effort to make the nomenclature easier, it is a common practice to designate the grade by just the lean mixture performance, i.e., Avgas 100/130LL is noted as Avgas 100LL (*otherwise pronounced as Avgas one-hundred low lead*).

Mogas (sometimes denoted by “E0” to indicate that the blend is ethanol free) is a generic term that identifies both a lead- and ethanol-free gasoline blend.

An example of the diversity of compounds that make up automotive gasoline is given in Table 66.1.

There are no drinking water standards established for gasoline. The EPA health advisory for gasoline (unleaded) is 5 µg/l (U.S. Environmental Protection Agency [USEPA], 1991). No other health advisories are indicated. Neither cancer risk levels nor reference doses have been established by the EPA.

PHYSICAL AND CHEMICAL PROPERTIES

Note: Since gasoline is a complex mixture, all its physical and chemical properties will vary with the composition of the mixture's components.

Average molecular weight: 80–118

Color: Colorless to pale brown in its un-dyed state; aviation blends are dyed to help field personnel visually determine the octane rating or grade.

Physical state: Liquid

Boiling point (initial): 26–49 °C (78–120°F, NFPA 921 Table 25.3-1)

Boiling point (final): 171–233 °C (340–451°F, NFPA 921 Table 25.3-1)

Density: Gasoline liquid ranges from 0.70 to 0.80 kg/l (averaging ~719.7 kg/m³; 0.026 lb/in³; 6.073 lb/US gal; 7.29 lb/imp gal), the heavier or higher densities having a greater volume of aromatics. Gasoline floats on water in all densities. *Gasoline vapors* are denser than air and will sink and collect at the lowest point of the area you're in such as basements, crawl spaces, tunnels, man holes, ditches, etc.

Color: In its natural state it is usually a colorless clear, red/pinkish, or light brown liquid. It can also be purposely dyed (especially with aviation fuels) to visually identify a grade or octane rating (e.g. 82UL—purple, 80/87—red, 100LL—blue, 100/130—green).

Odor: See box at the beginning of this chapter

Odor threshold: See box at the beginning of this chapter

Flash point: –35 to –40 °C (–49 to –40°F; NFPA 921 Table 25.3-1)

Melting point: –38 to –46 °C (–36 to –51°F)

Lower explosive limit (LEL): 1.4% (NFPA 921 Table 25.3-1)

Upper explosive limit (UEL): 7.4% (NFPA 921 Table 25.3-1)

Autoignition temperature: Minimum of 354 °C (minimum of 670°F; NFPA 921 Table 25.3-1)

Vapor pressure: 38–750 mmHg (0.6–14.5 psi; NIOSH NPG, 2007; ATSDR, 2014)

TABLE 66.1 Composition of Various Types of Gasoline (% Weight/Weight [in grams])

Chemical Name	Leaded, %	Unleaded (%) (Regular, Mid and Super grades)
Hydrocarbons (aromatic and aliphatic)	60	48.8–56.2
Benzene	3.9	0.9–4.4 (range difference is seen in the conventional, reformulated & oxygenated blends)
Toluene	4.5	4.8–6.0
Xylenes	5.6	6.6–7.4
Ethyl benzene	1.2	1.4
Other benzenes	9	6.9–7.4
Others and unknowns	15.8	20.9–24.6
Octane enhancers such as:		
Methyl <i>t</i> -butyl ether (MTBE)		
<i>t</i> -Butyl alcohol		
Ethanol		
Methanol		
Antioxidants		
Butylated methyl, ethyl, and dimethyl phenols		
Various other phenols and amines		
Metal deactivators		
Disalicylidene- <i>N</i> -methyldipropylene-triamine		
<i>N,N'</i> -disalicylidene-1,2-ethanediamine		
Other related amines		
Ignition controllers		
Tri- <i>o</i> -cresylphosphate (TOCP)		
Icing inhibitors		
Isopropyl alcohol		
Detergents/dispersants		
Various phosphates, amines, phenols, alcohols, and carboxylic acids		
Corrosion inhibitors		
Carboxylic, phosphoric, and sulfonic acids		
Ethanol	N/A	Ranges from 0 to 100% with the respect to the “E” blend number, e.g. E15 indicates 15% ethanol and 85% unleaded gasoline

Table is a compilation of literature sources from ATSDR and American Petroleum Institute.

Vapor density, relative to air with air = 1 : 3–4 (NFPA 921 Table 25.3-1)

Specific gravity (water = 1): 0.72–0.80 at 60°F (NIOSH NPG, 2007; ATSDR, 2014)

Water solubility: Practically insoluble (NIOSH NPG, 2007)

headache, nausea, and vomiting, as well as eye, nose, and throat irritation (Davis et al., 1960). Levels in excess of 5000 ppm can result in dizziness, deep anesthesia, pulmonary edema, and death within minutes (Ainsworth, 1960; Wang and Irons, 1961). Chemical pneumonitis resulting from aspiration of gasoline after ingestion is a serious clinical concern.

Signs of severe intoxication include mild excitation followed by loss of consciousness, occasional convulsions, cyanosis, congestion, and capillary hemorrhaging of the lungs and other internal organs, and finally death from circulatory failure. In adults, ingestion of as little as 20–50 g may produce severe poisoning. Cases of accidental poisonings in the literature have noted abnormal liver function tests and acute reversible injury to the upper portions of the kidneys (Kuehnel and Fisher, 1986).

Exposure to leaded gasoline may cause lead poisoning and all of the associated symptoms (Goldings and Stewart, 1982; Kovanen et al., 1983).

MAMMALIAN TOXICOLOGY

Acute Effects

The most common symptoms resulting from excessive gasoline exposure are headache, blurred vision, dizziness, inebriation, vomiting, dizziness, confusion, fever, and nausea. A level of 500–1000 parts per million (ppm) (for 30–60 min) can result in a euphoric condition followed by ataxia, drowsiness, and dizziness. Higher levels (1000–3000 ppm) result in irritation,

Chronic Effects

Long-term exposure to gasoline has been reported to result in anorexia, weight loss, weakness and cramps, and neurological effects, including poor coordination and tremor (Poklis and Burkett, 1977). The neurological effects appear to be reversible upon cessation of exposure. However, postmortem examinations of persons with high exposure levels of gasoline (gasoline sniffers) frequently show cerebral and pulmonary edema, as well as liver and kidney necrosis (Poklis and Burkett, 1977; Dueñas-Laita, A., 2007).

Based on reported exposures, it appears that adverse hematological effects can occur following short-term, high level exposure and longer-term, lower level exposures to gasoline. The effects are most likely the result of an exposure to benzene or lead, constituents of gasoline. The effects seen after an acute exposure are most likely reversible, whereas the effects seen after a long-term exposure may not be reversible.

Carcinogenicity Possible carcinogen. Experimental animal data provide inadequate evidence for the carcinogenicity of gasoline. The species-specific effects result from a mechanism involving the accumulation of globulin in male rat kidneys that cannot be anthropomorphized to humans. Similarly, human epidemiological studies are not adequate to support a conclusion that gasoline is carcinogenic. With this stated, the following entities have labeled gasoline as:

International Agency for Research on Cancer (IARC): Group 2B—possibly carcinogenic to humans.

American Conference for Governmental Industrial Hygienists (ACGIH): A3—confirmed animal carcinogen.

Mechanism of Action(s) and Chemical Pathology

No mechanistic or chemical pathology studies were located for gasoline. Information on the toxicokinetics of gasoline components (i.e., benzene, toluene, xylene, lead, etc.) are available separately and should be reviewed.

While gasoline is absorbed from all exposure routes, the dermal route appears to be slower than the oral and inhalation routes. Some of the gasoline components are more rapidly absorbed than others. For example, aromatic compounds (e.g., benzene, toluene, and xylene) that have both high blood/air partition coefficients and skin penetration rates are absorbed more rapidly than other gasoline components.

An acute exposure to gasoline has been associated with skin and sensory irritation, central nervous system depression, and effects on the respiratory system. A prolonged exposure also affects these organs as well as the kidney, liver, and blood system. In general, the effects that have been identified following gasoline exposure have also been identified for one or more of the components of gasoline (e.g. benzene, toluene, xylene, etc.). For example, all substances have been shown to be neurotoxic, and studies that indicate

that gasoline is hemotoxic are supported by the abundant literature on benzene hematotoxicity (Evaluation of the Health Effects From Exposure to Gasoline and Gasoline Vapors, Final Report NESCAUM, Air Toxics Committee, 1989).

Organic TEL is converted in the liver to triethyl lead, a water-soluble metabolite, which can accumulate in the brain (Robinson, 1978), which can then be further broken down to inorganic lead.

Biomarkers potentially can be used to identify exposure to gasoline:

Increased blood and urine levels for leaded gasoline

Increased urinary thioether output has a limited use due to hydrocarbon exposure (*Note:* Be aware that increased urinary thioether output is not specific to gasoline; it is also complicated by smoking)

Increased urinary phenol levels due to benzene exposure

Although gasoline vapor acts as an anesthetic at high levels (10,000 ppm), the major site of toxicity is the kidney (Kuna and Ulrich, 1984). Rats and monkeys were exposed to gasoline vapor, 284–1552 ppm (unleaded gasoline) or 103–374 ppm (leaded gasoline), both for 6 h/day, 5 days/week, for 90 days (Kuna and Ulrich, 1984). Although vomiting was noted in some monkeys after 2 weeks' exposure, no changes in body weight, hematology, or central nervous system (CNS) responses were noted in either species. Male rats in the 1552 ppm unleaded gasoline group did show regenerated epithelium and dilation of the kidney tubules, which was not present in any other group.

Gasoline vapor (100 ppm for 6 weeks) has also been reported to cause pulmonary damage in rats secondary to a decrease in production of pulmonary surfactant (Cooper, 1980). Other studies of the toxicity of chronic gasoline vapor exposure have reported eye damage in rabbits (Grant, 1974), decreased body weight in mice and rats, and a reduction in the incidence of cystic or enlarged uteri in female mice (International Research and Development Corporation [IRDC], 1983).

Chronic inhalation of unleaded gasoline vapor has also been shown to produce hepatocyte cell proliferation in mice (Tilbury et al., 1993). However, this effect was statistically significant only in mice exposed to 2056 ppm. There were no changes in liver-specific serum enzymes or histopathology in any dosage group.

The levels of gasoline that killed people are about 10,000–20,000 ppm when breathed in and about 12 ounces when swallowed (ATSDR, 2014; Harper and Liccione, 1995).

SOURCES OF EXPOSURE

Gasoline is typically in liquid form; therefore, the most likely source of exposure will be breathing its vapors when one is

filling a fuel tank. Drinking contaminated groundwater (ingestion), bathing in (dermal & inhalation), and spillage onto skin are also potential routes of exposures. In the vapor phase, the aromatics are depleted to about 2% aromatics (which can contain up to 0.9% benzene), and the smaller chained hydrocarbons, being more volatile, are enriched to about 90% alkanes (Page and Mehlman, 1989).

Intentional or accidental ingestion of gasoline often results in aspiration of the gasoline into the lungs because of its high volatility and low surface tension. Therefore, the most common effect with acute gasoline ingestion is aspiration pneumonia, which is often accompanied by respiratory distress, pulmonary edema, emphysema and focal alveolar hemorrhage. Death from asphyxia is often the result in cases of gasoline ingestion when aspiration pneumonia becomes severe (ATSDR, Toxicological Profile for Automotive Gasoline, 2014).

INDUSTRIAL HYGIENE

Occupational Safety and Health Administration (OSHA): There is a partially validated monitoring method cited by the OSHA (i.e., Method PV2028)

Real time:

- Detector sorbent tubes (e.g., SKC)
- Flame ionizing detector (FID)
- Photo ionizing detector (PID)
- Multi-gas detector ($O_2/LEL/H_2S/CO$ and some include PIDs)
- BTX or BTEX sorbent tubes (e.g., Draeger, SKC)

Note: Many times exposure monitoring can be performed by monitoring for individual components such as benzene, MTBE, ethanol (for gasohol), BTX (benzene, toluene, xylene), or BTEX (benzene, toluene, ethylbenzene, xylene) collectively

MEDICAL MANAGEMENT

First Aid/Pre-hospital Measures

Eye contact: Immediately flush with large amounts of water for at least 15 min, lifting the upper and lower lids. Remove contact lenses (if worn).

Skin contact: Quickly remove any contaminated clothing. Immediately wash contaminated skin with large amounts of soap and water. *Note:* Do not place the contaminated clothing near any potential ignition sources.

Inhalation: Remove the person from the exposure.

Ingestion: Swallowing gasoline may cause damage to the linings of the mouth, throat, esophagus, stomach, and intestines. Do not induce vomiting. Pulmonary aspiration of even small amounts of *ingested* gasoline can cause chemical pneumonitis. Do not induce emesis or use gastric lavage,

and do not administer activated charcoal. Gasoline is poorly absorbed from the stomach. Cathartics with magnesium or sodium sulfate are acceptable. If spontaneous vomiting occurs, watch for signs of pulmonary aspiration. *Note:* The harsh taste of gasoline makes it unlikely that large quantities will be swallowed. However, several cases of poisoning have occurred in persons trying to suck (siphon) gas from an automobile tank using a garden hose or other tube. This practice is extremely dangerous and not advised.

There is no antidote for gasoline poisoning. Treatment consists of support of cardiovascular and respiratory functions.

Medical Care

The health-care provider will measure and monitor the patient's vital signs, including temperature, pulse, breathing rate, and blood pressure. Symptoms will be treated as appropriate. The patient may receive:

Breathing tube

Bronchoscopy—a camera down the throat to see burns in the airways and lungs

Endoscopy—a camera through the mouth to see burns in the esophagus and stomach

Fluids through a vein (IV)

Oxygen

Surgical removal of burned skin (skin debridement)

Tube through the mouth into the stomach to wash out the stomach (gastric lavage)

Washing of the skin (irrigation)—perhaps every few hours for several days

How well a patient does depends on the amount swallowed and how quickly the treatment was received. The faster a patient gets medical help, the better the chance for recovery.

Systemic effects may also include renal failure and increased susceptibility to ventricular fibrillation (Mirkin, 2007).

Delayed Effects

Patients who have ingested gasoline should be observed for at least 6 h for signs of chemical pneumonitis. Systemic effects may develop over several hours and may include hemorrhage of the pancreas and fatty degeneration of the liver and of the proximal convoluted tubules and glomeruli of the kidneys. Acute renal toxicity may persist for several weeks following ingestion of gasoline but usually resolves with treatment.

Follow-up

Patients who have aspirated gasoline should receive follow-up pulmonary function tests.

Acute renal toxicity may persist for several weeks following ingestion of gasoline but usually resolves with treatment.

Patients who have corneal injuries should be reexamined within 24 h.

1-BROMOPROPANE

MAREK BANASIK

First aid: Eyes: Holding the eyelids apart, flush eyes promptly with copious flowing water for at least 20 min—get medical attention immediately; skin: remove contaminated clothing, wash the skin thoroughly with mild soap and plenty of water for at least 15 min, wash clothing before re-use—get medical attention immediately; inhalation: in case of mist inhalation or breathing fumes released from heated material, remove person to fresh air, keep him quiet and warm—apply artificial respiration if necessary, and get medical attention immediately; ingestion: if swallowed, wash mouth thoroughly with plenty of water and give water to drink—get medical attention immediately. Notes to the physician: irritant—in case of inhalation may cause central nervous system toxicity, no specific antidote, treat symptomatically and supportively.

Occupational exposure limits: Derived no effect level (DNEL) (systemic effects, long-term inhalation): 20.12 mg/m³; DNEL (systemic effects, short-term inhalation): 4,392 mg/m³; DNEL (local effects, short-term inhalation): 2,416 mg/m³ (ECHA, 2014).

Reference values: ACGIH TLV time-weighted average (TWA): 0.503 mg/m³; DNEL (systemic effects, long-term inhalation): 10.06 mg/m³; DNEL (systemic effects, short-term inhalation): 2,196 mg/m³; DNEL (local effects, short-term inhalation): 1,208 mg/m³ (ECHA, 2014).

Hazard statements: H225—highly flammable liquid and vapor; H315—causes skin irritation; H319—causes serious eye irritation; H335—may cause respiratory irritation; H336—may cause drowsiness or dizziness; H360—may damage fertility or the unborn child; H373—may cause damage to organs through prolonged or repeated exposure.

Precautionary statements: P201—obtain special instructions before use; P260—do not breathe the dust/fume/gas/mist/vapors/spray; P273—avoid release to the environment; P280—wear protective gloves/protective clothing/eye protection/face protection; P310—immediately call a poison center/doctor/. . .; P303 + 361 + 353—if on skin (or hair): take off immediately all contaminated clothing, rinse skin with water/shower; P304 + 340—if inhaled: remove person to fresh air and keep comfortable for breathing; P305 + 351 + 338—if in eyes: rinse cautiously with water for several minutes, remove contact lenses, if present and easy to do—continue rinsing.

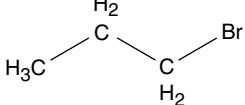

Risk phrases: R11—highly flammable; R36/37/38—irritating to eyes, respiratory system and skin; 48/20—harmful: danger of serious damage to health by prolonged exposure through inhalation; R60—may impair fertility; R63—possible risk of harm to the unborn child; R67—vapors may cause drowsiness and dizziness.

Safety phrases: S45—in case of accident or if you feel unwell seek medical advice immediately (show label where possible); S53—avoid exposure—obtain special instructions before use.

BACKGROUND AND USES

1-Bromopropane [1-BP; Chemical Abstracts Service Registry Number (CASRN): 106-94-5] is a halogenated solvent, which was initially marketed as a potential alternative to ozone-depleting chlorofluorocarbons. It is utilized in a variety of industrial sectors, including vapor decreasing, dry

TABLE 67.1 Chemical and Physical Properties of 1-Bromopropane

Characteristic	Information
Chemical structure	
Chemical name	1-Bromopropane
Synonyms/trade names	1-BP, CCRIS 30, n-propyl bromide, propyl bromide
CASRN	106-94-5
Chemical formula	C ₃ H ₇ Br
Molecular weight	122.99 g/mol
Physical state	Colorless liquid at 20 °C and 1,013 hPa
Melting point	-110 °C
Boiling point	71 °C
Vapor pressure	14.772 kPa at 20 °C
Vapor density	4.25
Relative density	1.353 at 20 °C
Water solubility	2,450 mg/l at 20 °C
Octanol/water partition coefficient (log K _{ow})	2.10
Henry's law constant	7.3 × 10 ⁻³ atm·m ³ /mol at 20 °C

Source: ECHA (2014); HSDB (2013).

cleaning, and as a solvent carrier for adhesives in foam cushion manufacturing.

1-Bromopropane is a high production volume chemical. In the United States (US), the national production volume in 2012 was 15,348,727 pounds (*ca.* 6,962,065 kg) (EPA, 2012). In the European Union (EU), three registrations were reported on 1-BP. Two of the registrations did not report production volumes; the data were claimed as confidential or for an intermediate use only. One registration reported an annual production volume range of *ca.* 2.2–22 million pounds (1,000–10,000 tonnes) (ECHA, 2014).

1-Bromopropane has undergone extensive toxicological testing, including 2-year carcinogenicity studies. Several regulatory agencies have initiated regulatory evaluations of 1-BP, especially in the occupational setting, due to recent reports on its carcinogenic potential and adverse effects identified in exposed workers. The sections that follow provide an overview of this information and the conclusions from these regulatory evaluations.

PHYSICAL AND CHEMICAL PROPERTIES

1-Bromopropane is a clear, colorless to pale yellow compound with a strong characteristic odor that exists as a liquid at room temperature. It is considered as a volatile organic compound, based on its moderate boiling point and high vapor pressure. Its liquid density is greater than water, and its vapor density is greater than air. 1-Bromopropane is readily soluble in water. A summary of 1-BP's physicochemical properties is presented in Table 67.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

The physicochemical properties and environmental fate testing on 1-BP supports that it will migrate in soil, based on its high water solubility and low log K_{ow}. It is hydrolytically unstable at environmentally relevant pH values (i.e., pH 7–9) with half-life >19 days. In the vapor phase, 1-BP has an estimated photodegradation half-life of approximately 12 days. Biodegradation data support that 1-BP is not readily biodegradable and is not expected to bioconcentrate in aquatic organisms. A summary of the available environmental fate and bioaccumulation data on 1-BP is presented in Table 67.2.

TABLE 67.2 Environmental Fate and Bioaccumulation Data on 1-Bromopropane

Endpoint	Protocol	Result
Hydrolysis	EU method C.7; OECD ^a method 111; EPA ^b OPPTS ^c method 830.2110	t _{1/2} ^d at pH 4 = 25 days, pH 7 = 23 days, and pH 9 = 19 days; conclusion: hydrolytically unstable
Photodegradation	Model estimate (AOPWIN TM v1.92) ^e	t _{1/2} = 11.6 days
28-day ready biodegradability study preceded by an acclimation phase	EU method C.4-E; OECD method 301D	19.2% biodegradation after 28 days; conclusion: not readily biodegradable

ECOTOXICOLOGY

The toxicity of 1-BP has been assessed in aquatic vertebrates, invertebrates, and plants. A summary of these data are presented in Table 67.3. The data support that 1-BP is moderately toxic to aquatic organisms. The manufacturers of 1-BP calculated the following predicted no effect concentrations (PNECs) for aquatic and terrestrial organisms and secondary poisoning for predators: PNEC_{freshwater} = 0.0243 mg/l, PNEC_{marine} = 0.00243 mg/l, PNEC_{sewage treatment plant} = 10 mg/l, PNEC_{sediment freshwater} = 0.249 mg/kg sediment dry weight (dw) (based on partition coefficient), PNEC_{sediment marine} = 0.0249 mg/kg sediment dw (based on partition coefficient), PNEC_{soil} = 0.0361 mg/kg soil dw (based on partition coefficient), and PNEC_{oral secondary poisoning} = 0.084 mg/kg food (ECHA, 2014).

MAMMALIAN TOXICOLOGY

1-Bromopropane is a member of halogenated alkanes and is a strong alkylating agent because bromine is a good leaving group, and an electrophilic intermediate is expected to be readily formed that can bind covalently with macromolecules such as proteins and DNA. Studies in experimental animals

and humans indicate that 1-BP can be absorbed following inhalation, oral, or dermal exposure (Cheever et al., 2009; Hanley et al., 2007). Metabolism studies show that oxidation by P450 enzymes (e.g., CYP2E1) and glutathione conjugation are the primary metabolic pathways (Garner et al., 2006; Ishida et al., 2002). Over 20 metabolites have been identified in rodent studies, including the four metabolites detected in urine samples of 1-BP-exposed workers (Hanley et al., 2009) and several reactive intermediate such as glycidol, propylene oxide, and α-bromohydrin (Ishida et al., 2002). Experimental animal studies have been performed on this substance to evaluate potential acute and repeated exposure hazards. A summary of these data and the conclusions from the US National Toxicology Program's (NTPs) evaluations are provided below.

Acute Studies

The acute toxicity of 1-BP has been evaluated in a series of guideline studies by the inhalation, dermal, and oral routes of exposure. The reported median lethal concentrations or doses in these studies were typically above classification concern levels (e.g., inhalation 4-h LC₅₀ = 72,306.04 mg/m³, dermal 24-h LD₅₀ > 2,000 mg/kg body weight, and oral LD₅₀ > 2,000 mg/kg body weight) (ECHA, 2014). 1-Bromopropane

is classified as a skin and eye irritant and is not regarded as a sensitization hazard. As discussed in the next section, the hazard concerns for 1-BP are primarily aimed at the identified toxicities that occur following repeated exposures in animals and occupationally exposed humans.

Repeated Dose Studies

National Toxicology Program extensively evaluated the subchronic and chronic health effects of 1-BP, which include studies on experimental animals and case reports from occupationally exposed humans (NTP, 2003, 2011, 2013). The available data support that 1-BP may cause adverse effects to the reproduction and development in rodents, cancer in rodents, and neurotoxicity in humans.

In 2003, NTP's former Center for the Evaluation of Risks to Human Reproduction evaluated the potential reproductive and developmental effects of this substance (NTP, 2003). Center for the Evaluation of Risks to Human Reproduction identified a developmental toxicity effect level of 1,534 mg/m³ in rats, based on a benchmark concentration (95th percentile lower confidence level) and reproductive toxicity effect levels of 1,257 mg/m³ and 1,006 mg/m³ in male and female rats, respectively, based on lowest-observed-adverse-effect concentrations. The no-observed-adverse-effect concentration for reproductive toxicity in male and female rats was 503 mg/m³. Center for the Evaluation of Risks to Human Reproduction concluded that 1-BP may cause reproductive and developmental toxicity independent of systemic toxicity.

In 2011, NTP released the results of the 2-year carcinogenicity studies in male and female rats and mice in which animals were exposed to 1-BP for 6 h per day, 5 days a week (NTP, 2011). Rats were exposed to concentrations of 1-BP at

ca. 0, 628.75, 1,257.5, or 2,515 mg/m³; mice were exposed to concentrations of *ca.* 0, 314.375, 628.75, or 1,257.5 mg/m³. Based on the tumor incidence data presented in Table 67.4, NTP concluded that there was “. . . some evidence of carcinogenic activity . . .” in male rats, “. . . clear evidence of carcinogenic activity . . .” in female rats and mice, and “. . . no evidence of carcinogenic activity . . .” in male mice. In 2013, NTP's Office of the Report on Carcinogens concluded that 1-BP is “. . . reasonably anticipated to be a human carcinogen . . .” This conclusion was based on the 2-year carcinogenicity studies and on data, which support that 1-BP directly or *via* reactive metabolites causes alterations, such as genotoxicity, oxidative stress, and glutathione depletion that are relevant to possible mechanisms of human carcinogenicity (NTP, 2013).

In addition to the adverse effects identified from experimental animal studies, several studies have reported adverse health effects in workers exposed to 1-BP. The typical findings include various neurological symptoms. For example, a case study of six foam cushion gluers reported that the worker's serum bromide concentrations ranged from 440 to 1,700 mg/l (44–170 mg/dl) while air samples taken at the workplace 1 day after the cessation of gluing operation showed concentrations of 1-BP ranging from 457.73 to 885.28 mg/m³ [91–176 parts per million (ppm)] (Majersik et al., 2004, 2007). These workers reported neuropathies, including lower extremity pain or paresthesias, difficulty in walking, weakness and twitching in the legs, and loss of sensation in the feet and legs. Fifteen months after the initial examination, two of the most severely affected workers had regained only minimal function, and still required assistance to walk while three workers continue to experience chronic neuropathic pain.

TABLE 67.4 Summary of Tumors in Rats and Mice Exposed to 1-Bromopropane for 2 Years

Species, Sex	Tumor Type	Concentration (mg/m ³)	Incidence
F344/N rats, male	Skin (keratoacanthoma, squamous cell carcinoma, basal cell adenoma, or carcinoma combined)	0	1/50 (2%)
		628.75	7/50* (14%)
		1,257.5	9/50** (18%)
		2,515	10/50*** (20%)
F344/N rats, female	Large intestine (colon or rectum adenoma)	0	0/50 (0%)
		628.75	1/50 (2%)
		1,257.5	2/50 (4%)
		2,515	5/50* (10%)
B6C3F1 mice, female	Lung (alveolar/bronchiolar adenoma or carcinoma combined)	0	1/50 (2%)
		314.375	9/50** (18%)
		628.75	8/50* (16%)
		1,257.5	14/50*** (28%)

SOURCES OF EXPOSURE

Occupational

1-Bromopropane is utilized in a variety of industrial processes, which include emissive and non-emissive uses. Worker exposures are the greatest with emissive uses, such as dry cleaning, vapor degreasing, and spray adhesives. Several occupational exposure limits have been proposed by the government and non-government entities. In 2003, the EPA recommended an acceptable exposure limit of 25 ppm (125.75 mg/m³) over an 8-h TWA (EPA, 2003). The American Conference of Governmental Hygienists (ACGIH) initially issued in 2009, a threshold limit value (TLV) TWA of 10 ppm (50.3 mg/m³); however, in 2012, it released a draft TLV TWA of 0.1 ppm (0.503 mg/m³), based on the recent NTP 2-year carcinogenicity studies (NTP, 2013). The US Occupational Safety and Health Administration (OSHA) has not issued a permissible exposure limit for 1-BP. Under its compliance monitoring program, OSHA collected personal breathing-zone data on workers from 18 facilities. Of the 164 samples, detectable measures ranged from 0.0477 to 423 ppm (*ca.* 0.24 to *ca.* 2,127.7 mg/m³). Sixty-two of the samples collected from nine facilities exceeded the ACGIH TLV TWA value of 10 ppm; seven of these facilities utilized 1-BP for vapor degreasing or spray adhesives (NTP, 2013). The US National Institute of Occupational Safety and Health is in the process of preparing a recommended exposure limit for 1-BP.

Environmental

No environmental monitoring data were identified for non-occupational human exposures. The primary opportunities for environmental exposures to 1-BP to occur are through waste streams from industrial facilities or chemical spill incidents. Consumers may be exposed by using spot removal products where 1-BP is incorporated as a replacement to compounds such as trichloroethylene; however, no market data were identified for this use.

INDUSTRIAL HYGIENE

The personal protection equipment and mechanical controls recommended in the work place are designed to minimize eye, skin, and respiratory exposures (ECHA, 2014). Tightly sealed goggles are recommended for eye protection against liquid and aerosol. A protective suit is recommended to avoid skin exposures. Protective gloves are recommended for hand protection, and a respirator is recommended to limit the inhalation exposures. Mechanical controls are aimed at providing adequate ventilation.

RISK ASSESSMENTS

No formal risk assessments have been issued on 1-BP by the governmental agencies. The EPA is currently assessing 1-BP under its Toxic Substances Control Act work plan chemical risk assessments (EPA, 2013). No additional information is available on the status of the Agency's assessment or anticipated release date.

DIACETYL

DAVID J. HEWITT

Target organ: Lung

Occupational exposure limits: 0.005 ppm (NIOSH REL, proposed); 0.025 (NIOSH STEL, proposed); 0.01 ppm (ACGIH TLV); 0.02 ppm (ACGIH TLV-STEL)

Reference values: None

Hazard statements: None

Precautionary statements: None

Risk phrases: None

Safety phrases: None

BACKGROUND AND USES

Diacetyl (2,3-butanedione) is a naturally occurring product and can be found in numerous foods such as butter, milk, cheese, smoked or roasted meats, breads, fruits, vegetables, coffee, beer, and wine. Diacetyl is synthesized to be used as a food additive to impart a buttery flavor and has been designated as a generally recognized as safe (GRAS) substance with low acute toxicity (FDA, 1980). Desirable flavor concentrations in food are approximately 0.05–5.0 ppm and above that range it imparts a disagreeable taste. The most recognized recent use has been in microwave popcorn, but it has also been used for many other products (NTP, 1994, 2007). Diacetyl may be used in additives as a liquid, paste, or powder (Boylstein et al., 2006).

PHYSICAL AND CHEMICAL PROPERTIES

The physical and chemical properties of diacetyl are presented in Table 68.1 (NTP, 2007).

MAMMALIAN TOXICOLOGY

Acute Effects

Inhalation or airborne exposure is the primary exposure route of toxicological concern. At sufficient levels, acute health effects associated with airborne exposure to diacetyl include mucous membrane irritation of the eyes and respiratory tract and potential exacerbation of preexisting asthma. Severe acute irritant effects from airborne exposure have not been a prominent finding in occupational studies. A specific irritant threshold has not been established. The irritant and damaging effects of diacetyl on the respiratory tract were demonstrated in Sprague-Dawley rats in which exposure levels ranging from 99.3 to 294.6 ppm produced inflammation and necrosis. The nose showed the most sensitivity to diacetyl (Hubbs et al., 2008). Larsen et al. (2009) noted that the no observed adverse effect level (NOAEL) for mice was above 100 ppm and estimated that the sensory irritation threshold for humans was above 20 ppm.

Chronic Effects

The primary health effect of concern associated with diacetyl has been constrictive bronchiolitis obliterans (BO) after reports of the condition in microwave popcorn workers. BO is a rare pulmonary condition in which inflammation and fibrosis occurs at the bronchiolar level (i.e., small airways just proximal to the alveoli where gas exchange occurs) and severely narrows or obliterates the lumen. Causes include chemical inhalation exposures such as chlorine, nitrogen dioxide, or sulfur dioxide; rare sequelae of infections such as influenza; and connective tissue disorders such as rheumatoid arthritis or scleroderma. It is a relatively

TABLE 68.1 Physical and Chemical Properties of Diacetyl

Molecular Formula	C ₄ H ₆ O ₂
Molecular weight	86.09
Physical form	Greenish-yellow liquid at room temperature
Melting point	-2.4 °C
Boiling point	88.0 °C
Vapor pressure	57 mmHg at 25 °C
Odor	Quinone, chlorine-like odor in vapors, rancid butter
Odor threshold	<1 ppb
Conversion factors	1 ppm = 3.52 mg/m ³ ; 1 mg/m ³ = 0.284 ppm

frequent complication of lung transplantation and may also be seen with bone marrow or stem cell transplants. Presenting symptoms include gradually increasing dyspnea on exertion, which may be accompanied by cough or wheezing and may resemble asthma. A physical examination may show evidence of hyperinflation along with wheezing or end inspiratory crackles. Pulmonary function tests show airway obstruction that unlike asthma, does not respond well to bronchodilators. The diffusing capacity is minimally affected in the early stages since the gas exchange region of the lung is not initially affected. Air trapping and fibrosis may be seen on chest computed tomography (CT) and it classically shows a mosaic pattern. Diagnosis is based on a characteristic clinical history, pulmonary function testing, and chest imaging findings. In lung transplant evaluations, BO is suspected when there is a substantial unexplained decline in the forced expiratory volume (FEV)₁. A lung biopsy is considered the only way to definitively diagnose BO (Chan and Allen, 2004). Treatment may include corticosteroids, prompt treatment of respiratory infections, and lung transplant for end-stage disease. Although the course may be variable, the prognosis is generally poor with gradually decreasing respiratory function (Epler, 2007).

The association of diacetyl with BO was initially identified when a cluster of eight workers at a microwave popcorn facility in Missouri were reported to have a severe fixed obstructive lung condition (Parmet and Von Essen, 2002). A review of the index cases indicated that they became symptomatic after a median of 1.5 years of employment (range 5 months to 9 years) during 1993–2000 (Akpinar-Elci et al., 2004). Five identified cases worked in the mixing room and the others worked in a packaging area. Symptoms included a dry persistent cough, dyspnea, and wheezing. Chest CT scans showed mosaic patterns. Two of the three cases that underwent lung biopsy showed findings consistent with BO. Five of the cases were reported to be awaiting lung transplant.

A National Institute of Occupational Safety and Health (NIOSH) investigation initially concluded that the fixed obstructive lung conditions identified at the facility were

associated with exposure to microwave popcorn butter flavors but was unable to identify a specific substance that could explain the condition. Diacetyl was used as a marker for airborne exposure to flavoring vapors and found to be increased in certain areas of the facility, particularly the mixing room (CDC, 2002). The prevalence of airway obstruction increased with increasing cumulative exposure to diacetyl. Diacetyl exposure levels showed a mean of 32.27 ppm in the mixing room (1.34–97.94 ppm); 1.88 ppm in the packaging lines (0.26–6.80 ppm); and 0.56 ppm in the quality control or maintenance area (0.33–0.89 ppm). In the mixing room, flavorings were added by a worker who opened the lid of a heated tank (Kreiss et al., 2002). Peak air concentrations of diacetyl in the air space above the heated flavorings tank were reported as high as 1230 ppm (NIOSH, 2006).

Diacetyl has been implicated as a cause of BO in subsequent case reports or studies, including other U.S. microwave popcorn facilities (Kanwal et al., 2006), potato crisp flavoring exposure (Hendrick, 2008), California flavor manufacturing workers (CDC, 2007), a butter flavoring manufacturing worker (Modi et al., 2008), and diacetyl manufacturing workers (Van Rooy et al., 2007). Prior to the microwave popcorn cluster, BO was reported in two Indiana flavor manufacturing workers (NIOSH, 1986). A specific cause was not identified, although diacetyl was listed as one of over 100 different flavoring agents used at the facility. Egilman et al. (2007) have described several other cases of BO in flavoring industry workers prior to the microwave popcorn cases. Egilman and Schilling (2012) reported three cases of BO among consumers who had high exposure to microwave popcorn fumes and reportedly ate 1–5 bags on a daily basis. The authors suggested that the consumer exposures were comparable to the threshold cumulative diacetyl exposure that was associated with pulmonary disease in occupationally exposed individuals.

Exposure to diacetyl and associated butter flavorings has also been associated with increased respiratory complaints and a higher rate of obstructive findings on pulmonary function tests in exposed workers. In the initial study, Kreiss et al. (2002) reported that workers had 3.3 times the expected rate of airway obstruction, which was increased to 10.8 times the expected rate in never-smokers. Kanwal et al. (2006) reported that at the index facility and five other U.S. microwave popcorn plants, there was a higher prevalence of respiratory symptoms such as dyspnea, cough, and wheezing in ever-mixers compared to never-mixers. The percent predicted FEV₁, a measure of airway obstruction, was also significantly decreased in the ever-mixers compared with the never-mixers. Longitudinal studies of pulmonary function in flavoring manufacturing workers correlated abnormal declines in FEV₁ with greater company use of diacetyl (Kreiss et al., 2012). Lockey et al. (2009) reported decreased pulmonary function and FEV₁ in mixers prior to respirator use in a study of over 700 microwave popcorn workers at four different facilities. Mean exposure levels for the mixers

ranged from 0.057 to 0.860 ppm. Cumulative exposure of ≥0.8 ppm-years was significantly associated with obstructive patterns on pulmonary function testing with an adjusted odds ratio of over 8.0 compared with those with <0.8 ppm-years. The authors noted no significant effects in nonmixing room employees. The authors concluded that exposure to diacetyl by itself or in combination with other butter flavoring ingredients increased the risk of obstructive lung disease.

The specific level of diacetyl or associated flavoring chemicals, which may cause BO, has not been established. Larsen et al. (2009) concluded that sensory irritation was not a reliable warning property to protect against levels that have been associated with BO. Lockey et al. (2009) reported increased obstructive lung findings in workers with average exposure levels that were <1 ppm.

The association of diacetyl with BO has been questioned. Galbraith and Weill (2009, 2010) noted that diacetyl is neither a strong acid nor a base; has high water solubility that would not appear consistent with causing deeper lung damage; animal studies did not show evidence of distal airway damage at the levels of the bronchioles; studies of microwave popcorn workers and California flavoring company workers did not have biopsy-proven diagnoses of BO; and findings in some case reports suggested other conditions such as extrinsic allergic alveolitis. Harber et al. (2006) noted that despite compelling data that flavoring exposures were associated with BO, it was not clear if diacetyl was the sole cause, whether it was one of the many different flavoring agents causing the illness, or if it was a marker of an unidentified agent. A difficulty in analyzing the causal association is that there can be multiple other causes for obstructive lung disease such as asthma, extrinsic alveolitis, or smoking.

BO has also been associated with microwave popcorn facilities in which diacetyl use appeared minimal. A NIOSH (2007) Health Hazard Evaluation at a Montana microwave popcorn plant reported that three workers were identified with respiratory disease suggestive of asthma that developed during their work. Two of the cases were also noted to be suggestive of BO. However, diacetyl concentrations in the facility were noted as too low to be quantified (i.e., below 0.01 ppm). The maximum identified level was 0.14 ppm, which was found over a heated container of butter-flavored oil. A number of other substances were identified in air samples. The authors concluded that many flavoring chemicals other than diacetyl may be responsible for respiratory disease. Diacetyl concentrations associated with other substances used at the facility prior to the investigation were unknown.

Additional inconsistencies regarding the association of relatively low dose inhalation levels of diacetyl and BO can also be seen when evaluating exposures from cigarette smoke. The diacetyl content in mainstream cigarette smoke from regular-sized cigarettes has been reported as

0.307–0.433 mg/cigarette (Fujioka and Shibamoto, 2006). Smoking a pack of cigarettes a day and assuming an average of 0.35 mg of diacetyl/cigarette would result in an inhalation dose of 7 mg/day. In comparison, occupational exposure to diacetyl at a concentration of 0.1 ppm (i.e., 0.352 mg/m³) and assuming an upper limit inhalation rate of 20 m³/day would also result in a comparable dose of 7 mg/day. Although cigarette smoking is associated with multiple adverse respiratory effects, it is not known to be a cause of BO.

Animal studies have demonstrated toxicity to the respiratory tract with repeated diacetyl exposure. In a subchronic study of mice, Morgan et al. (2008) noted an evidence of airway toxicity at exposures as low as 25 ppm for 12 weeks and were unable to determine a NOAEL. In order to bypass the removal of diacetyl by the nasal cavity, oropharyngeal aspiration was used to provide a higher dose to the deeper airways and resulted in fibrohistiocytic lesions in the terminal bronchioles. It was noted that the lesions developed only 4 days after a single dose and suggested that diacetyl may be highly fibrogenic in the small airways. The authors concluded that the overall findings supported the hypothesis that workplace exposures to diacetyl contributed to the development of BO in humans. Finley et al. (2008) reported several criticisms of this study, including the use of exposure levels orders of magnitude higher than typical time-weighted average(TWA) levels in mixing rooms; the lack of a control group in which animals were exposed to other heated organic vapors; the lack of distal airway damage even at levels, which caused death in some animals; and the possibility that oropharyngeal instillation of other substances would be associated with similar bronchiolar effects.

To summarize, diacetyl has been associated with serious pulmonary toxicity in workers with inhalational exposure to flavoring agents. However, there are questions as to whether diacetyl and/or some other substance with which it may be used is the primary cause of the observed toxicity.

Mechanism of Action

The specific mechanism by which diacetyl or associated substances may cause BO is unknown. Diacetyl has been hypothesized to cause direct injury to the airway epithelium in which the repair process is disorganized and produces uncontrolled fibroblastic and myoblastic proliferation. An allergic sensitization process was considered unlikely (Harber et al., 2006).

SOURCES OF EXPOSURE

Individuals may be exposed to diacetyl on a daily basis due to its natural presence and/or additive presence in various foods, beverages, cigarette smoke, and even automobile exhaust. Diacetyl has also been identified as an indoor air pollutant

and in carpeting adhesive emissions (NTP, 1994). The overall use of diacetyl as a food additive has decreased due to concerns of pulmonary toxicity. The biggest makers of microwave popcorn in the United States reportedly replaced diacetyl with other substances (Popcorn Firms, 2007). Diacetyl is still considered a GRAS food ingredient by the Food and Drug Administration (FDA, 2011). The primary source of occupational exposure has been related to the use of diacetyl and other flavoring substances in the production of various foods.

INDUSTRIAL HYGIENE

Because diacetyl and related flavoring substances have been associated with serious pulmonary toxicity, engineering measures to decrease worker exposure are recommended. These include substitution of less hazardous substances when possible, using closed production processes that limit the opportunity for inhalation exposure, isolating high exposure processes from the rest of the workplace, and using the lowest possible temperatures for heated processes. Periodic air monitoring should be performed to ensure that the control efforts are effective. Respirators are recommended for individuals working directly with diacetyl. The minimum protective respirator is a half-mask, negative-pressure respirator with organic vapor cartridges and particulate filters (NIOSH, 2006).

The Occupational Safety and Health Administration (OSHA) has not published an occupational exposure standard for diacetyl. The American Conference of Governmental Industrial Hygienists (ACGIH) recommended a threshold limit value—time-weighted average (TLV—TWA) of 0.01 ppm. ACGIH noted that peak exposure may be potentially more important among the causes of BO. The European Commission, (2010) has recommended an occupational exposure limit (OEL) for diacetyl of 0.1 ppm. In a draft criteria document, NIOSH (2011) proposed a much more conservative recommended exposure limit (REL) TWA of 0.005 ppm and noted that at this concentration the risk of decreased lung function was no more than 1 in 1000 and there was a less chance for BO. A short-term exposure limit (STEL) of 0.025 ppm was recommended for a 15-min period.

MEDICAL MANAGEMENT

A medical surveillance program is recommended for individuals working with diacetyl and associated food flavorings. Components of such a program include a baseline medical evaluation focused on respiratory health, a baseline pulmonary function test prior to starting work, and a periodic pulmonary function testing. This surveillance can be included as part of the OSHA Respiratory Protection Standard for

individuals who may be required to wear respirators. NIOSH (2006) has recommended at least biannual spirometry for workers with increased exposures. A decrease in FEV₁ of 300 ml or 10% from baseline is recommended as a threshold for further evaluation, including worksite assessment of exposure levels.

Acute inhalation exposure to diacetyl under most circumstances is unlikely to result in significant immediate health effects requiring medical care. Irritant symptoms or aggravation of a preexisting respiratory condition should be treated symptomatically focusing on airway maintenance. Of greater concern is the potential for irreversible lung disease manifested by the gradual onset of increasing respiratory obstruction and dyspnea. The primary treatment should be prevention of exposure. Individuals suspected of having diacetyl or other work-related BO should undergo appropriate diagnostic testing, including pulmonary function testing, chest imaging, and, if necessary, a diagnostic lung biopsy. They should be removed from areas with potential exposure until their diagnosis is clarified. If confirmed to be work related, the individual should be permanently removed from positions with potential exposure. Treatment is dependent on the severity of the underlying condition and may include corticosteroids, inhaled corticosteroids, bronchodilators, and aggressive treatment of secondary pulmonary infections.

PERFLUOROALKYL COMPOUNDS

JASON S. GARCIA AND RAYMOND D. HARBISON

PERFLUORO BUTYL SULFONATE (PFBS)

Target organ(s): Skin, eyes, respiratory tract, liver, kidneys

Occupational exposure limits: NIOSH/OSHA/ACGIH—not established

Reference values: RfD/reference concentration (RfC)/minimal risk level (MRL)—not established

Risk/safety phrases: Corrosive

BACKGROUND AND USES

Perfluoro butyl sulfonate (PFBS, nonafluoro-1-butanesulfonic acid, perfluorobutane sulfonic acid, 1-perfluorobutane sulfonic acid; CASRN 375-73-5) is a four-carbon compound in the perfluoroalkyl family of chemicals. It can be found in stain repellents used for carpets and furniture. A specific form of the chemical, potassium perfluorobutane sulfonate, is being used as a flame retardant in place of brominated retardants. Perfluoro butyl sulfonate is being used as a substitute for other perfluoroalkyl compounds because it is not believed to bioaccumulate in the environment.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluoro butyl sulfonate exists as a colorless liquid. The chemical has a molecular weight of 300.1 g/mol, a boiling point ranging from 112 °F to 114 °F, and a density of 1.81 g/cm³. Perfluoro butyl sulfonate has the ability to react violently with water, so preventing exposure to moisture should be a priority. It

may also be incompatible with strong oxidizers. Upon decomposition, PFBS can form carbon oxides, sulfur oxides, and hydrogen fluoride. Additional information related to the physical and chemical properties of PFBS are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

It is believed that exposure to PFBS can result in acute effects, including changes in blood chemistry, hepatotoxicity, and nephrotoxicity. Decreased hemoglobin and hematocrit, increased liver weight, and histological changes in the kidney have been noted at a laboratory animal reference dose (RfD) of 0.0042 mg/kg/day. Decreased serum protein, albumin, red blood cell count, as well as increased serum chloride may also result. While not related to mammalian toxicology, a study of mallard ducks and bobwhite quails exposed to dietary PFBS concentrations of 1000, 1780, 3160, 5620, and 10,000 mg PFBS/mg feed for 5 days found no associated mortalities as a result of the acute exposure (Newsted et al., 2008). Perfluoro butyl sulfonate may also be associated with neurotoxicity. Slotkin et al. (2008) found that PFBS repressed differentiation of the dopamine and acetylcholine neurotransmitter phenotypes in PC12 cells lines, indicating possible neurotoxic action. The study also noted that when compared to other perfluoroalkyl compounds, PFBS ranked lower with regard to the potential to produce adverse effects.

Chronic Effects

Chronic exposure to PFBS can result in exaggerated effects similar to the acute effects previously described. Decreased

hemoglobin and hematocrit may be seen along with tissue abnormalities in the kidneys and liver. The Minnesota Department of Health (2011) reported these effects as a result of a PFBS RfD of 0.0014 mg/kg/day in a laboratory animal. While not related to mammalian toxicological effects, one study examining the chronic effects of PFBS found that some adult quail exposed to the chemical developed reproductive tissue abnormalities, however, the results were not statistically significant (Newsted et al., 2008). Lou et al. (2013) found that frogs exposed to PFBS had increased expression of estrogen receptor and androgen receptor proposing a potential link between the chemical and adverse reproductive effects. The mentioned studies point to a potential link between PFBS and reproductive abnormalities, however, it is not known whether this can be extrapolated to the mammalian systems.

Mechanism of Action(s)

Most perfluoroalkyl compounds persist in the mammalian tissue and elicit adverse health effects over time. This does not seem to be the case with PFBS. A study of dairy cows fed with PFBS-contaminated feed for 28 days found that chemical concentrations in the blood were low, the chemical was barely detectable in secreted breast milk, and there were low concentrations of the chemical in the liver and kidney (Kowalczyk et al., 2013). One study estimated that PFBS distribution in rat and monkey models is primarily extracellular with urine appearing to be the major route of elimination (Olsen et al., 2009). Olsen et al. (2009) also reported that the geometric mean half-life of PFBS in human subjects followed for 180 days was 25.8 days with the chemical being primarily excreted in the urine. Perfluoro butyl sulfonate that is not excreted can lead to hematological, hepatic, and renal abnormalities. The molecular size of this chemical prevents it from bioaccumulating in the body unlike larger, longer carbon-chained perfluoroalkyls.

Chemical Pathology

It has been noted that perfluoroalkyl compounds bioaccumulate in the mammalian tissue. The larger the chemical, the more it appears to bioaccumulate in the body tissue. Perfluoro butyl sulfonate is a smaller, shorter carbon-chained compound, so accumulation is believed to be minimal. Most of the chemical encountered by the body is excreted in the urine. Based on the available information, PFBS seems to interact with the tissue in the hematologic, hepatic, reproductive, and renal systems. Information related to the exact mechanism of pathology for the different body systems is limited. It has been noted that perfluoroalkyls, including PFBS, have the ability to activate the nuclear receptor peroxisome proliferator-activated receptor alpha (PPAR α), which is involved in the transcription of the genetic material (Rosen et al., 2009). Any deviation in the production of genetic material could result in adverse health effects, including cancer. There has been speculation that

PFBS may be associated with cancer, however, there is no documented evidence to support this speculation.

SOURCES OF EXPOSURE

Occupational

Individuals handling PFBS in the work environment should take precautions as the chemical can react violently with water. Since the chemical exists as a liquid, dermal contact is the most probable route of exposure. The use of personal protective equipment, including aprons, gloves, and goggles, can prevent the liquid from contacting the skin. Inhalation of PFBS can also occur. Dust in the work environment can become contaminated with the chemical. Good housekeeping procedures can prevent the buildup of dust and PFBS. Proper ventilation and personal respirators may be necessary if PFBS concentrations are high. Perfluoro butyl sulfonate and other perfluoroalkyls are used in waxes that are applied to snow skis to increase their performance. Environmental testing of ski shop waxing areas has identified PFBS in the air, making inhalation of the chemical a possibility (Nilsson et al., 2010). Ingestion of the chemical is not likely; however, employees that handle PFBS should wash their hands thoroughly before eating, drinking, or using tobacco products.

Environmental

Perfluoro butyl sulfonate is embedded into the carpet and furniture to offer protection against stains and spills. It is also applied to various household products as it may play a role in the retarding of flames during a fire. Over time as furniture, carpet, and other household products begin to degrade, the chemical may be introduced into the indoor environment in house dust. Perfluoro butyl sulfonate, along with other perfluoroalkyl compounds, has been detected in house dust samples indicating a potential route for exposure for occupants (Strynar and Lindstrom, 2008). Frequent vacuuming and dust removal can prevent buildup of the contaminant in household dust and the indoor environment. Perfluoro butyl sulfonate can also be found in water systems as a result of human waste streams. Samples of tap water collected in China, Japan, India, the United States, and Canada, all contained detectable levels of PFBS (Mak et al., 2009). While the chemical has been detected in both the indoor environment and drinking water, the lack of toxicological data related to PFBS makes it hard to determine what levels of exposure are acceptable.

INDUSTRIAL HYGIENE

In many industries, PFBS has gained popularity because it appears to be less harmful and is not known to bioaccumulate

like other perfluoroalkyl compounds. The Occupational Safety and Health Administration (OSHA), the National Institute for Occupational Safety and Health (NIOSH), and the American Conference of Governmental Industrial Hygienists' (ACGIH) have not established exposure limits for PFBS. While there are no formal guidelines in place, several precautions should be taken to reduce the potential for inhalation, ingestion, and dermal exposure to PFBS. Inhalation to PFBS can be curtailed by utilizing personal respirators. Personal respirators should have proper cartridges installed to capture harmful vapors. Ventilation may also be necessary to remove vapors and particles from the atmosphere. Proper hygienic practices can prevent the ingestion of PFBS. Individuals using the chemical should ensure that they wash their hands prior to eating, drinking, applying cosmetics, and using tobacco products. Using personal protective equipment, such as gloves, rubber boots, and goggles, can prevent dermal contact with the chemical. Contaminated clothing should be removed in a proper manner to prevent additional contamination.

MEDICAL MANAGEMENT

Blood testing can be used to assess whether exposure to PFBS has occurred; however, the dose information related to adverse health effects in humans is not well understood. The route of exposure to PFBS will determine the type of medical management to be utilized. If PFBS vapors are inhaled, the exposed individual should be moved into an area with fresh air. If strenuous breathing occurs, oxygen may need to be provided. If an exposed individual is not breathing, emergency artificial respiration will be needed. If PFBS is ingested, vomiting should not be induced and the mouth should be rinsed with water. If PFBS penetrates the skin, it should be cleansed with soap and water to remove the chemical from the skin. If PFBS contacts the eyes, they should be rinsed with water for a minimum of 15 min. In all situations, medical attention may be necessary if the exposure was excessive or if symptoms do not resolve.

PERFLUOROBUTYRATE (PFBA)

Target organ(s): Skin, eyes, respiratory tract, thyroid, liver
Occupational exposure limits: NIOSH/OSHA/ACGIH—not established
Reference values: RfD/RfC/MRL—not established
Risk/safety phrases: Corrosive

BACKGROUND AND USES

Perfluorobutyrate (PFBA, perfluorobutyric acid, perfluorobutanoic acid, perfluoropropane carboxylic acid; CASRN 375-22-4) is a four-carbon compound in the perfluoroalkyl family of chemicals. Perfluorobutyrate is a breakdown product of stain- and grease-proof coatings applied to various consumer products. Specifically, it can be found on furniture, carpets, upholstery, and food packaging. Perfluorobutyrate can also be detected in water systems as a result of human industrial waste streams.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluorobutyrate exists as a colorless liquid. The chemical has a pH of 1.0, a molecular weight of 214.04 g/mol, a boiling point of 248 °F, a vapor pressure of 10 mmHg, and a density of 1.645 g/cm³. Perfluorobutyrate has the ability to react with bases, reducing agents, and oxidizing agents. Upon decomposition, PFBA can form carbon oxides and hydrogen fluoride. Additional information related to the physical and chemical properties of PFBA are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

Perfluorobutyrate can result in acute effects, including changes in blood chemistry, hepatotoxicity, and thyroid dysfunction. Decreased hemoglobin and hematocrit, increased liver weight, and morphological changes in the thyroid gland have been noted at a laboratory animal RfD of 0.0038 mg/kg/day. Increased thyroid weight, decreased total thyroxine, and free thyroxine may also result from acute exposure to PFBA. Thyroid gland dysfunction can lead to hormonal imbalance thereby disrupting an organism's metabolism. Hepatomegaly and other hepatotoxic manifestations are possible with exposure to the chemical. A study of perfluorinated chemicals found that they had the ability to disrupt the mitochondrial respiration in rat liver cells (Ray, 2010). Male rats exposed to NH₄⁺PFBA showed increased liver weight, hepatocellular hypertrophy, decreased serum cholesterol, and reduced serum thyroxin (Butenhoff et al., 2012). Cessation of exposure to PFBA is believed to reverse the symptoms that were described. Inhalation or dermal contact with PFBA can result in respiratory tract and skin irritation.

Chronic Effects

Chronic exposure to PFBA may result in the morphological and weight changes with respect to the liver. The thyroid gland may also be impacted by chronic exposure. Changes in the thyroid gland can result in disruption of body metabolism. Decreased hemoglobin and hematocrit may also be seen. The Minnesota Department of Health (2011) reported these effects as a result of a PFBA RfD of 0.0029 mg/kg/day in a laboratory animal. Information related to PFBA's ability to cause cancer is not very reliable. There have been some reports that indicate an increase in cases of prostate and bladder cancer in exposed individuals but there is no certainty in the exact cause. Besides exposure to PFBA, there may be other confounding factors that play a role in disease development. Rats fed with perfluoroalkyls, not including PFBA, developed tumors. While rats developed tumors in the laboratory, species differences between rats and humans may prevent the extrapolation of this information to the human population.

Mechanism of Action(s)

Unlike other perfluoroalkyl compounds, PFBA does not distribute into serum, the kidneys, and liver. The concentration of PFBA in the liver of pregnant mice has been found to be lower than in the serum by about 35–55% (Das et al., 2008). Much like PFBS, PFBA has a short half-life and is eliminated from the body via urine. The half-life of PFBA is noted to be 3 days. A study that examined the pharmacokinetics of PFBA in rats, mice, monkeys, and humans found that among individuals

exposed to the chemical via drinking water, 96% of serum PFBA concentrations were <2 ng/ml (maximum = 6 ng/ml) indicating that PFBA is efficiently eliminated from serum without accumulation (Chang et al., 2008). Perfluorobutyrate has also been noted to cause peroxisome proliferation, induction of fatty acid oxidation, and hepatomegaly indicating that PFBA activates the nuclear receptor PPAR α (Foreman et al., 2009). Activation of PPAR α may indicate hepatotoxic response to PFBA in mammalian models.

Chemical Pathology

The specific chemical pathology of PFBA is not well understood. Some research indicates that PFBA has the ability to activate specific nuclear receptors thereby inducing adverse health responses. A study conducted by Foreman et al. (2009) found that PFBA had the ability to modify gene expression resulting in hepatomegaly and hepatocyte hypertrophy through a mechanism that requires PPAR α . The researchers continued to explain that PPAR α -dependent increase in PFBA-induced hepatocyte necrosis with inflammatory cell infiltrate was facilitated by the mouse PPAR α but not the human PPAR α (Foreman et al., 2009). These results may indicate that PFBA is successful in activating PPAR α in both mice and humans, but species differences result in different hepatotoxic pathologies. Perfluorobutyrate may also play a role in the abnormal development of offspring. A study conducted by Das et al. (2008) found that mouse pups exposed to PFBA had delays in eye opening and onset of puberty in groups exposed to 350 mg/kg. Other chemical pathologies may be discovered through additional research of PFBA.

SOURCES OF EXPOSURE

Occupational

Individuals working with PFBA are at a risk for exposure through inhalation or dermal contact. Engineering controls and personal protective equipment should be used to reduce the exposure to acceptable levels. A cohort of current and former 3M employees were studied and were found to have traces of PFBA in their serum indicating exposure (Chang et al., 2008). Individuals working in professional ski shops may be at risk for PFBA exposure. Perfluoroalkyls are applied to skis to increase their performance. The rubbing of the ski wax may introduce contaminated particles into the work environment atmosphere. The highest median perfluoroalkyl concentration was found to be 50 ng/ml, which was 25 times higher than the baseline levels (Freberg et al., 2010). In a situation such as the one described, the installation of a ventilation system can capture and remove particles from the indoor air. In addition, it may be necessary to provide respirators to prevent those applying the wax from inhaling airborne PFBA.

Environmental

Perfluorobutyrate has been known to contaminate waterways when it is improperly disposed. An example would be in Minnesota where perfluoroalkyl waste at four different sites, contaminated the groundwater supplies. The Minnesota Department of Health conducted water testing and found that PFBA contamination was widespread with some concentrations over 1.0 parts per billion (ppb) (MDH, 2012). The Minnesota Department of Health (2012) uses a health-based value (HBV) of 1.0 ppb for PFBA as an advisory guideline to protect the public's health. Exposure to PFBA and other perfluoroalkyl compounds can occur from the inhalation of contaminated house dust. A study of homes in Catalonia, Spain detected 10 different perfluoroalkyl compounds, including PFBA, present in house dust (Ericson Jogsten et al., 2012). Occupants breathing in air or contacting surfaces in these indoor environments could be at risk for exposure. Individuals may also be exposed to PFBA by eating food, such as fish, contaminated with the chemical. Reducing waste streams can prevent PFBA from entering the environment and impacting the population.

INDUSTRIAL HYGIENE

Much like PFBS, PFBA has gained popularity because it appears to be less harmful and is not known to bioaccumulate like other perfluoroalkyl compounds. The Occupational Safety and Health Administration, NIOSH, and ACGIH have not established exposure limits for PFBS. While there are no formal guidelines in place, several preventative measures can be utilized to reduce the potential for inhalation, ingestion, and dermal exposure to PFBA. Inhalation of PFBA can be prevented by utilizing personal respirators. Personal respirators should have the proper accessories installed to capture harmful vapors. An additional measure to remove particles and vapors from the atmosphere would be to utilize a ventilation system. Good hygiene practices can prevent the ingestion of PFBA. Individuals using the chemical should ensure that they wash their hands prior to eating, drinking, applying cosmetics, and using tobacco products. Using personal protective equipment, such as gloves, rubber boots, and goggles, can prevent dermal contact with the chemical. Contaminated clothing should be removed in a proper manner to prevent additional contamination.

MEDICAL MANAGEMENT

Perfluorobutyrate can be detected in serum of exposed individuals. A study of current and former 3M employees

found that out of 177 individuals 96.1% had traces of PFBA in their serum with the highest concentration being 6.2 ng/ml (Chang et al., 2008). Establishing a biomonitoring program can help identify employees exposed to PFBA in the work environment. Serum testing should be completed prior to employment, during employment, and at termination to get an idea of the levels of exposure that occurred. Individuals that are exposed to PFBA will be treated differently depending on their route of exposure. If PFBA vapors are encountered, the exposed individual should be moved into an area with fresh air. If breathing is labored, oxygen may need to be necessary. If an exposed individual is not breathing, emergency artificial respiration will be needed. If PFBA is ingested, vomiting should not be induced and the mouth should be rinsed with water. If PFBA penetrates the skin, it should be cleansed with soap and water to remove the chemical from the skin. If PFBA contacts the eyes, they should be rinsed with water for a minimum of 15 min. In all situations, medical attention may be necessary if the exposure was excessive or if symptoms do not subside.

PERFLUOROHXANE SULFONATE (PFHxS)

Target organ(s): Eyes, skin, respiratory system, liver, kidney, thyroid

Occupational exposure limits: NIOSH/OSHA/ACGIH—not established

Reference values: RfD/RfC/MRL—not established

Risk/safety phrases: Irritant

BACKGROUND AND USES

Perfluorohexane sulfonate (PFHxS, perfluorohexane sulfonic acid, perfluorohexane-1-sulphonic acid; CASRN 355-46-4) is a six-carbon compound in the perfluoroalkyl family of chemicals. Perfluorohexane sulfonate was once used in fire-fighting foam and carpet treatment solutions. It was once widely used by 3M as a stain and water repellent but was phased out due to U.S. Environmental Protection Agency regulations. Much like other perfluoroalkyls, PFHxS can persist in the environment.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluorohexane sulfonate is slightly soluble in water, has a molecular weight of 400.1 g/mol, a boiling point of 238.5 °F, and a density of 1.841 g/cm³ (Ark Pharm Inc., 2013). Perfluorohexane sulfonate has the ability to react with strong oxidizing agents. Upon decomposition, PFHxS can form carbon monoxide, carbon dioxide, hydrogen fluoride, and oxides of sulfur. Additional information related to the physical and chemical properties of PFHxS are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

Perfluorohexane sulfonate has been described as an irritant. Contact with the eyes, mucous membranes, and skin may result in irritant effects. Respiratory irritation may also occur if the chemical is inhaled into the respiratory tract. Exposure to PFHxS was found to result in decreased body weight, decreased cholesterol levels, and increased prothrombin in rats. The Minnesota Department of Health (2009) also noted that microscopic changes in thyroid tissue were reported at high doses of PFHxS. Exposure to PFHxS was also found to disrupt the expression of genes related to PPAR α function, including fatty acid metabolism, inflammation, peroxisome biogenesis, and proteasome biogenesis (Rosen et al., 2011).

These findings indicate that PFHxS may act similar to other perfluoroalkyl compounds, in which they disturb the PPAR α function. Renal toxicity is also possible with PFHxS exposure. A 2013 study found that children living near a chemical plant exposed to PFHxS had decreased estimated glomerular filtration rates indicating possible renal impairment (Watkins et al., 2013).

Chronic Effects

As previously discussed, exposure to PFHxS may result in acute hepatic, renal, neurological, and reproductive toxicity. Chronic exposure to the chemical may result in acute effects becoming chronic in nature. Elimination of the chemical may reduce its burden on the body. The half-life of PFHxS in female rats, male rats, and monkeys has been approximated at 2 days, 1 month, and 4 months, respectively (Sundstrom et al., 2012). Gender and species differences may play a role in the chemical's elimination. The major chronic effect of concern with respect to chemical exposure is the development of cancer. A 2014 case-control study examined the exposure to perfluorinated alkyl acids and the risk of prostate cancer and found higher risks for prostate cancer when heredity was considered as a risk factor (Hardell et al., 2014). Another case-control study found a significant association between serum perfluoroalkyl levels and the risk of breast cancer (Bonefeld-Jorgensen et al., 2011). While both of these studies show a possible association between chemical exposure and disease development, additional research is needed to understand the exact mechanism of action and to make a more definitive determination on causality.

Mechanism of Action(s)

There has been some investigation into the mechanism of action of PFHxS. The chemical appears to result in renal, hepatic, and neurological effects. A study conducted in 2013 found that dairy cows fed with contaminated feed at a concentration of 4.6 µg/kg of body had increased levels of the chemical in their plasma along with high levels of PFHxS in the liver and kidney after only 29 days of exposure (Kowalczyk et al., 2013). The kidney and the liver appear to be organs where the chemical concentrates. There is also some evidence that PFHxS is associated with neurotoxic effects as well. Lee and Viberg (2013) found that neonatal mice exposed to PFHxS experienced neurotoxic effects due to increased levels of neuroproteins, including CaMKII, GAP-43, and synaptophysin in the hippocampus, and decreased levels of GAP-43 in the brain cortex. An additional study noted that there are indications that PFHxS induces apoptosis of cerebellar granule cells in the developing brain, which may signify a mechanism of action via the ERK1/2 pathway (Lee et al., 2014).

Chemical Pathology

The literature indicates that PFHxS may be associated with adverse health effects of the liver, kidney, and thyroid. Wen et al. (2013) found that elevated levels of PFHxS in 1181 subjects was associated with elevated thyroid hormones, including total T₃, total T₄, and free T₄. Disruption in hormonal activity may result in reproductive effects. Many speculate that the chemical may play a role in abnormal development and reproductive toxicity, however, research does not currently support the speculation. One study found that rats exposed to PFHxS concentrations of 0.3, 1, 3, and 10 mg/kg/day experienced no abnormal reproductive effects (Butenhoff et al., 2009). Another study found that exposure to PFHxS did not adversely affect the sperm concentration, sperm count, and semen volume in a cohort of partners of pregnant women (Toft et al., 2012). Additional research must be conducted to help determine if the chemical is associated with the development of reproductive pathologies.

SOURCES OF EXPOSURE

Occupational

Exposure to PFHxS can occur in the work environment, and employees using the chemical should take proper precautions. A study of workers in a fluorochemical plant detected several perfluoroalkyl compounds, including PFHxS, at elevated levels (Wang et al., 2012). Perfluorohexane sulfonate was also detected in plasma samples from workers responding to the World Trade Center Disaster (NYSDOH, 2008). The use of engineering controls, administrative controls, and personal protective equipment can prevent exposure in the work environment. Inhalation of PFHxS-contaminated dust may be associated with the development of adverse health effects. Employees working in contaminated areas should wear proper personal protective equipment and utilize the correct engineering controls to reduce the potential for the exposure. Splashes of PFHxS may result in dermal contact. The use of gloves, long-sleeved work apparel, and boots can prevent the chemical from penetrating the skin. If clothes become contaminated with PFHxS, they should be discarded using proper measures. Ingestion of the chemical in the work environment is not likely but could occur. Personal hygiene measures should be enforced to prevent exposure.

Environmental

Most environmental exposure to PFHxS occurs through the consumption of contaminated drinking water. A study conducted in 2008 found significant increases of PFHxS concentrations in drinking water, with age and gender being significant predictors in regression analysis (Holzer et al., 2008). Another study conducted in 2009 found PFHxS in

31 out of 40 samples with levels in drinking water up to 5.30 ng/ml (Ericson et al., 2009). Perfluorohexane sulfonate not only contaminates water supplies, but it can also impact air quality. One study found that PFHxS levels in indoor environments exceeded those of PFOS, another perfluoroalkyl compound (Goosey and Harrad, 2012). The researchers indicated that this may be due to the increased utilization of PFHxS over more persistent chemicals. While PFHxS can be detected in water and air samples, the lack of established exposure guidelines makes interpretation of the data complicated. It may be necessary to ensure that PFHxS levels stay as low as reasonably possible until additional dose-response data becomes available.

INDUSTRIAL HYGIENE

The use of PFHxS has been discontinued and other chemicals have been used in its place. The U.S. Environmental Protection Agency, in conjunction with chemical manufacturers, began phasing out the use of the chemical in 2000 with the program being completed in 2002 (USEPA, 2011). The Occupational Safety and Health Administration, NIOSH, and ACGIH have not established exposure limits for PFHxS. While there are no formal guidelines in place, several measures can be used to reduce inhalation, ingestion, and dermal exposure to PFHxS. Inhalation to PFHxS can be prevented by utilizing personal respirators. An additional measure to remove particles and vapors from the environment would be to engineer a ventilation system. Good hygiene can avert the ingestion of PFHxS. Individuals using the chemical should ensure that they wash their hands prior to eating, drinking, and using tobacco. Using personal protective equipment, such as gloves, rubber boots, and goggles, can prevent dermal contact with the chemical.

MEDICAL MANAGEMENT

Perfluorohexane sulfonate can be detected in the human blood serum. A study of 2420 donors identified PFHxS in human blood at a mean concentration of 3.1 ng/ml with children <15 years old having the highest mean concentrations (Toms et al., 2009). The institution of a biomonitoring program can help protect employees from exposure to the chemical. Testing for the chemical should occur at a frequency that will allow for the early detection of exposure. If it is determined that an individual has been exposed to PFHxS, it may be necessary to remove them from the area where the exposure has taken place until blood levels decrease. If dermal contact with the chemical occurs, it should be rinsed from the skin with contaminated clothing disposed of properly. The use of personal respiratory protection can reduce the potential for inhalation of PFHxS but respirators must be fitted properly to be effective. Ingestion of

the chemical is not likely but could occur and individuals working with PFHxS should thoroughly clean their hands before eating, drinking, or smoking to prevent exposure via this route. In cases where symptoms of exposure do not subside or when individuals are exposed to high concentrations of PFHxS, prompt medical attention is recommended.

PERFLUOROHEXANOIC ACID (PFHxA)

Target organ(s): eyes, skin, respiratory system

Occupational exposure limits: NIOSH/OSHA/ACGIH—not established

Reference values: RfD/RfC/MRL—not established

Risk/safety phrases: Corrosive

BACKGROUND AND USES

Perfluorohexanoic acid (PFHxA, perfluorocaproic acid, undecafluorohexanoic acid, undecafluoro-1-hexanoic Acid; CASRN 307-24-4) is a six-carbon compound in the perfluoroalkyl family of chemicals. Perfluorohexanoic acid is used in stain- and grease-proof coatings on furniture, carpet, and food packaging. Perfluorohexanoic acid is the six-carbon version of the highly persistent and outlawed PFOA. Much like other perfluoroalkyls, PFHxA can persist in the environment.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluorohexanoic acid exists as a liquid, it is insoluble in water, has a molecular weight of 314.05, and a density of 1.759. Perfluorohexanoic acid has the ability to react with

strong oxidizing agents. Upon decomposition, PFHxA can form carbon oxides and hydrogen fluoride. Additional information related to the physical and chemical properties of PFHxA are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

Several research studies have been conducted to determine the acute effects PFHxA may have on mammalian systems. Available safety information explains that inhalation and dermal contact may result in some acute effects. Inhalation of the chemical may cause irritation to the eyes and upper respiratory tract while dermal contact with the chemical may cause irritation to the skin. One study utilized promyelocytic leukemia rat and glioma rat cell lines to determine the chemical cytotoxicity and found that PFHxA has a low acute biological activity (Mulkiewicz et al., 2007). The researchers also found that the level of toxicity was dependent on perfluoroalkyl chain length (Mulkiewicz et al., 2007). Another study that used human colon carcinoma cells *in vitro* agreed that PFHxA and other perfluoroalkyl compounds do not appear to be acutely toxic at the cellular level (Kleszczynski et al., 2007). Additional research is needed to fully understand the potential acute effects related to PFHxA exposure.

Chronic Effects

There is sparse information related to the chronic effects of PFHxA exposure. Perfluoroalkyl exposure may be associated with abnormal immune system function. A study in 2012 found that high exposures to perfluoroalkyl compounds in children aged 5–7 was associated with decreased humoral immune response to routine childhood immunizations (Grandjean et al., 2012). According to the available literature, exposure to PFHxA does not appear to lead to chronic effects associated with the liver or thyroid gland. The relationship between cancer development and exposure to PFHxA and related compounds remains unclear. A cross-sectional study conducted in 2014 found a strong inverse association between perfluoroalkyl exposure and the likelihood of colorectal cancer diagnosis (Innes et al., 2014). Hardell et al. (2014) conducted a study that indicated an elevated risk for prostate cancer, with an odds ratio of 1.8, in cases where heredity was a risk factor. Additional research into the chronic effects of PFHxA exposure is needed.

Mechanism of Action(s)

The mechanism of action of PFHxA appears to be much like that of other perfluoroalkyl compounds. Many studies

of perfluoroalkyl compounds suggest that the chemicals concentrate and disrupt cell development in the liver. However, one study found that PFHxA did not generate reactive oxygen species or DNA damage in human hepatoma HepG2 cell lines like other perfluoroalkyl compounds (Eriksen et al., 2010). The elimination of PFHxA from the body systems has been considered during the scientific investigation. A 2009 study found that serum clearance of PFHxA was more rapid when compared to PFBS and systemic exposure to PFHxA was lower when compared to PFBS in rats and monkeys (Chengelis et al., 2009). When compared to other, longer chained perfluoroalkyls, PFHxA may be eliminated from the body faster limiting the impact it may have on mammals. Additional investigation is needed to fully describe the PFHxA mechanism of action in the mammalian systems.

Chemical Pathology

Perfluorohexanoic acid has been suggested to impact the liver and the thyroid gland. A study of chicken embryos found that PFHxA accumulated in the yolk sac, liver, and cerebral cortex but did not disrupt thyroid hormone levels (Cassone et al., 2012). It remains unclear if the liver and thyroid gland are sites of pathological manifestations as a result of PFHxA exposure. Research in mammals indicates that PFHxA may be associated with other abnormalities. Human serum albumin has been identified as the site of interaction for PFHxA in human sera (D'eon et al., 2010). Molecular interactions of this nature may explain how perfluoroalkyl compounds, like PFHxA, bioaccumulate in mammalian tissue. Perfluorohexanoic acid introduced to rats orally at concentrations of 10, 50, and 200 mg/kg/day was associated with lower body weight gains, lower red blood cell parameters, higher reticulocyte counts, and lower globulin levels (Chengelis et al., 2009). Further research will help explain how PFHxA is distributed in the body and how it leads to adverse health effects.

SOURCES OF EXPOSURE

Occupational

Workers in direct contact with PFHxA are at risk for exposure. Perfluorohexanoic acid and similar compounds may be a component of ski wax. Wax is applied to skis to improve their performance when they contact the snow. Ski wax technicians may be at risk for exposure during the wax-application process when particles are introduced into the atmosphere as a result of wax buffing. Russell et al. (2013) explains that PFHxA and its salts are quickly absorbed into the body, distributed, and eliminated. If these particles are inhaled into the respiratory tract or are deposited on the skin,

irritant effects may occur. One ski wax technician suffered pulmonary injury, described as acute respiratory distress syndrome (ARDS), resulting from aerosolized perfluoroalkyl compound inhalation (Bracco and Favre, 1998). Since ski waxes contain perfluoroalkyl compounds many believe that they should no longer be considered toxic, however, this is debated. In order to reduce exposure, engineering controls, administrative controls, and personal protective equipment should be utilized.

Environmental

Perfluorohexanoic acid has been used in many applications as it is less persistent than its longer chained chemical counterparts. Perfluorohexanoic acid, like other perfluoroalkyl compounds, can contaminate water systems when it is released via human waste streams. Sediment samples from a lake in Austria identified concentrations of PFHxA up to $5.1 \mu\text{g/kg}^{-1}$ dry weight along with concentrations of other chemically similar compounds (Clara et al., 2009). Perfluorohexanoic acid can also contaminate environments if the chemical is emitted into the atmosphere. When carpets and furniture impregnated with PFHxA begin to degrade, PFHxA can enter the air as it attaches to dust particles. A study of perfluoroalkyl compounds in the indoor environment detected PFHxA at a highest median concentration of 28 ng/g (Haug et al., 2011). The length of time a perfluoroalkyl compound persists in the environment appears to be directly related to the size of the chemical. Substituting PFHxA with other chemicals can prevent its release into the environment lessening its impact on both terrestrial and aquatic organisms.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration, NIOSH, and ACGIH have not established exposure limits for PFHxA. While there are no formal guidelines in place, several measures can be used to reduce inhalation, ingestion, and dermal exposure to PFHxA. Individuals using the chemical should be careful not to inhale PFHxA. Inhalation of PFHxA can be prevented by utilizing personal respiratory protection. Installing a ventilation system capable of removing the chemical may also be used to prevent unnecessary exposure. Good hygiene can avert the ingestion of PFHxA. Individuals using the chemical should ensure that they wash their hands prior to eating, drinking, and using tobacco. Using personal protective equipment, such as gloves, rubber boots, and goggles, can prevent dermal contact with the chemical. A fully encapsulating suit may be necessary in environments where high concentrations and quantities of the chemical are used. If applicable, PFHxA should be substituted with less persistent, shorter carbon-chained chemicals of similar structure.

MEDICAL MANAGEMENT

Perfluorohexanoic acid can be detected in human blood samples. A study of ski wax technicians found that the half-life of PFHxA in the body of highly exposed individuals ranged from 14 to 49 days with a geometric mean of 32 days (Russell et al., 2013). Employees with the potential for exposure to PFHxA should be entered into a medical surveillance program. Examining employees at the time of hire, during employment, and at termination or transfer to different positions can help to identify exposure. If exposure is identified early, the impact on the employee could potentially be reduced. If it is determined that an individual has been exposed to PFHxA, it may be necessary to remove them from the contaminated area. Since PFHxA exists as a liquid, the chemical could be splashed into the eyes or onto the skin. If dermal contact with the chemical occurs, the eyes and skin should be rinsed thoroughly. Contaminated clothing should be disposed of properly. The use of personal respiratory protection can protect against inhalation exposure to PFHxA. Ingestion of the chemical is not likely but could occur and individuals working with PFHxA should thoroughly clean their hands before eating, drinking, or smoking to prevent exposure via this route. In cases where symptoms of exposure do not subside or when individuals are exposed to high concentrations of PFHxA, immediate medical attention should be provided.

PERFLUOROHEPTANOATE (PFHpA)

Target organ(s): Eyes, skin, respiratory system, reproductive system

Occupational exposure limits: NIOSH/OSHA/ACGIH—not established

Reference values: RfD/RfC/MRL—not established

Risk/safety phrases: Corrosive

BACKGROUND AND USES

Perfluoroheptanoate (PFHpA, perfluoroheptanoic acid, perfluoro-n-heptanoic acid, tridecafluoro-1-heptanoic acid; CASRN 375-85-9) is a seven-carbon compound in the perfluoroalkyl family of chemicals. Perfluoroheptanoate is used in stain- and grease-proof coatings on furniture, carpet, and food packaging. Perfluoroheptanoate is the seven-carbon chemical that is structurally similar to the highly persistent and outlawed PFOA. Much like other perfluoroalkyls, PFHpA can persist in the environment.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluoroheptanoate exists as beige crystals, it has a molecular weight of 364.06 g/mol, density of 1.792 g/cm³, freezing

point of 30 °C, boiling point of 175 °C, and a flash point >113 °C. Perfluoroheptanoate has the ability to react with strong oxidizing agents. Upon decomposition, PFHpA can form carbon oxides and hydrogen fluoride. Additional information related to the physical and chemical properties of PFHpA are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

Perfluoroheptanoate's acute effects on mammalian systems have been the topic of several research studies. Available safety information explains that inhalation and dermal contact may result in some acute effects. Inhalation of the chemical may cause irritation to the eyes, mucous membranes, and upper respiratory tract while dermal contact with the chemical may cause irritation to the skin. The major concern related to PFHpA and related compounds are that they have the ability to bioaccumulate in the biological tissue. Perfluoroalkyl compounds were detected in several animals from the Barents Sea food web, including sea ice amphipod, polar cod, black guillemot, and glaucous gull (Haukas et al., 2007). It has been determined that the longer the chemical carbon chain, the more persistent the chemical. Perfluorinated compounds have been detected in tigers (1.18 ng/ml) and lions (2.69 ng/ml), however, there is uncertainty with regards to the actual risk and toxicity associated with the chemical (Li et al., 2008). While PFHpA is known to bioaccumulate in the biological tissue, additional research is needed to fully understand what potential acute systemic effects can occur as a result of the chemical bioaccumulation.

Chronic Effects

Some perfluoroalkyl chemicals, including PFHpA, have been linked to chronic effects associated with the liver, thyroid, and kidneys. Concrete evidence supporting these links is lacking and therefore is deserving of additional investigation. There has been some evidence that PFHpA and related compounds may be associated with adverse effects on the reproductive system. A study of 495 women found that those exposed to perfluorinated compounds had higher odds of being diagnosed with endometriosis when compared with those who did not have exposure (Louis et al., 2012). There has also been some research conducted to investigate the relationship between PFHpA exposure and the development of cancer. Bonefeld-Jorgensen et al. (2011) conducted a case-control study that examined the exposure to perfluoroalkyl compounds and the risk of breast cancer in Greenlandic Inuit woman and found a significant association between serum perfluoroalkyl compound levels and the risk of breast cancer. Additional research into the chronic effects of PFHxA exposure is needed.

Mechanism of Action(s)

It is believed that perfluoroalkyl compounds, including PFHpA, share a similar mechanism of action. The Agency for Toxic Substances & Disease Registry (ATSDR) indicates that these chemicals bind to serum albumin and other plasma proteins such as gamma globulin, alpha globulin, alpha-2-macroglobulin, transferrin, and beta-lipoproteins (ATSDR, 2013). Once in the blood, PFHpA distributes into tissues. Wolf et al. (2012) found that when compared to other perfluorinated compounds, PFHpA induced some of the highest activities for human PPAR α when compared with structurally similar compounds. The same study further determined that increased PPAR α activity was directly associated with increased perfluoroalkyl compound chain length (Wolf et al., 2011). Some research indicates that the thyroid and kidney may be the target organs but up to this point there is no conclusive evidence to support these speculations. Perfluoroheptanoate has a shorter half-life in the body than longer chained perfluoroalkyl compounds and is eliminated from the body in urine, which appears to be an adequate biomarker to determine the exposure.

Chemical Pathology

Like many of the other perfluoroalkyl compounds, PFHpA is believed to target the liver. Frisbee et al. (2009) explain that exposure to these chemicals has been reported to cause hepatotoxic effects, including liver enlargement, hepatocellular adenomas, and peroxisome proliferation. Some researchers believe that exposure to PFHpA and related chemicals may have an impact on the male reproductive system as a result of endocrine disruption. The semen quality of 105 Danish men was analyzed and it revealed that high levels of perfluoroalkyl compounds were related to a decrease in the amount of normal sperm (Joensen et al., 2009). Recent research indicates that exposure to perfluoroalkyl compounds may increase cardiovascular risk. Watkins et al. (2014) examined whether exposure to this class of chemicals was associated with LINE-1 DNA methylation and found that serum levels of perfluoroalkyl compounds were associated with LINE-1 DNA methylation. In order to determine the exact mechanisms of action and additional pathological manifestations, more research is required in this area.

SOURCES OF EXPOSURE

Occupational

Exposure to PFHpA can occur in the work environment and employees using the chemical should take proper precautions. Firefighters are a special population that may be at a risk for exposure to a variety of perfluoroalkyl compounds. When consumer products that contain PFHpA are burned

during a fire, the chemical may be released into the atmosphere. Firefighters should take precaution by utilizing personal respiratory protection. Levels of perfluoroalkyl compounds were found to be significantly high in a study that examined 37 firefighters (Jin et al., 2011). The use of engineering controls, administrative controls, and personal protective equipment can prevent exposure in the occupational environment. Dermal contact with PFHpA is possible so the use of gloves, long-sleeved work apparel, and boots may be necessary to prevent the chemical from penetrating the skin. If clothes become contaminated with PFHpA, they should be discarded using proper measures. Ingestion of the chemical in the occupational environment is not likely but could occur.

Environmental

Environmental exposure to PFHpA occurs by contacting contaminated water and air. Improper release and disposal of perfluorinated compounds allows the chemical to impact water systems and the surrounding environments. A study of Japanese river ways found a correlation between PFHpA concentration and population density with the chemical being measured in the sewage effluent at a total sewage flux of 2.6 t/year (Murakami et al., 2008). When human consumer products containing PFHpA and related compounds begin to deteriorate, the chemical can be released into the air where it can adhere to house dust. The particles may settle on surfaces or be inhaled into the respiratory tract of building inhabitants. Kato et al. (2009) analyzed 39 house dust samples and found that PFHpA had a frequency of detection of 61.2%. Ventilating indoor settings can help prevent the buildup of perfluoroalkyl particles. In addition, purchasing consumer products that are free of PFHpA and other perfluoroalkyl compounds will eliminate exposure to the chemical.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration, NIOSH, and ACGIH have not established exposure limits for PFHpA. While there are no formal guidelines in place, several measures can be used to reduce inhalation, ingestion, and dermal exposure to PFHpA. Individuals using the chemical should be careful to avoid inhalation of PFHpA. Inhalation of PFHpA can be prevented by utilizing personal respiratory protection. Installing a ventilation system capable of removing the chemical may also be necessary to prevent exposure. Good hygiene practices can prevent the ingestion of PFHpA. Eating, drinking, or using tobacco products should be prohibited when individuals use the chemical. Hands should be washed thoroughly with soap and water to remove the contaminant. Dermal contact with the chemical can be prevented by using personal protective

equipment, such as gloves, rubber boots, and goggles. A fully encapsulating suit may be necessary in environments where high concentrations and quantities of the chemical are utilized. If applicable, PFHpA should be substituted with less persistent, shorter carbon-chained chemicals of similar structure.

MEDICAL MANAGEMENT

Perfluoroheptanoate can be detected in the blood and it has been the topic of a variety of research studies. Perfluoroheptanoate and other perfluoroalkyl compounds were detected in 30 blood samples from five cities in China (Yeung et al., 2008). It is recommended that employees that use or have the potential to contact PFHpA should be entered into a medical surveillance program. If exposure is identified early, the burden on the employee could be decreased. If it is determined that an individual has been exposed to PFHpA, it may be recommended to remove them from the contaminated work environment. Since PFHpA exists as a crystalline solid, small particles may be inhaled into the respiratory tract where they can deposit deep in the lung. The use of personal respiratory protection can protect against inhalation exposure to PFHpA. There may be some applications where PFHpA is mixed into solution that could lead to splashing or other types of dermal contact with the chemical. If dermal contact with the chemical occurs, the skin should be rinsed thoroughly. Contaminated clothing should be disposed of properly. Ingestion of the chemical is not likely but could occur and individuals working with PFHpA should thoroughly clean their hands before eating, drinking, or smoking to prevent exposure via this route. In cases where symptoms of exposure do not subside or when individuals are exposed to high concentrations of PFHpA, individuals should seek prompt medical attention.

PERFLUOROOCTANE SULFONATE (PFOS)

Target organ(s): Eyes, skin, respiratory tract, liver, thyroid, reproductive system

Occupational exposure limits: NIOSH/OSHA/ACGIH—not established

Reference values: RfD/RfC/MRL—not established

Risk/safety phrases: Corrosive/carcinogen/teratogen

BACKGROUND AND USES

Perfluorooctane sulfonate (PFOS, 1-octanesulfonic acid, heptadecafluorooctanesulfonic acid, perfluorooctanesulfonic acid, 1-perfluorooctanesulfonic acid; CASRN 1763-23-1) is an eight-carbon compound in the perfluoroalkyl family of chemicals. Perfluorooctane sulfonate is used in a variety of applications, including textiles, leather products, cleaning products, and pesticides. Its main use was as a stain repellent on carpet, furniture, and other consumer products. 3M was the primary manufacturer of the chemical until it voluntarily phased it out in 2002 (USEPA, 2012). Perfluorooctane sulfonate is not manufactured any longer in the United States, but it can be imported for use in specific applications.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluorooctane sulfonate can exist as a liquid or a powder. It has a molecular weight of 500.13 g/mol, a vapor pressure 0.002 mmHg, a boiling point of 133 °C, and is soluble in water (NTP, 2013). Perfluorooctane sulfonate has the ability to react with strong oxidizing agents. Upon decomposition, PFOS can form carbon oxides, sulfur oxides, and hydrogen fluoride. Additional information related to the physical and chemical properties of PFOS are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

Dermal contact with PFOS has the ability to cause skin burns and eye damage. Inhalation of the chemical can reduce lung function and cause respiratory irritation. If PFOS is ingested, it can cause serious harm. Mammalian toxicology studies related to PFOS exposure have identified other acute effects. Prenatal exposure to PFOS in rats was found to cause neonatal mortality while those that survive have abnormal lung function possibly due to thickened alveolar walls (Grasty et al., 2005). Abnormal thyroid function has also been seen with PFOS exposure. Rats exposed to 3.2 mg PFOS/kg during gestation and lactation developed hypothyroxinemia (Yu et al., 2009). Studies of other organisms exposed to PFOS also showed that the chemical disrupts normal function. Short-term exposures of PFOS in fish have been found to increase hepatic fatty acyl-CoA oxidase activity and increased oxidative damage (Oakes et al., 2005). In addition, zebrafish embryos exposed to 0.1, 0.5, 1, 3, and 5 mg/l of PFOS experienced delayed hatching, reduced hatching, and reduced survivorship (Shi et al., 2008). Hypopigmentation, tail and heart malformations, and spinal curvature were also seen at exposure above 1 mg/l (Shi et al., 2008).

Chronic Effects

Cui et al. (2009) conducted a study that exposed rats to high levels of PFOS over a 28-day period and found that they experienced abnormal behavior, drastic weight loss, as well as hepatic and renal tissue abnormalities. The authors also found that the bioaccumulation in mammalian tissue appeared to target the liver followed by the heart, kidney, blood, lung, testicle, spleen, and brain, respectively (Cui et al., 2009). Concentrations of PFOS in southern sea otters was found to range from <1 to 884 ng/g wet weight (Kannan et al., 2006). The authors also found that animals with infectious diseases were found to have significantly higher concentrations of PFOS and PFOA in their tissue when compared to non-diseased otters (Kannan et al., 2006). This may indicate that PFOS degrades the mammalian immune system but additional research is needed to

make a definitive conclusion. A reference dose of 0.00008 mg/kg/day in monkeys was found to promote a variety of chronic effects, including disruption of estrus cycle, decreased sperm count and quality, increased neoplasms, and increased mortality.

Mechanism of Action(s)

The mechanism of action of PFOS has been the topic of much discussion. There has been some research, which indicates that perfluorinated chemicals target the liver, thyroid, kidneys, and/or the reproductive system. Exposure to PFOS has the ability to promote the creation of reactive oxygen species, which has been another topic of investigation. Human microvascular endothelial cells exposed to PFOS increased the production of reactive oxygen species at both low and high concentrations (Qian et al., 2010). The presence of reactive oxygen species has the potential to increase oxidative stress in the exposed organism. Perfluorooctane sulfonate can also result in the dissipation of mitochondria membrane potential and the apoptosis of splenocytes and thymocytes, possibly disrupting the immune system function (Zhang et al., 2013). Perfluorooctane sulfonate is believed to be associated with the development of cancer; however, the association is not clear. Innes et al. (2014) found an inverse relationship between colorectal cancer prevalence and serum level of PFOS. Research in this area continues so that we can gain a better understanding of the relationship between PFOS exposure and the development of adverse health effects, including cancer.

Chemical Pathology

Most research related to PFOS pathology has focused on hepatotoxic effects. Perfluorooctane sulfonate has also been implicated in the development of neurological dysfunction. Mice exposed to a single dose of 21 µmol of PFOS had significantly increased levels of CaMKII, GAP-43, and synaptophysin in the hippocampus and significantly increased levels of synaptophysin and tau in the cerebral cortex (Johansson et al., 2009). Deviations in these protein levels may affect the normal development of the brain resulting in behavioral defects. There may also be an association between thyroid abnormalities and PFOS exposure. Tadpoles exposed to 0.1, 1, 10, and 100 µg/l of PFOS in water had up regulation of the thyroid hormone-regulated genes—thyroid receptor beta A (TR β A), basic transcription element-binding protein (BTEB), and type II deiodinase (DI2) mRNA expression (Cheng et al., 2011). These results show that PFOS may cause thyroid system imbalance. While PFOS is no longer used in industry, those that worked with the chemical and were acutely or chronically exposed may develop pathologies not previously considered.

SOURCES OF EXPOSURE

Occupational

Anyone working with or close to PFOS in the occupational setting is at risk for exposure. A study of 126 fluorochemical plant employees randomly selected for blood testing had a PFOS geometric mean of 0.941 that was one order of magnitude higher when compared to 60 film plant employees (Olsen et al., 2003). Animal studies of PFOS show that the chemical is well-absorbed orally, distributes in the blood and the liver, and may lead to increased mortality (Butenhoff et al., 2006). It is unknown at this time if these results can be extrapolated from animal models to humans. However, there is some literature that identifies potential associations between PFOS exposure and the development of cancer. Alexander et al. (2003) conducted a study of 2083 perfluorooctanesulphonyl fluoride plant workers and identified 145 deaths with 65 occurring in high PFOS exposure jobs. The risk of death from bladder cancer was increased for the entire group of plant workers with a standard mortality ratio (SMR) of 4.81 (Alexander et al., 2003). Since PFOS manufacture has been eliminated in the United States, occupational exposure to the chemical is believed to be on the decline.

Environmental

Perfluorooctane sulfonate has been known to contaminate water, soil, and air and can be found in both indoor and outdoor environments. Perfluorooctane sulfonate has been detected in environmental water at concentrations of 0.4 ng/l in remote areas and 4.0 ng/l in urban areas (Jin et al., 2009). The chemical has also been detected in rainwater at a concentration of 0.59 ng/l (Loewen et al., 2005). Contact with contaminated water is a potential route of exposure. Research studies have also been completed that have identified PFOS accumulation in the indoor environment. Moriwaki et al. (2003) examined environmental dust from vacuum cleaners that were collected in Japanese homes and identified concentrations of PFOS ranging from 11 to 2500 ng/g. Perfluorooctane sulfonate concentration of 2.2 ng/l was also detected in indoor dust samples from home and offices (D'Hollander et al., 2010). Since PFOS production in the United States has ceased, the frequency of PFOS detection in outdoor and indoor environments should be on the decline as consumer products no longer contain the chemical.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration, NIOSH, and ACGIH have not established exposure limits for PFOS. Even though PFOS is no longer used in industry

and, although there are no formal guidelines in place, several measures can be used to reduce inhalation, ingestion, and dermal exposure if one comes into contact with PFOS. Individuals using the chemical should be careful to avoid inhalation of PFOS. Personal respiratory protection may be needed if PFOS concentrations are high. Installing a ventilation system capable of removing the chemical may also be necessary to prevent exposure. Ingestion of PFOS can be prevented by using good hygiene practices. Eating, drinking, or using tobacco products should be prohibited when individuals are in contact with the chemical. Hands should be washed thoroughly with soap and water to remove the contaminant. Dermal contact with the chemical can be prevented by using personal protective equipment, such as gloves, rubber boots, and goggles. A fully encapsulating suit may be necessary in environments where high concentrations and quantities of the chemical are utilized. Perfluorooctane sulfonate has been substituted in industry and manufacturing in favor of less persistent and less harmful compounds.

MEDICAL MANAGEMENT

Perfluorooctane sulfonate can be detected in human blood samples. A study of pregnant women identified PFOS in serum ranging from 4.9 to 17.6 ng/ml with fetal samples ranging from 1.6 to 5.3 ng/ml (Inoue et al., 2004). Another study of 263 employees from two perfluorooctyl-manufacturing plants identified a mean serum concentration of PFOS to be 1.32 parts per million (ppm) and 1.78 ppm, respectively (Olsen et al., 2003). Since PFOS is no longer used in industry, there are not likely to be any new cases of exposure. However, employees that were exposed prior to the cessation of the chemicals production may be at risk for the development of adverse health outcomes. In situations where the chemical is still being used, it is recommended that employees are entered into a biomonitoring program. The goal of the biomonitoring program should be to identify the exposure and reduce it to the lowest possible level. Since PFOS can exist as a powder, small particles may be inhaled into the respiratory tract where they can deposit deep in the lung. Personal respiratory protection can protect against inhalation exposure to PFOS. There may be some applications where PFOS is in solution that could lead to splashing or other types of dermal contact with the chemical. The skin should be cleansed thoroughly if the chemical contacts it. Ingestion of the chemical is not likely but could occur and individuals working with PFOS should thoroughly clean their hands before eating, drinking, or smoking to prevent exposure via this route. In cases where symptoms of exposure do not subside or when individuals are exposed to high concentrations of PFOS, individuals should seek prompt medical attention.

PERFLUOROOCTANOIC ACID (PFOA)

Target organ(s): Skin, eyes, respiratory tract, nervous system
Occupational exposure limits: NIOSH/OSHA/ACGIH—not established

Reference values: RfD/RfC/MRL—not established

Risk/safety phrases: Corrosive

BACKGROUND AND USES

Perfluorooctanoic acid (PFOA, C8, pentadecafluorooctanoic acid, perfluoro caprylic acid; CASRN 335-67-1) is an eight-carbon compound in the perfluoroalkyl family of chemicals. Perfluorooctane sulfonate is used in a variety of applications, including nonstick cookware, waterproof clothing, leather products, cleaning products, and pesticides. Its main use was as a stain repellent on carpet, furniture, and other consumer products. In 2006, the U.S. Protection Agency along with eight major companies that utilized PFOA embarked on a program to reduce emissions and use of the chemical by 2015 (USEPA, 2012).

PHYSICAL AND CHEMICAL PROPERTIES

Perfluorooctanoic acid can exist as colorless flakes. It has a molecular weight of 414.07 g/mol, a pH of 2.6, a vapor pressure 0.052 mmHg, a melting point ranging from 55 to

56 °C, a boiling point of 189 °C, and a density of 0.900 g/cm³ (NTP, 2013). Perfluorooctanoic acid has the ability to react with bases, oxidizing agents, and reducing agents. Upon decomposition, PFOA can form carbon oxides and hydrogen fluoride. Additional information related to physical and chemical properties of PFOA are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

Perfluorooctanoic acid is known to cause acute effects upon inhalation, ingestion, and dermal exposure. Inhalation of PFOA can occur by breathing chemical particles or vapors into the respiratory tract. Upon inhalation, PFOA is known to result in severe irritation and destruction of the mucous membranes and upper respiratory tract. Ingestion of the chemical is not likely but can be very harmful if swallowed. The Agency for Toxic Substances and Disease Registry (2009) indicates that ingestion of the chemical is likely to occur from hand-to-mouth transfer from treated carpets especially among young children. Ingestion can also occur from eating contaminated food or drinking contaminated water (ATSDR, 2009). Chemical contact with the skin will result in skin irritation and chemical burns. Franko et al. (2012) found statistically significant, dose-response increases in serum PFOA concentrations in mice exposed to a topical application of the chemical. This indicates that dermal absorption may serve as an important route of exposure.

Chronic Effects

Research on the chronic effects of PFOA in mammalian model has identified possible neurologic, physiologic, anatomic, and hormonal abnormalities as a result of chemical exposure. Mice exposed to PFOA have developed neurologic deviations. Male mice exposed to a single-oral dose of 0.58 or 8.70 mg of PFOA exhibited deranged spontaneous behavior, reduced or lack of habituation, and hyperactivity suggesting that the chemical is a developmental neurotoxicant (Johansson et al., 2008). Perfluorooctanoic acid can also disrupt normal anatomic development. Pregnant mice exposed orally to 5 mg PFOA/mg showed signs of altered milk protein gene expression and reduced mammary epithelial growth (White et al., 2007). Many have suspected that PFOA may alter thyroid function in mammalian systems. An analysis of PFOA versus disease status in 3974 adults found that higher concentrations of serum PFOA was associated with current thyroid disease after adjusting for age, sex, race/ethnicity, education, smoking status, body mass index, and alcohol intake (Melzer et al., 2010). The association between exposure to PFOA and cancer is not conclusive; however, Nakayama et al. (2005) described

an epidemiologic study conducted by 3M that showed increases in both prostate and bladder cancer.

Mechanism of Action(s)

Perfluorooctanoic acid can be absorbed into the body through the lungs, through the gastrointestinal tract from contaminated food and water, or through dermal contact with the skin. Once in the body, PFOA does not bioaccumulate in fatty tissue rather it binds to serum proteins with large concentrations residing in the liver. While ATSDR reports that the liver is the target organ for PFOA concentration, other research indicates that the chemical may concentrate elsewhere. Cui et al. (2009) found that PFOA concentration in the mammalian tissue appear to follow the order of the kidneys, liver, lung, heart/whole blood, testicle, spleen, and brain with the highest concentrations in the kidney ranging from 191 to 265 µg/g. What is known is that the liver and kidney both seem to be effected by PFOA exposure. Additional research in this area may help to define the exact mechanism of PFOA action in the mammalian liver and kidney.

Chemical Pathology

Several different pathologies have been noted following exposure(s) to PFOA. Several types of tumors, neonatal death, and toxicity of the immune, hepatic, and endocrine systems have been described in the literature (Steenland et al., 2010). A study of male rats indicated that the LD₅₀/30 day for PFOA was 189 (208–175) mg/kg with all lethal dose-treated rats dying during the first 5 days (Olson and Andersen, 1983). Wang et al. (2013) explain that PFOA has been found to disrupt serum lipid and lipoprotein levels and cause degeneration of hepatocytes leading to the interference with transportation and metabolism of fatty acids. Researchers believe that the abnormal localization of lipid droplets may be associated with PFOA hepatic toxicity (Wang et al., 2013). Reproductive pathologies may also develop as a result of PFOA exposure. Low doses of PFOA, 0, 0.01, 0.1, and 1 mg PFOA/kg, resulted in histopathologic changes in the uterus, cervix, and vagina of exposed mice (Dixon et al., 2012).

SOURCES OF EXPOSURE

Occupational

Individuals involved in the processing, distribution, and handling of PFOA is at risk for exposure. The ATSDR estimates that occupational intake of PFOA by workers ranges from 3.2×10^{-4} to 2.4 ng/kg/day (ATSDR, 2009). Several research studies have speculated that PFOA has powerful hepatotoxic effects. A cross-sectional study of 115 PFOA occupationally exposed workers investigated the relationship between chemical exposure and hepatic

enzymes, lipoproteins, and cholesterol, and found no significant hepatic toxicity (Gilliland and Mandel, 1996). An additional study of 506 occupationally exposed workers found no significant data regarding the relationship between PFOA exposure and hepatic and thyroid toxicity (Olsen and Zobel, 2007). Based on the available information, occupational exposure to PFOA may not be related to hepatotoxic effects; however, more research must be completed before this can be confirmed. Some researchers have speculated whether or not PFOA has adverse reproductive effects on mammalian systems. A 1998 study of 191 production workers failed to describe statistically significant associations between PFOA exposure and reproductive hormone abnormalities (Olsen et al., 1998). The specific effects resulting from occupational exposure to PFOA are not conclusive and therefore deserve additional investigation.

Environmental

Perfluorooctanoic acid is a man-made compound and therefore is not naturally found in the environment. It can be found in the soil, air, and water as a result of manufacturing waste streams, improper disposal, and from the breakdown of other chemicals. Perfluorooctanoic acid has been detected in water from remote areas at median concentrations of 0.1 ng/l and maximum concentrations of 1.3 ng/l while water from urban areas has had PFOA median concentrations of 3.9 ng/l and maximum concentrations of 30.8 ng/l (Jin et al., 2009). These results appear to indicate that human interaction with the environment is directly related to elevated PFOA concentrations. Perfluorooctanoic acid has also been detected in indoor dust samples identifying another potential site for exposure. Vacuum cleaner dust samples have measured PFOA concentrations ranging from 69 to 3700 ng/g (Moriwaki et al., 2003). Individuals who breathe in this contaminated dust may experience both acute and chronic effects as a result of exposure. The cessation of PFOA use in the near future should reduce the amount of contamination in both indoor and outdoor environments.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration, NIOSH, and ACGIH have not established exposure limits for PFOA. Since the use of PFOA in industry is on the decline, one may expect that exposure levels should also be on the decline. Several preventive measures can be taken to reduce inhalation, ingestion, and dermal exposure of PFOA. Individuals using the chemical should be careful to avoid inhalation of the chemical. Personal respiratory protection may be needed if PFOA concentrations are high. Engineering controls, such as a ventilation system capable of removing the chemical, may also be necessary to prevent exposure.

Ingestion of PFOA can be prevented by using good hygiene practices in the workplace. Eating, drinking, or using tobacco products should be prohibited when individuals are in contact with the chemical. Hands should be washed thoroughly with soap and water to remove traces of PFOA. Dermal contact with the chemical can be prevented by using personal protective equipment, such as gloves, rubber boots, and goggles. A fully encapsulating suit may be necessary in environments where high concentrations and quantities of the chemical are utilized. Perfluorooctanoic acid has been substituted in industry and manufacturing in favor of less persistent and less harmful compounds.

MEDICAL MANAGEMENT

Perfluorooctanoic acid can be measured via human serum. Among 100 serum samples from American Red Cross blood donors that were analyzed, PFOA had a geometric mean of 4.5 ng/ml in the year 2000 and a geometric mean of 2.2 ng/ml in the year 2005 (Olsen et al., 2007). The decrease in geometric mean may be a result of the chemical substitution in industrial practice; however, this is only a speculation. Since PFOA is being phased out of the industry, the number of cases reporting adverse health effects should begin to decline. However, employees that were exposed prior to the phasing out of the chemical's production may be at risk for the development of adverse health outcomes. Biomonitoring programs should be instituted in situations where the chemical is still being used. Since PFOA exists as flakes, small pieces may be inhaled into the respiratory tract where they can deposit deep in the alveolar tissue. Personal respiratory protection can protect against the inhalation exposure to PFOA. There may be some applications where PFOA is in solution that could lead to dermal contact with the chemical. The skin should be cleansed thoroughly if the chemical penetration occurs. Ingestion of the chemical is not likely but could occur and individuals working with PFOA should thoroughly clean their hands before eating, drinking, or smoking to prevent exposure via this route. In cases where symptoms of exposure do not subside or when individuals are exposed to high concentrations of PFOA, individuals should seek prompt medical attention.

PERFLUORONONANOIC ACID (PFNA)

Target organ(s): eyes, skin, respiratory system, liver

Occupational exposure limits: NIOSH/OSHA/ACGIH—not established

Reference values: RfD/RfC/MRL—not established

Risk/safety phrases: Irritant

BACKGROUND AND USES

Perfluororonanoic acid (PFNA, heptadecafluororonanoic acid, perfluoro-n-nonanoic acid, perfluororonan-1-oic acid; CASRN 375-95-1) is a nine-carbon compound in the perfluoroalkyl family of chemicals. Perfluororonanoic acid is used in a variety of applications, including in stain- and grease-proof coatings on food packages, furniture, upholstery, and carpet. Like many other perfluoroalkyl compounds, PFNA persists in the environment due to its long carbon chain. Research related to PFNA is sparse and therefore deserve additional investigation.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluororonanoic acid can exist as beige crystals. It has a molecular weight of 464.08 g/mol, a melting point ranging from 59 to 62°C, and a boiling point of 218°C. Perfluororonanoic acid has the ability to react with bases, oxidizing agents, and reducing agents. Upon decomposition, PFNA can form carbon oxides and hydrogen fluoride. Additional information related to the physical and chemical properties of PFNA are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

Research indicates that PFNA and its derivatives have the potential to cause acute effects in mammalian models. Kinney et al. (1989) investigated the acute toxicity of a PFNA derivative, ammonium perfluororonanoate, in male rats. The researchers exposed male rats to a dust atmosphere of 99% ammonium perfluororonanoate. Nose-only inhalation exposure was conducted at concentrations ranging from 67 to 4600 mg/m³ for 4 h. Mortality rates were 0, 4, 6, and 6 out of six animals at 620, 910, 1600, and 4600 mg/m³, respectively. The LC₅₀ was calculated to be 820 mg/m³ with visible clinical signs, including hunched posture, ruffled or discolored fur, red or brown discharge from the eyes, nose, and mouth, wet or stained perineum, pallor, lung noise or labored breathing, lethargy, limpness, and hair loss. In a subsequent

experiment, male rats were exposed to ammonium PFNA via nose-only inhalation at concentrations ranging from 0 to 590 mg/m³ for 4 h. The purpose was to investigate the effects of PFNA on hepatic tissue. Mortality rates were 0 and 1 out of five animals at 67 and 590 mg/m³, respectively. Statistically significant increases in both absolute and relative liver weight at 67 mg/m³ and at 590 mg/m³ were seen. The LC₅₀ for PFNA was determined to be 820 mg/m³ (Kinney et al., 1989).

Chronic Effects

Human HepG2 cells were exposed to PFNA at concentrations of 0.4, 4, 40, 200, 400, 1000, or 2000 μM and the production of reactive oxygen species was examined every 15 min for 3 h (Eriksen et al., 2010). Perfluoronanoic acid did not produce statistically significant increases in reactive oxygen species production. Perfluoronanoic acid propensity to induce DNA damage was the topic of a second experiment. Human HepG2 cells treated with PFNA at concentrations of 100 or 400 μM for 24 h and the amount of DNA damage was measured using the Comet assay (Eriksen et al., 2010). Perfluoronanoic acid at both concentrations was associated with statistically significant frequency of strand breaks. No treatment-related effect related to the amount of oxidative damage to purines was seen. Perfluoronanoic acid was cytotoxic to the HepG2 cells at elevated concentrations as shown by lactate dehydrogenase (LDH) release. Perfluoronanoic acid exposure was associated with genotoxicity in this assay.

Mechanism of Action(s)

There has been some research into PFNA's mechanism of action. Wild type and PPAR α knockout mice were exposed to PFNA at concentrations of 0, 0.83, 1.1, 1.5, or 2 mg/kg in drinking water on gestational days (Wolf et al., 2010). Maternal weight gain, implantation, litter size, and pup weight at birth were unaffected in both strains. The number of live pups at birth and pup survival was diminished in PFNA wild-type treated animals at 1.1 and 2 mg/kg with 36% and 31% survival, respectively. Eye opening was delayed and pup weight was statistically significantly reduced in wild-type male pups at 2 mg/kg and in wild-type female pups at 2 mg/kg. These effects were not seen in the knockout mice. Relative liver weight was increased in a dose-dependent manner in dams and pups of the wild-type strain at all dose levels with only slight increases in the highest dose group in the knockout strain. These data suggest that the PPAR α may play a crucial role in the developmental endpoints with other pathways in addition to PPAR α available to mediate PFNA effects on liver weight.

Chemical Pathology

Many believe that PFNA concentrates in the kidney and the liver. One study conducted a comparison of PFNA pharmacokinetics in rats and mice found both species and gender differences (Tatum-Gibbs et al., 2011). Rats were exposed orally to a dose of 1, 3, or 10 mg/kg and blood was collected at 1, 2, 3, 4, 7, 16, 21, 38, 35, 42, and 50 days after treatment. Liver and kidney were collected for PFNA analysis at the end of the study. Serum elimination of PFNA in the rat was found to be linear with exposure with the rate of elimination much lengthier in males when compared to females at 30.6 days and 1.4 days, respectively. Perfluoronanoic acid was specially stored in the liver but not in the kidneys in rats with higher levels of accumulation occurring in male rats. Mice were given a single oral dose of 1 or 10 mg/kg. In the mouse, serum elimination was observed to be nonlinear with exposure dose and slightly faster in females than in males with serum half-life determined to be 25.8–68.4 days and 34.3–68.9 days in females and males, respectively. As observed in rats, PFNA was stored in the liver but not in the kidneys of mice with higher accumulation of PFNA in males than in females.

SOURCES OF EXPOSURE

Occupational

A retrospective cohort of 630 workers exposed to PFNA at a polymer production facility was investigated to observe differences in clinical measures between exposed and nonexposed employees (Mundt et al., 2007). Work histories, which were available for all employees, provided the basis for categorizing the employees into high, low, or no exposure categories. Records were abstracted for height, weight, date of exam, and 32 clinical chemistry variables. A limited number of baseline blood samples were used to validate the exposure categories, but were insufficient for use in any analysis. Five time periods were selected for cross-sectional analysis and annual measures of the 32 clinical chemistry variables were used for the longitudinal analysis. This accounted for multiple measurements per person and was conducted independently for men and women by exposure group. After adjusting for age and BMI, some small but not clinically significant differences between groups were found. These observations were not consistent between men and women or over the five analysis windows. Seven variables, including total cholesterol, GGT, AST, ALT, alkaline phosphatase, bilirubin, and triglycerides that were examined in separate longitudinal models showed no significant increase or decrease by unit increase in exposure intensity score. No significant relationships between exposure to PFNA and liver, kidney, or thyroid parameters were witnessed.

Environmental

Perfluorononanoic acid can contaminate water, air, and soil. Examination of water samples from the Cantabrian Sea identified PFNA as the perfluoroalkyl compounds with the second highest concentration level ranging from 0.04 to 1.40 ng/l (Gomez et al., 2011). The same study also identified PFNA in port waters at concentrations ranging from 0.04 to 0.20 ng/l. The results of this study indicate that the large population living near the water system may be directly responsible for perfluoroalkyl pollution. In addition, individuals living in the region will be at risk for exposure to the chemical if they contact the water. Haug et al. (2011) conducted a study to examine the presence of perfluoroalkyl compounds in paired house dust and indoor air samples. Forty-one households were examined and identified PFNA as the perfluoroalkyl compound with the second highest median concentration at 23 ng/g. Reducing the use of PFNA will decrease the accumulation of the chemical in indoor environments. Lessening the accumulation will drop the risk of exposure for building inhabitants.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration, NIOSH, and ACGIH have not established exposure limits for PFNA. Different preventive measures can be taken to reduce inhalation, ingestion, and dermal exposure to PFNA. Individuals using the chemical should be careful to avoid breathing in the chemical. Personal respiratory protection is recommended if PFNA concentrations are high. Engineering controls, such as a ventilation system capable of removing the chemical, may also be necessary to prevent exposure. Ingestion of PFNA can occur via hand-to-mouth and can be prevented by using good hygiene practices in the workplace. Eating, drinking, or using tobacco products should be prohibited when individuals are in contact with the chemical. Hands should be cleansed thoroughly with soap and water to remove traces of PFNA. Dermal contact with the chemical can be prevented by using personal protective equipment, such as gloves, rubber boots, and goggles. Perfluorononanoic acid has been substituted in industry and manufacturing in favor of less persistent and less harmful compounds.

MEDICAL MANAGEMENT

Two studies indicate that PFNA can be detected in human breast milk. One study analyzed 45 human breast milk samples collected in Massachusetts and identified PFNA in 64% of the samples at a median concentration of 6.97 pg/ml (Tao et al., 2008). Another study analyzed 19 human breast milk samples collected from China and identified PFNA in 100% of the samples with a median concentration of 16 pg/ml (So et al., 2006). Like other perfluoroalkyl compounds, PFNA can also

be detected in human serum. Employees that have been exposed to the chemical may be at risk for the development of adverse health effects. Biomonitoring programs should be instituted in situations where the chemical is still being used. Since PFOA exists as crystals, small pieces may be inhaled into the respiratory tract where they can deposit deep in the alveolar region of the lung. Personal respiratory protection can protect against inhalation exposure to PFNA. There may be some applications where PFNA is in solution that could lead to dermal contact with the chemical. The skin should be cleansed thoroughly if the chemical contact occurs. Ingestion of the chemical is not likely but could occur and individuals working with PFNA should thoroughly clean their hands before eating, drinking, or smoking to prevent exposure via this route. In cases where symptoms of exposure do not subside or when individuals are exposed to high concentrations of PFNA, individuals should seek prompt medical attention.

PERFLUORODECANOIC ACID (PFDA)

Target organ(s): Skin, eyes, respiratory system, liver

Occupational exposure limits: NIOSH/OSHA/ACGIH—not established

Reference values: RfD/RfC/MRL—not established

Risk/safety phrases: Irritant

BACKGROUND AND USES

Perfluorodecanoic acid (PFDA, nonadecafluorodecanoic acid, nonadecofluorocapric acid, perfluorodecanoic acid, perfluorocapric acid; CASRN 375-95-1) is a ten-carbon compound in the perfluoroalkyl family of chemicals. Perfluorodecanoic acid is used in a variety of applications, including in stain- and grease-proof coatings on food packages, furniture, upholstery, and carpet. Like many other perfluoroalkyl compounds, PFDA persists in the environment due to its long carbon chain. Some research related to PFDA has been conducted but additional investigation is recommended for better understanding of how the chemical reacts with organisms and the environment.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluorodecanoic acid exists as a white powder. It has a molecular weight of 514.08 g/mol, a melting point ranging from 77 to 81 °C, and a boiling point of 218 °C. Perfluorodecanoic acid has the ability to react with bases, oxidizing agents, and reducing agents. Upon decomposition, PFDA can form carbon oxides and hydrogen fluoride. Additional information related to the physical and chemical properties of PFDA are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

A study of the comparative toxicity of PFDA in rats, mice, hamsters, and guinea pigs was conducted by Van Rafelghem et al. (1987). Male animals were exposed once with PFDA and were monitored for up to 28 days. The study revealed that, with some deviation, the toxic potency of PFDA was the same in the four species examined. Severe body weight reduction was apparent in the four species studied. It should be noted that rats stopped eating for 5–6 days after about 6 days post dosing while hamsters continued to consume food at a decreased level. Perfluorodecanoic acid caused marked hepatomegaly in rats, mice, and hamsters, and a moderate swelling in guinea pigs. Microscopic examination of the liver showed similar alterations in the species studied consisting of a panlobular swelling of the parenchymal cells. Perfluorodecanoic acid induced thymic atrophy in hamsters, mice, and guinea pigs. Perfluorodecanoic acid also induced seminiferous tubular degeneration in the testes from rats, but not mice. The lesion in hamsters and guinea pigs was less

severe than in rats. The liver from all species showed disturbance of the rough endoplasmic reticulum, rounding and swelling of the mitochondria, and mild to extensive proliferation of peroxisomes. The latter response was greatest in mice and almost absent in guinea pigs. Accumulation of lipid droplets in liver cells was more pronounced in treated hamsters and guinea pigs than in rats and mice.

Chronic Effects

Perfluorodecanoic acid is known as a peroxisome proliferator, which may result in adverse effects on the liver. Adinehzadeh and Reo (1998) explain that PFDA and related compounds encourage the development of liver peroxisomes and may result in differing degrees of hepatotoxicity and carcinogenesis in rodents. Thyroid function may also be disrupted as a result of PFDA exposure. Rats exposed to the chemical decreased their food consumption and experienced weight loss (Langley and Pilcher, 1985). The study further explains that body temperature and heart rate were also adversely affected by chemical exposure. Serum thyroxine and serum triiodothyronine both experienced reductions suggesting that PFDA disrupts normal hormone levels in mammals. Some research indicates that PFDA may be responsible for immunotoxicity as well. Nelson et al. (1992) conducted a study in which rats were injected with PFDA concentrations of 20 mg/kg or 50 mg/kg, and immunized with keyhole limpet hemocyanin. The result was a significant decrease in keyhole limpet hemocyanin specific IgG_{2a} production when the experimental group was compared with the control group indicating an immunomodulatory effect caused by PFDA.

Mechanism of Action(s)

Much like other perfluoroalkyl compounds, PFDA-induced effects in rats and mice are mediated through PPAR α , and it is generally agreed that humans and nonhuman primates are less responsive than rodents to PPAR α -mediated effects (Klaunig et al., 2003; Maloney and Waxman, 1999). A study with PFDA-exposed rats by intraperitoneal injections reported decreased serum testosterone and 5 α -dihydrotestosterone and reductions in the weight of accessory sex organs (Bookstaff et al., 1990). Experiments in castrated rats implanted with testosterone-containing capsules displayed that the androgenic deficiency caused by PFDA was the result of diminished secretion of testosterone from the testis rather than amplified clearance from blood. Since luteinizing levels in blood were unaffected, the decreased secretion of testosterone from the testis appeared to be due to decreased testicular responsiveness to luteinizing hormone stimulation. Bookstaff et al. (1990) suggested that PFDA upsets the normal feedback relationships that occur between plasma androgen and luteinizing hormone concentrations.

Chemical Pathology

Research indicates that PFDA may play a role in hepatic pathological manifestations. Rats exposed to a single dose of 50 mg/kg of PFDA exhibited abnormal function of the endoplasmic reticulum, mitochondrial swelling, and increases in intracellular lipid droplets in hepatocytes (Harrison et al., 1988). In another study, rats exposed to a single dose of 50 mg/kg of PFDA had decreased food intake resulting in severe weight loss with late lethality (Van Rafelghem and Andersen, 1988). Langley (1990) explains that basic metabolic processes may be disrupted as a result of PFDA exposure. The researcher suggests that PFDA induces the uncoupling of electron transport and oxidative phosphorylation. Further mitochondrial respiration is affected potentially leading to the severe weight loss associated with PFDA toxicity. Perfluorodecanoic acid has been found to alter 13 proteins in rats, many of which are involved in mitochondrial processes (Witzmann and Parker, 1991). While some research has been conducted related to the chemical pathology of PFDA, additional research is needed to get a more concrete understanding of how the chemical elicits its effects on mammalian tissue.

SOURCES OF EXPOSURE

Occupational

Anyone working with or near perfluoroalkyl compounds is at risk for exposure. Ski wax technicians are a special population that may experience exposure to PFDA. Perfluoroalkyl compounds are often integrated into ski waxes. When applied to snow skis, the wax increases the performance of the skis. The rubbing and buffing of the wax can aerosolize PFDA particles capable of being inhaled by employees. Freberg et al. (2010) conducted a study to examine occupational exposure to airborne perfluorinated compounds during professional ski waxing and found that the median inhalable fraction of PFDA particles was 8.9 mg/g of dust, the median thoracic fraction was 9.2 mg/g of dust, and the median respirable fraction was 9.3 mg/g of dust. These results show that PFDA particles vary in size and have the potential to deposit in different regions of the respiratory tract. In a time-trend study of ski wax technicians exposed to PFDA, the chemical was detected in all 57 blood samples with concentrations ranging from 0.9 to 24 ng/ml (Nilsson et al., 2010).

Environmental

Perfluorodecanoic acid is distributed into the environment via human waste streams. Once in the environment, the chemical can bioaccumulate in the tissue of many different organisms. Perfluorodecanoic acid has the capability to

contaminate soil, water, and air. A study of rainbow trout found that PFDA accumulated in the fish with a half-life of 11 days, a steady state bioconcentration factor of 450 l/kg, and a 12-day accumulation ratio of 350 (Martin et al., 2003). Perfluorodecanoic acid, like other perfluoroalkyl compounds, can also be found in house dust. A study that included 102 individual house dust samples detected PFDA with a mean concentration of 15.5 ng/g of dust and a median concentration of 6.65 ng/g of dust (Strynar and Lindstrom, 2008). In another study of paired indoor air and dust samples, PFDA had a mean concentration of 4.1 ng/g of dust (Haug et al., 2011). Individuals breathing in contaminated air or dust samples are at risk for acute and chronic exposure to PFDA and other perfluoroalkyl compounds.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration, NIOSH, and ACGIH have not established exposure limits for PFOA. Various preventive measures can be taken to reduce inhalation, ingestion, and dermal exposure of PFDA. Since PFDA exists as a white powder, individuals using the chemical should be cautious of inhalation exposure. Personal respiratory protection may be needed if PFDA concentrations are high. Engineering controls, such as a ventilation system capable of removing the chemical, may also be recommended to prevent exposure. Ingestion of PFDA can be prevented by using good hygiene practices in the occupational environment. Eating, drinking, or using tobacco products should be prohibited when individuals are in contact with the chemical. Hands should be washed thoroughly with soap and water to remove traces of PFDA from the skin. Dermal contact with the chemical can be prevented by using personal protective equipment, such as gloves, rubber boots, and goggles. A fully encapsulating suit may be necessary in environments where high concentrations and quantities of the chemical are utilized. Perfluorodecanoic acid has been substituted in industry and manufacturing in favor of less persistent and less harmful compounds.

MEDICAL MANAGEMENT

Several studies indicate that PFDA can be detected in human serum. One study analyzed 85 whole human blood samples from nine cities in China and recovered PFDA in 94.6% of the samples (Yeung et al., 2006). Another study of whole blood samples from residents in Catalonia, Spain identified PFDA concentrations of 0.30 and 0.31 ng/ml in individuals aged 25 (+/-) 5 years and age 55 (+/-) 5 years, respectively (Ericson et al., 2007). Like other perfluoroalkyl compounds, PFDA can also be detected in

human serum. Employees that have been exposed to the chemical may be at risk for the development of adverse health effects. Surveillance programs should be instituted in situations where the chemical is still used. Since PFDA exists as a powder, tiny particles may be inhaled into the respiratory tract where they can deposit deep in the alveolar region of the lung. Personal respiratory protection can protect against inhalation exposure to PFDA. There may be some applications where PFDA is in solution that could lead to dermal contact with the chemical. The skin should be cleansed thoroughly if the chemical contact occurs. Ingestion of the chemical is not likely but could occur and individuals working with PFDA should thoroughly clean their hands before eating, drinking, or smoking to prevent exposure via this route. In cases where symptoms of exposure do not subside or when individuals are exposed to high concentrations of PFDA, individuals should seek prompt medical attention.

PERFLUOROUNDECANOIC ACID (PFUnA)

Target organ(s): Eyes, skin, respiratory system, liver, thyroid, reproductive system

Occupational exposure limits: NIOSH/OSHA/ACGIH—not established

Reference values: RfD/RfC/MRL—not established

Risk/safety phrases: Irritant

BACKGROUND AND USES

Perfluoroundecanoic acid (PFUnA, perfluoro-n-undecanoic acid, heneicosfluoroundecanoic acid; CASRN 2058-94-8) is an eleven-carbon compound in the perfluoroalkyl family of chemicals. Perfluoroundecanoic acid is used in a variety of applications, including in stain- and grease-proof coatings on food packages, furniture, upholstery, and carpet. Like many other perfluoroalkyl compounds, PFUnA persists in the environment due to its long carbon chain. Some research related to PFUnA has been conducted but additional inquiry is recommended for better understanding of how the chemical interacts with organisms and the environment.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluoroundecanoic acid exists as a solid. It has a molecular weight of 564.09 g/mol, a melting point ranging from 96 to 101 °C, a flash point of 113 °C, and a boiling point of 160 °C. Perfluoroundecanoic acid has the ability to react with oxidizing agents. Upon decomposition, PFUnA can form carbon oxides and hydrogen fluoride. Additional information related to the physical and chemical properties of PFUnA are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

Perfluoroundecanoic acid is known to cause acute effects upon inhalation, ingestion, and dermal exposure. Inhalation of PFUnA can occur by breathing aerosolized particles or vapors into the respiratory tract. Upon inhalation, PFUnA is known to result in severe irritation of the mucous membranes and upper respiratory tract. Ingestion of the chemical is not likely but can be very harmful if swallowed. Ingestion of the chemical can occur from hand-to-mouth transfer from PFUnA-treated objects especially among young children. If an individual consumes contaminated water or food, exposure via ingestion can occur. Chemical contact with the skin will result in skin irritation and possible chemical burns. If PFUnA contacts the eyes, severe irritation may occur. In many circumstances, the use of engineering controls, administrative controls, and personal protective equipment can reduce PFUnA exposure to the lowest possible levels. Additional research is needed to determine what other acute effects are possible as a result of PFUnA exposure.

Chronic Effects

Perfluoroundecanoic acid is suspected to have chronic effects on the liver, thyroid, and reproductive system in mammals. Some evidence is available to support these thoughts but more investigation is needed. One study examined perfluoroalkyl compound's effects on the thyroid system and hinted at a weak association for free thyroxine (FT_4) with PFUnA at low concentrations (Bloom et al., 2010). If PFUnA is able to disrupt the thyroid function, mammalian development may be altered. A study of PFUnA on reproductive dysfunction in rats exposed to 0, 0.1, 0.3, and 1.0 mg/kg/day found that rats exposed to 1.0 mg/kg/day experienced body weight gain and a decrease in fibrinogen (Takahashi et al., 2014). The same study revealed that pup body weight was reduced and weight gain over 4 days was inhibited at 1.0 mg/kg/day. Researchers determined that the no-observed-adverse-effect level (NOAEL) for reproductive/developmental toxicity is measured to be 0.3 mg/kg/day. While not an exposure study on a mammalian system, rainbow trout were exposed to PFUnA

and other perfluoroalkyl compounds and it was determined that the chemical was a potent inducer of the estrogen-responsive biomarker protein vitellogen at very high dietary exposures (Benninghoff et al., 2011).

Mechanism of Action(s)

Perfluoroundecanoic acid's mechanism of action is believed to be through PPAR α activation similar to other perfluoroalkyl compounds. One study transfected cells with either mouse or human PPAR α -luciferase reporter plasmid and exposed them to PFUnA and other related compounds at concentrations of 0.5 μ M and 100 μ M with the researchers finding that PFUnA ranked fourth in the induction of human PPAR α and ranked second in the induction of mouse PPAR α (Wolf et al., 2012). The results of this study show that the longer chain length compounds may be related to lower PPAR α activity in both human and mouse models. One study examined whether PFUnA and other perfluoroalkyl compounds had an effect on the thyroid hormone system and found that PFUnA failed to elicit an activating effect on the aryl hydrocarbon receptor (AhR) (Long et al., 2013). While exposure to PFUnA is speculated to have adverse effects on the thyroid, the present evidence is inconclusive.

Chemical Pathology

The major pathological manifestation induced by PFUnA is believed to be related to hepatic abnormalities. A study of harbor seal determined that the mean whole body burden of PFUnA was 13 (+/- 2.8) μ g (Ahrens et al., 2009). The study determined that a majority of perfluoroalkyl compounds were concentrated in the blood and the liver. A study of polar bears with exposure to perfluoroalkyl compounds investigated whether exposure was related to the development of mononuclear cell infiltrations, lipid granulomas, and bile duct hyperplasia (Sonne et al., 2008). The study determined that the presence of liver lesions did not appear to be influenced by perfluoroalkyl concentrations; however, the present hepatic lesions were similar to some produced in the laboratory setting. One study found that rats orally exposed to perfluoroalkyl compounds had high hepatic β -oxidation and liver weight with hepatocellular hypertrophy visible at doses of 0.125 and 0.6 mg/kg/day (Mertens et al., 2010). The bioaccumulation of PFUnA in mammalian tissue may play a role in how various pathologies develop.

SOURCES OF EXPOSURE

Occupational

Workers in direct or indirect contact may be at risk for PFUnA exposure. Inhalation and dermal contact are the

most probable routes of exposure with ingestion not being likely. Ski wax technicians may be at a higher risk for PFUnA if they utilize perfluoroalkyl-containing wax. A study by Nilsson et al. (2010) identified PFUnA in blood samples from eight ski wax technicians with concentrations ranging from 0.11 to 2.8 ng/ml. Samples were collected during the course of a ski season from September 2007 to March 2008. Applying and buffing of the chemical may aerosolize it increasing the potential for it to be inhaled into the respiratory tract. Freberg et al. (2010) examined occupational exposure to airborne perfluorinated compounds during professional ski waxing and found that the PFUnA inhalable aerosol fraction ranged from 1.8 to 6.5 mg/g of dust, the thoracic fraction ranged from 2.0 to 7.0 mg/g of dust, and the respirable aerosol fraction ranged from 1.9 to 8.4 mg/g of dust. The median concentrations (mg/g of dust) for inhalable, thoracic, and respirable aerosol fractions were 3.0, 3.2, and 3.2, respectively. Engineering controls, administrative controls, and personal protective equipment are recommended to reduce PFUnA to the lowest possible levels.

Environmental

Perfluoroundecanoic acid, along with other perfluoroalkyl compounds, contaminates air, water, and soil. Once air, water, and soil are contaminated, exposure may occur by way of inhalation, ingestion, or dermal contact leading to bioaccumulation of the chemical in organism tissue. A study examining effluent water and percolate from four industrial plants and two landfill sites in Denmark detected PFUnA at concentrations ranging from <2.2 to 18.8 ng/l (Bossi et al., 2008). Since the chemical is man-made, it should not be found in water systems at these concentrations. Another study detected PFUnA in water and other biological samples. The mean chemical concentrations in water, fish, crab, gastropod, and bivalve were 0.58 ng/l, 0.043 ng/g wet weight, 0.20 ng/g wet weight, 0.045 ng/g wet weight, and 0.062 ng/g wet weight, respectively (Naile et al., 2013). The literature explains that the longer carbon chain compounds tend to persist in the environment longer when compared to their shorter chain counterparts. Substituting for other, less persistent chemicals can prevent the contamination of water systems and human exposure to PFUnA.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration, NIOSH, and ACGIH have not established exposure limits for PFUnA. Various preventive measures can be taken to reduce inhalation, ingestion, and dermal exposure of PFDA. Individuals using the chemical should be aware of the possibilities for inhalation of the chemical. Personal

respiratory protection may be needed if PFUnA concentrations are high or if the chemical becomes aerosolized. Engineering controls, including ventilation systems, may be necessary to capture airborne particles and remove them from the work atmosphere. Ingestion of PFUnA can be prevented by using good hygiene practices in the occupational environment. Eating, drinking, or using tobacco products should be forbidden when individuals are in contact with the chemical. Hands should be washed thoroughly with soap and water to remove traces of PFUnA from the skin. Dermal contact with the chemical can be prevented by using personal protective equipment, such as gloves, rubber boots, and goggles. A fully encapsulating suit may be necessary in environments where high concentrations and quantities of the chemical are utilized. Perfluoroundecanoic acid has been substituted in industry and manufacturing in favor of less persistent and less harmful compounds.

MEDICAL MANAGEMENT

Several studies have been conducted that have identified PFUnA in human serum. Lindh et al. (2012) conducted a study of Greenlandic Inuit populations and detected PFUnA in human serum from 196 individuals at a mean concentration of 1.76 ng/ml and a median concentration of 1.28 ng/ml. A study of tea workers in Sri Lanka identified PFUnA from human blood at a mean concentration of 0.042 ng/ml and a median concentration of 0.043 ng/ml (Guruge et al., 2005). Individuals that have been exposed to the chemical may be at risk for the development of both acute and chronic health effects. Surveillance programs may be recommended in situations where the chemical is still used. If PFUnA becomes aerosolized, it may be inhaled into the respiratory tract where it can deposit. Personal respiratory protection can protect against inhalation exposure to PFUnA. There may be some applications where PFUnA is mixed into solution that could lead to dermal contact with the chemical. The skin should be rinsed thoroughly if the chemical contact occurs. Ingestion of the chemical is not likely but could occur and individuals working with PFUnA should be diligent about cleaning their hands before eating, drinking, or smoking to prevent exposure. In cases where symptoms of exposure do not subside or when individuals are exposed to high concentrations of PFUnA, individuals should seek prompt medical attention.

PERFLUORODODECANOIC ACID (PFDoA)

- Target organ(s): Eyes, respiratory system, skin, reproductive system, liver, reproductive system
- Occupational exposure limits: NIOSH/OSHA/ACGIH—not established
- Reference values: RfD/TDI/MRL—not established
- Risk/safety phrases: Irritant, corrosive

BACKGROUND AND USES

Perfluorododecanoic acid (PFDoA, tricosafluorododecanoic acid, perfluoric acid, tricosafluorolauric acid; CASRN 307-55-1) is a twelve-carbon compound in the perfluoroalkyl family of chemicals. It is a byproduct of stain- and grease-proof coatings on food packages, furniture, and carpets. It is known to bioaccumulate in the environment, although research related to the toxicity of the chemical is scarce.

PHYSICAL AND CHEMICAL PROPERTIES

Perfluorododecanoic acid exists as solid white, fine crystals. The chemical has a molecular weight of 614.1 g/mol, a boiling point of 473 °F, and a melting point ranging from 221 to 226 °F. Perfluorododecanoic acid may be incompatible with strong oxidizers. Upon decomposition, PFDoA can form carbon monoxide, carbon dioxide, and hydrogen fluoride. Additional information related to the physical and chemical properties of PFDoA are not currently available.

MAMMALIAN TOXICOLOGY

Acute Effects

The acute effects of PFDoA on mammalian systems have not been extensively investigated. Since the chemical has been defined as an irritant, contact with the skin, eyes, and respiratory tract can result in irritating effects. While mammalian toxicology has not been researched, some research has been completed on aquatic organisms since PFDoA is a known environmental contaminant. Acute exposure to PFDoA has been found to induce liver damage in female zebrafish, including swollen hepatocytes, vacuolar degeneration, and nuclei pycnosis (Liu et al., 2008). The study explains that fish were provided with a single injection of PFDoA at concentrations of 0, 20, 40, and 80 µg of PFDoA/g of body weight and sacrificed after 48 h, 96 h, and 7 days after the initial administration. Hepatotoxic manifestations were seen upon examination of histopathological samples. In order to completely understand the acute effects of PFDoA on mammalian systems, additional research must be completed.

Chronic Effects

Research studies have associated PFDoA with adverse reproductive effects in mammals. A study conducted in 2007 found that male rats exposed to 1, 5, and 10 mg of PFDoA/kg/day for 14 days developed decreased testicular weight, decreased luteinizing hormone, and decreased testosterone levels (Shi et al., 2007). Shi et al. (2009) also

found that male rats exposed to concentrations of 0.2 PFDoA/kg/day and 0.5 PFDoA/kg/day for 110 days exhibited decreased testosterone levels, decreased protein levels, disruption in testicular steroidogenesis, and disruption of expression of related genes. Research also indicates that PFDoA may result in hepatotoxic effects. Perfluorododecanoic acid was found to decrease liver weights in rats and increase the amount of lipid accumulation in the liver (Zhang et al., 2008). Male rats exposed to PFDoA for 110 days developed hepatic lipidosis characterized by an increase in hepatic triglycerides and a decrease in serum lipoprotein levels (Ding et al., 2009). Indications of cancer development as a result of perfluorododecanoic acid have not been identified in the literature.

Mechanism of Action(s)

The available literature related to PFDoA indicates that the mechanism of action is not well understood. A study conducted by Shi et al. (2010) investigated the mechanism of action in rodents exposed to PFDoA and found that several pathways may be associated with adverse effects of PFDoA on the testes. The authors explain that PFDoA toxicity may be associated with changes in protein expression in the mitochondrial respiratory chain, oxidative stress, sperm activity, cytoskeleton, and intracellular signaling transduction in rodent testes (Shi et al., 2010). Another study conducted by Shi et al. (2010) attempted to investigate PFDoA mechanism of action and found that PFDoA inhibited steroidogenesis in adenosine 3',5'-cyclophosphate (cAMP)-stimulated Leydig cells by decreasing the expression of steroidogenic acute regulatory protein (StAR) through a model containing oxidative stress. Current literature has focused on PFDoA and its possible association with adverse reproductive effects. Further research may identify additional mechanisms of action not currently considered.

Chemical Pathology

Based on available information, PFDoA appears to have pathological effects on the liver and reproductive system. Dose-response information related to these effects is limited. The chemical seems to elicit irritant effects on the skin, liver, and respiratory system upon acute exposure. Hepatotoxicity and reproductive toxicity are thought to occur upon chronic exposure. Shi et al. (2013) found that the MAPK pathway and CDC2 protein phosphorylation may be involved in PFDoA testicular toxicity. There is some research, which indicates that PFDoA may be associated with renal toxicity as well. Male rodents exposed to 0, 0.05, 0.2, and 0.5 mg/kg/day of PFDoA for 110 days exhibited disorders in glucose and amino acid metabolism, which researchers believed was contributing to the pathological findings in the kidneys

(Zhang et al., 2011). Additional research is needed to gain a better understanding of how PFDoA interacts with the human body thereby resulting in pathological findings. Information related to the manifestation of different cancers as a result of PFDoA exposure is inconclusive.

SOURCES OF EXPOSURE

Occupational

Any individual that uses or handles PFDoA during processing, manufacturing, and distribution is at risk for inhalation or dermal exposure to the chemical. Specific populations that may be at risk for exposure to PFDoA are firefighters. Perfluorododecanoic acid is commonly used in the manufacture of furniture and carpet. In the event that these products are burned in a fire, PFDoA fumes may be released into the surrounding atmosphere posing a risk to those nearby. Firefighters should utilize personal respiratory protection to ensure that their inhalation risk is kept to a minimum. The FOX Project, instituted by the state of California, is a biomonitoring program that has been developed for firefighters (OEHHA, 2014). The aim of the program is to investigate occupational exposures that may be encountered by this population. In addition to monitoring for various metals and pesticides, perfluoroalkyl compounds, including PFDoA, are monitored. Exposure to PFDoA should be reduced as companies that use the chemical have been encouraged by regulatory agencies to substitute PFDoA with other chemicals.

Environmental

Perfluorododecanoic acid is not found in the natural environment. Once it enters the environment, it does not normally breakdown easily. Air, water, and soil can become contaminated by the chemical from human waste streams or when similar compounds begin to degrade. Human waste streams introduce it into water systems where it has been noted to bioaccumulate in aquatic organisms. In addition to bioaccumulating in aquatic organisms, humans may be exposed to the chemical if they consume contaminated drinking water. The ATSDR explains that using bottled water for cooking and drinking as well as using carbon water filters has the potential to reduce the exposure to PFDoA and structurally similar compounds (ATSDR, 2009). Another possible source of environmental exposure involves the use of consumer products containing PFDoA. Perfluorododecanoic acid is found in many household products, including furniture and carpet. Purchasing and using household products that do not contain the chemical can help reduce the risk from environmental exposure.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration, NIOSH, and ACGIH have not established exposure limits for PFDoA. Several precautions should be taken to prevent inhalation, ingestion, and dermal exposure to PFDoA. Inhalation to PFDoA can be prevented by utilizing personal respirators. Personal respirators will prevent inhalable particles from settling deep in lung tissue. Ventilation may also be necessary to collect particles and remove them from the work environment. Ingestion of PFDoA can be prevented by utilizing good hygiene practices. Individuals using the chemical should ensure that they wash their hands prior to eating, drinking, applying cosmetics, and using tobacco products. Dermal contact can be prevented by covering the skin with personal protective equipment, including gloves, rubber boots, and safety glasses. Any contaminated clothing should be removed to prevent secondary contamination to others. It may also be necessary to provide workers with showers at the worksite so that they can cleanse their skin and remove the chemical before returning to their place of residence.

MEDICAL MANAGEMENT

Perfluorododecanoic acid can be detected in the blood; however, it is not considered a routine test that can be performed by physicians (ATSDR, 2009). Individuals exposed to high levels of the chemical should consult a physician to determine if testing is needed. The route of exposure to PFDoA will determine the type of medical management to be used. If PFDoA is inhaled, the exposed individual should be removed out of the contaminated area and into fresh air. If labored breathing occurs, oxygen may need to be provided. If an exposed individual is not breathing, emergency artificial respiration will be required. If PFDoA is ingested, the mouth should be rinsed out with copious amounts of water if the individual is conscious. If PFDoA contacts the skin, it should be washed with soap and large amounts of water to remove the chemical from the skin.

The eyes should be rinsed with excessive amounts of water for a minimum of 15 min if PFDoA exposure occurs. In all situations, medical attention may be necessary if the exposure was excessive or if symptoms do not subside.

70

TETRAHYDROFURAN

GHAZI A. DANNAN

Target organ(s): CNS, respiratory system, liver, kidneys

Occupational exposure limits: OSHA, NIOSH, and ACGIH
200 ppm (590 mg/m³) as an 8-h TWA or 250 ppm
(735 mg/m³) as a 15-min TWA

Reference values: RfD = 0.9 mg/kg/day, RfC = 2 mg/m³
(U.S. EPA, 2012)

Risk/safety phrases: DOT label: Flammable liquid; may form explosive peroxides

BACKGROUND AND USES

Tetrahydrofuran (THF; CASRN 109-99-9) is a synthetic organic compound that is not found in the natural environment (ACGIH, 2001). Most of the 2006 worldwide consumption of 439×10^3 tons of THF, with a projected annual growth rate of about 5%, was towards manufacturing poly(tetramethylene) ether glycol (PTMEG), which is essential for producing polyurethane elastomers, elastic polymers, copolyesters, or copolyamides (Müller, 2012). It is also a versatile solvent for polyvinyl chlorides and natural and synthetic resins as well as in top coating solutions, polymer coatings, cellophane, protective coatings, adhesives, magnetic strips, and printing inks. It is also a common laboratory reagent and an intermediate in chemical syntheses of consumer and industrial products such as nutraceuticals, pharmaceuticals, and insecticides (HSDB, 2011).

PHYSICAL AND CHEMICAL PROPERTIES

It is a colorless, volatile liquid with an ethereal or acetone-like smell and is miscible in water and most organic solvents.

It is highly flammable and may thermally decompose to carbon monoxide and carbon dioxide. Prolonged storage in contact with air and in the absence of an antioxidant may cause THF to decompose into explosive peroxides. Synonyms of THF include diethyleneoxide; tetramethyleneoxide; 1,4-epoxy butane; furanidine; oxacyclopentane. Some of the physical and chemical properties for THF are as follows.

Empirical formula	C ₄ H ₈ O
Molecular weight	72.10
Melting point	-108.5 °C
Boiling point	65/66 °C
Vapor pressure	0.173 atm at 20 °C
Density at 20 °C relative to the density of H ₂ O at 4 °C:	0.89
Water solubility	Miscible
Log K _{ow}	0.46
Conversion factors	1 ppm = 2.95 mg/m ³

Chemical structure

Additional properties may be found elsewhere (HSDB, 2011; Müller, 2012).

MAMMALIAN TOXICOLOGY

Acute Effects

Following single-dose gavage administration of THF, the median lethal dose (LD₅₀) values in male Sprague-Dawley rats (6–12/group) were estimated at 2038 mg/kg in 14-day-

old rats, 3190 mg/kg in young adult rats (80–160 g), and 2835 mg/kg in older adult rats (300–470 g) (Kimura et al., 1971). Other estimates, including a lower LD₅₀ value of 1650 mg/kg in rats, have also been cited (IUCLID, 2000).

Following six daily gavage doses of 1–5 g/kg into rats (10/group, sex and strain not specified), there was no mortality in the 2 g/kg group, while 20 and 80–90% of the rats died in the groups that received 3 or 4–5 g/kg (Stasenkova and Kochetkova, 1963). Clinical signs of sedation, including immobility, drowsiness, reduced response to external stimuli, and reduced respiratory rate, were observed after 3–9 min of exposure. Mucous membranes appeared to have a cyanotic discoloration. Histopathological lesions were observed in the stomach, brain, liver, heart, spleen, and kidneys and included necrosis, edema, hemorrhage, and excess of blood or fluid in the blood vessels or tissues.

According to LaBelle and Brieger (1955), the median lethal concentration (LC₅₀) following a single 4-h exposure by inhalation in male albino rats was 18,000 ppm (53,100 mg/m³) with narcosis (sleep) preceding death. In the same study, white mice (6/group, sex not specified) that were exposed continuously to saturated THF vapor (approximately 47,000 ppm or 138,650 mg/m³) had a mean survival time of 41 min. Another study estimated the LC₅₀ to be 21,000 ppm (61,950 mg/m³) in male Sprague-Dawley rats following a single 3-h exposure (Horiguchi et al., 1984).

In an acute inhalation toxicity study, in which CD rats (6/sex/group) had a single 6-h exposure to THF at concentrations of 3010–20,500 ppm (8880–60,475 mg/m³), the non-narcotic concentrations in male and female rats were identified at 5380 ppm (15,871 mg/m³) and 5700 ppm (16,815 mg/m³), respectively (DuPont Haskell Laboratory, 1979). During the exposure period, rats of both sexes demonstrated clinical signs of pawing and scratching and decreased or no response to sound at all concentrations. Male rats also exhibited signs of rapid respiration, and females showed signs of paralysis. Based on the clinical signs of central nervous system (CNS) toxicity, the lowest exposure concentration of 8880 mg/m³ was the study lowest observed adverse effect level (LOAEL).

Several acute inhalation studies in animals suggest that the primary effects observed following single exposures to THF—at concentrations ranging from 300 to more than 200,000 mg/m³ and from 30 min to several hours—are CNS toxicity and respiratory tract irritation. Symptoms of CNS toxicity, including sedation, coma, altered respiration, and decreased response to external stimuli, were observed in dogs at 150,000 mg/m³ (the only concentration tested) (Stoughton and Robbins, 1936), mice at the lowest tested concentrations of 7000 mg/m³ (Stasenkova and Kochetkova, 1963) or 30,000 mg/m³ (Stoughton and Robbins, 1936), and rats at 9000–15,000 mg/m³ (DuPont Haskell Laboratory, 1979; Horiguchi et al., 1984; Stasenkova and Kochetkova, 1963). Clinical signs of possible respiratory tract irritation,

observed only in rat studies at 9000–15,000 mg/m³, included scratching, head shaking, face washing, tearing, salivation, and bleeding from the nose (DuPont Haskell Laboratory, 1979; Horiguchi et al., 1984). In addition, at least one acute study in rats observed structural or functional changes in respiratory tissue, including edema and hemorrhage in the lungs and bronchi (Stasenkova and Kochetkova, 1963), while studies in rabbits reported decreased ciliary beat frequency and vacuolation/degeneration of nasal mucosa at 3000 mg/m³ (Ohashi et al., 1983) as well as decreased ciliary beat frequency and vacuolation of tracheal mucosa at 750 and 35,000 mg/m³, respectively (Ikeoka et al., 1988).

In an acute neurotoxicity study, Crl:CD BR rats (12/sex/group) were exposed to THF vapor at concentrations of 0, 500, 2500, or 5000 ppm (0, 1475, 7375, or 14,750 mg/m³) for a single 6-h exposure, and the animals were then observed for 2 weeks following the day of exposure (Malley et al., 2001). Motor activity assessments and functional observational battery (FOB) assessments were conducted before exposure and on test days 2, 8, and 15. Midway during the exposure at the mid and high THF concentrations, the startle response to an unexpected auditory stimulus was diminished or completely absent. Other signs of sedation in the high concentration group included a significant increase in the incidence of lethargy and abnormal gait in both male and female rats at 14,750 mg/m³. Several parameters in the FOB were also affected in this group immediately following the exposure period only, including affected palpebral closure and increased incidence of slow or absent righting reflex in males and females. However, there were no statistically significant changes or remarkable effects on forelimb grip strength, hind limb grip strength, or foot splay. None of the FOB parameters were affected during test days 2, 8, or 15, suggesting that the sedative effects of THF were short lived. The LOAEL for this study is 7375 mg/m³ based on the observations of the sedative effects, and the no observed adverse effect level (NOAEL) was 1475 mg/m³.

Short-Term Effects

There are a few short-term oral toxicity studies in animals, including one in which rats were treated with a total of six daily gavage administrations of THF in distilled water resulting in increased mortality at doses >2000 mg/kg (Stasenkova and Kochetkova, 1963). Toxicity observed in this study included CNS toxicity (immobility, drowsiness, reduced response to external stimuli) and necrosis, edema, and hemorrhage of stomach, brain, liver, heart, spleen, and kidneys. In another short-term rat study, there were no changes in mortality, body weight, food or water consumption, clinical signs of CNS toxicity, hematology, or serum chemistry following administration of THF in drinking water for 4 weeks at concentrations of 1–1000 mg/l (daily doses 0.1–95.5 mg/kg/day) (Komsta et al., 1988). There were increased incidences of minimal to mild cytoplasmic

homogeneity and anisokaryosis in the liver and tubular cytoplasmic inclusions in the kidneys of the high dose group males and females; however, no histopathology was performed on the lower dose groups. The study authors concluded that THF in drinking water at concentrations up to 1000 mg/l (95.5 mg/kg/day) did not produce overt toxicity and that the observed effects at the high dose were mild and adaptive and could not be related to any functional changes (Komsta et al., 1988).

The ability to irritate the respiratory tract was also evaluated following short-term inhalation exposure of male Sprague-Dawley rats (3–6/group) to 0, 100, or 5000 ppm (0, 295, or 14,750 mg/m³) THF vapor for up to 3 weeks (Horiguchi et al., 1984). The daily exposure duration was not specified. No differences were observed in the tracheal mucosa between the treated groups and the controls following 1 day or 1 week of exposure; at week 3, however, the tracheal mucosa in the 14,750 mg/m³ group showed a disordered cilia and epithelial cells and darkening of the cell bodies. The nasal mucosa of animals exposed to 14,750 mg/m³ for either 1 week or 3 weeks demonstrated disruption of the epithelial architecture, congestion, and sloughing of ciliary and goblet cells, in addition to vacuolation and darkening of the cell bodies. Based on these effects, the study LOAEL was determined to be 14,750 mg/m³ and the study NOAEL was 295 mg/m³.

Developmental studies conducted in both rats and mice reported maternal toxicity, including decreased maternal body weights and CNS effects as well as prenatal developmental findings, including reduction in the percent live pups/litter and delayed ossification of the sternum (Mast et al., 1992). Pregnant rats and mice were exposed by inhalation to THF concentrations of 0, 600, 1800, or 5000 ppm (0, 17, 70, 5310, or 14,750 mg/m³) for 6 h/day on gestation days 6–19 in rats or 6–17 in mice (Mast et al., 1992). Due to high toxicity and mortality, the regimen was discontinued in the 14,750 mg/m³ female mice after 6 days of exposure. Maternal toxicity in both species included symptoms of CNS effects and significant decreases in body weight accompanied by decreases in gravid uterine weight. Decreased fetal weight was observed at the same concentration that resulted in maternal toxicity in rats. In both species, decreased fetal survival also occurred at the same concentrations that resulted in maternal toxicity (14,750 mg/m³ in rats and 5310 mg/m³ in mice). There were no effects on the number of implantations, the fetal sex ratio, or the incidence of abnormalities in fetuses. However, an increased incidence of incomplete or delayed sternal ossification was observed in fetuses of rats (14,750 mg/m³) and mice (5310 mg/m³) (Mast et al., 1992; U.S. EPA, 2012).

Chronic Effects

There are no human studies on the health effects from exposure to THF by the oral route; however, limited

information is available on possible long-term effects from a two-generation reproduction toxicity study in animals (BASF, 1996; Hellwig et al., 2002). In this study, four groups of Wistar rats (25/sex/group) were continuously administered THF in drinking water through two successive generations at concentrations from 0 to 9000 ppm for a minimum of 70 days prior to and during mating, and throughout gestation, parturition, and lactation to weaning. In the high dose (approximately 700–900 mg/kg/day) parental animals, there was a slight decrease in food and water consumption as well as in body weight in addition to a slight increase in kidney weights. There were no treatment-related effects on clinical signs, necropsy, histopathology, fertility and reproductive indices, malformations, or offspring viability. However, the body weight gains of the F1 and F2 pups in the high dose group were significantly decreased during lactation. Also, the F2 pups in the high dose group had delayed opening of eyes and increased number of sloped incisors, with both findings being indicative of a slight developmental delay (BASF, 1996; Hellwig et al., 2002). The finding of decreased pup weight gain was used to set the oral reference dose (RfD) for THF (U.S. EPA, 2012).

Several case studies illustrate the potential for human health effects following an occupational exposure to THF by the inhalation and dermal routes for periods from a few weeks to a few months. In almost all of these cases, workers were exposed while performing activities where THF was present as a component of other chemicals such as solvents or adhesives. Therefore, it is not possible to conclusively attribute the observed effects to THF exposure alone. In addition, quantitative estimates of exposure were not provided in most of the published reports. Nonetheless, target organs in humans appear to be the CNS, respiratory tract, liver, and kidney. Symptoms of CNS toxicity included headache, dizziness, fatigue, and loss of sense of smell (Emmett, 1976; Garnier et al., 1989; Horiuchi et al., 1967). Symptoms of respiratory tract irritation included cough, chest pain, rhinorrhea, and dyspnea (Emmett, 1976; Garnier et al., 1989). In three cases, liver enzymes, namely alanine aminotransferase (ALT), aspartate aminotransferase (AST), and gamma-glutamyl transferase (GGT), were elevated above normal values (Edling, 1982; Garnier et al., 1989; Horiuchi et al., 1967), and in one case a liver biopsy revealed fatty changes following THF exposure (Edling, 1982). In one study, decreased white blood cell counts were reported in THF-exposed workers (Horiuchi et al., 1967). In another case study, autoimmune glomerulonephritis was observed in a man who worked with THF in adhesives for 9 years (Albrecht et al., 1987).

Some of the studies that were performed in animals reported portal-of-entry findings, including irritation of the nasal and respiratory tracts (Horiguchi et al., 1984; Kawata and Ito, 1984; Stasenkova and Kochetkova, 1963); however, there is a lack of consistency among the portal-of-entry study findings, as well as incomplete reporting of the effects and/or study design. Additionally, there is some suggestive

evidence that respiratory tract responses may be transient in nature, waning with increasing exposure duration (Horiguchi et al., 1984). Several systemic effects have been observed following subchronic or chronic inhalation exposure of animals to THF. Decreased body weight has been observed in rats (Horiguchi et al., 1984; Kawata and Ito, 1984; Stasenkova and Kochetkova, 1963). Decreased blood pressure was observed in dogs (BASF, 1938) and rats (Stasenkova and Kochetkova, 1963). There were minor changes in hematology parameters in rats following subchronic exposures to relatively high THF concentrations, including decreased or increased white blood cells (Horiguchi et al., 1984; Stasenkova and Kochetkova, 1963), as well as increased hematocrit, hemoglobin, mean cell volume, mean cell hemoglobin, and neutrophils (NTP, 1998).

However, the most notable and reproducible systemic toxicity findings in subchronic and chronic inhalation rat and mouse studies (NTP, 1998) were the effects on the CNS and liver, which the U.S. EPA (2012) selected as end points for setting an inhalation reference concentration (RfC) for THF. In a chronic toxicity study, groups of F344 rats and B6C3F₁ mice (50/sex/group) were exposed to 0, 200, 600, or 1800 ppm (0, 590, 1,770, or 5310 mg/m³) THF 6 h/day, 5 days/week for 105 weeks (NTP, 1998; chronic). Clinical signs of CNS toxicity (narcosis) were the only effects observed in male (but not female) mice during and up to 1 h after cessation of exposure to THF at 5310 mg/m³. Similar effects were observed following subchronic exposure in both male and female rats, which had narcosis and ataxia at 14,750 mg/m³ THF, and in mice, which had narcosis (stupor) at ≥5310 mg/m³ (NTP, 1998; subchronic). As discussed above, similar CNS effects, including sedation, coma, altered respiration, and decreased response to external stimuli, were observed in a variety of acute, short-term, developmental, and subchronic animal toxicity studies. Additionally, the only findings in another subchronic study designed to assess neurotoxicity in male and female rats were sedative effects characterized as transient acute behavioral sedation, which dissipates rapidly upon termination of exposure to THF at concentrations of 4425 or 8850 mg/m³ (Malley et al., 2001). As stated earlier, symptoms of CNS toxicity, including headache, dizziness, fatigue, and loss of sense of smell, were also reported in occupational exposure studies (Emmett, 1976; Garnier et al., 1989; Horiuchi et al., 1967).

The liver also seems to be a target organ of toxicity following chronic or subchronic inhalation exposure to THF in rats and mice. Following chronic exposure, a slight increase in liver necrosis was reported in high exposure (5310 mg/m³) female mice (from 6% in controls to 14.6%); however, liver weights were not measured (NTP, 1998; chronic). Under the conditions of this 2-year bioassay, the NTP (1998) concluded that there was clear evidence of carcinogenic activity of THF in female B6C3F₁ mice due to increased incidences of hepatocellular adenomas or

carcinomas. After adjusting for intercurrent mortality, the frequency of liver tumors were 61.3–93.0% in each of the three THF exposure groups compared to 46.3% in the control female mice (U.S. EPA, 2012).

In the accompanying subchronic 13-week study, female rats of the high exposure (14,750 mg/m³) group had increased liver weight, which was accompanied by increased serum bile acids signifying a possible altered hepatic function (NTP, 1998; subchronic). Male and female mice also had increased liver weights (6–36% above control) at THF exposure concentrations of ≥1770 mg/m³ accompanied by increased centrilobular cytomegaly (graded minimal or mild) in males and females of the high exposure group (14,750 mg/m³) from 0/10 in the controls to 7/10 and 10/10, respectively (NTP, 1998; subchronic). The affected hepatocytes were described as having slight karyomegaly (enlarged nucleus), increased cytoplasmic volume, and granular cytoplasm with less vacuolation than that of midzonal and periportal hepatocytes (NTP, 1998; subchronic). Liver tissues from male and female mice of the three lower exposure groups were not examined, and no clinical chemistry measurements were performed in mice.

There is additional evidence that the liver is a target organ for THF exposure. In a short-term inhalation exposure study (BASF, 2001; Gamer et al., 2002), female mice had fatty liver degeneration (infiltration), which is a likely adverse finding since certain drugs may cause similar changes, which may predispose the liver to oxidative stress, lipid peroxidation, and possible mitochondrial and organ damage (Begriche et al., 2006; Letteron et al., 1996). In another subchronic inhalation toxicity study, Horiguchi et al. (1984) reported mild liver toxicity in male rats in the form of increased serum liver enzymes, bilirubin, and cholesterol at THF exposure concentrations of 2950 and 14,750 mg/m³ in addition to increased relative liver weight at 14,750 mg/m³, but no liver histopathology findings were reported. Other studies also reported liver effects when THF was administered in animals using exposure routes other than inhalation (Komsta et al., 1988; Stasenkova and Kochetkova, 1963). As discussed earlier, the human liver may also be a target organ, although exposure to THF might have been confounded by coexposure to other chemicals (Edling, 1982; Garnier et al., 1989; Horiuchi et al., 1967).

Kidney findings were also reported in some of the studies. A case of autoimmune glomerulonephritis was reported in a plumber who worked for over 9 years with pipe cement containing THF resulting in estimated air concentrations of 389–757 ppm (1148–2233 mg/m³) during periods that the pipe cement was in use (Albrecht et al., 1987). In subchronic inhalation exposure rat studies, the relative kidney weights of male rats were slightly increased (by 7–8%) only in the high exposure 5000 ppm (14,750 mg/m³) groups without changes in histopathology (Horiguchi et al., 1984; NTP, 1998). However, another subchronic rat study (Kawata and Ito,

1984) reported protein casts and hyaline droplet degeneration in the kidney tubule lumen epithelium at 3000 ppm (8850 mg/m³). In the two-generation reproduction THF drinking water study (BASF, 1996; Hellwig et al., 2002), the relative kidney weights of the high dose F0 parental rats were also slightly increased (by 5–8%) in the absence of the histopathology findings.

Based on increased incidences of renal tubular adenoma or carcinoma of the kidney, the NTP (1998) concluded that there was *some evidence* of carcinogenic activity of THF in male F344 rats. The mortality adjusted rates for these tumors were 16.7–38.3% in each of the three THF exposure groups compared to 8.3% in the control group (U.S. EPA, 2012). Based on increased incidences of hepatocellular tumors in female mice and renal tubule tumors in male rats, the U.S. EPA (2012) concluded that there is “suggestive evidence of carcinogenic potential” by all routes of exposure to THF. According to the European Committee for Risk Assessment (RAC), THF was classified in Categories 3 (Directive 67/548/EEC) and 2 (CLP Regulation). The RAC also concluded that there were no significant grounds to limit the concern to the inhalation route of exposure (ECHA, 2010).

Mechanism of Action(s)

Studies on the absorption, distribution, metabolism, and excretion of THF were recently summarized in U.S. EPA (2012). Overall, the available data show that THF is readily absorbed by the inhalation or oral routes of exposure, is systemically distributed, and is rapidly metabolized and excreted in exhaled air and urine. Based on a number of studies, a metabolic pathway was proposed in which THF is successively metabolized to succinic acid and CO₂ (U.S. EPA, 2012). Some of the intermediate metabolites, such as γ-butyrolactone (GBL) or 5-hydroxy-THF, are expected to be unstable and may be susceptible to further metabolism or hydrolysis to γ-hydroxy-butyric acid (GHB), which undergoes successive metabolism to succinic acid and ultimately CO₂ via the citric acid cycle (TCA cycle); GHB may also be converted to the neurotransmitter γ-aminobutyric acid (GABA). Several enzymes, including CYP450, PON1, and dehydrogenases, were thought to be involved in metabolizing THF and some of the intermediate metabolites (U.S. EPA, 2012).

Several studies attempted to characterize the mode(s) of action (MOA) by which THF causes toxicity and carcinogenesis. A brief description is provided below on the scope and conclusions in some of these studies. A more comprehensive evaluation may be found in U.S. EPA (2012).

Since GBL and GHB are known to affect the nervous system, the CNS effects caused by THF were considered to be likely due to its intermediate metabolites GBL and GHB, which may be converted to GABA (U.S. EPA, 2012). For instance, the most sensitive effects in a chronic gavage

bioassay of GBL were clinical signs of CNS toxicity (lethargy) in rats and mice (NTP, 1992). In addition, GBL is considered a drug of abuse that can lead to neurotoxicity, including addiction, anxiety, depression, and tremors (Herald and Sneed, 2002). On the other hand, clinical studies of GHB reported drowsiness and unconsciousness at high doses (Metcalfe et al., 1966) or transient dizziness and a sense of dullness at relatively lower doses (Ferrara et al., 1999).

A number of studies explored the ability of THF to cause mutagenicity/genotoxicity or other possible MOA that may be considered as precursors or key event(s) to rat kidney and mouse liver tumors. NTP (1998) and U.S. EPA (2012) reviewed the results of a battery of mutagenicity/genotoxicity tests, including bacterial and mammalian mutagenicity, DNA damage, chromosomal aberration, clastogenicity, and cell transformation. NTP (1998) concluded that there was little evidence of mutagenic activity with most data being conclusively negative. The U.S. EPA (2012) also concluded that THF is not likely to be mutagenic or genotoxic since nearly all the results were conclusively negative, with equivocal findings reported in a small number of assays.

Also, the ability of THF and several individual tobacco smoke compounds to cause cytotoxicity were evaluated in a number of short-term *in vitro* assays, including inhibition of cell growth of ascites sarcoma BP 8 cells, inhibition of oxidative metabolism in isolated brown fat cells, plasma membrane damage, and ciliotoxicity in cultures of trachea from unborn chickens (Curvall et al., 1984; Pettersson et al., 1982). The results of these studies suggested that THF is not cytotoxic. Similar results were found in other test systems, including human hepatoma, HepG2 cells (Dierickx, 1989), and the BALB/c-3T3 cell transformation assay (Matthews et al., 1993).

Some data suggested that male rat kidney tumors in the NTP (1998) bioassay may be due to the accumulation of α_{2u}-globulin, which is a marker of rodent kidney disease. This MOA is commonly recognized to require three criteria, namely, increased hyaline droplets in the renal proximal tubule cells, evidence that α_{2u}-globulin is in the droplets, and presence of additional pathological lesions associated with α_{2u}-globulin. While the first two criteria were met by the available data, it was concluded that an area of uncertainty is the absence of α_{2u}-globulin associated histopathological lesions characteristic of this MOA (U.S. EPA, 2012). Chronic progressive nephropathy (CPN), which is a spontaneous age-related renal disease in rats, was also suggested as a likely MOA for the rat kidney tumors (Fenner-Crisp et al., 2011a). After analyzing the available information, the U.S. EPA (2012) concluded that there is inadequate evidence to support this MOA. Tetrahydrofuran did not increase the incidence or severity of CPN, and there was no direct evidence that it may have exacerbated the development of proliferative lesions within CPN-affected tissue. Overall, the U.S. EPA (2012) concluded that the

mode of carcinogenic action of THF-induced renal tumors was not established.

The existing information on the rat kidney tumors and both α_{2u} -globulin and CPN also were evaluated by the European RAC which concluded that, though the carcinogenic response was small, a positive exposure-related response was seen for adenomas and/or carcinomas and that neither α_{2u} -globulin nor CPN could account for the rat kidney tumor findings (ECHA, 2010).

An analysis was also performed on the experimental data suggesting that the development of liver tumors in the THF-exposed female mice may involve a cell proliferation-related MOA (U.S. EPA, 2012). Among the key events for this MOA are histopathological evidence of cytotoxicity/necrosis and regenerative growth as well as possible changes in cellular apoptosis that can impact the net rate of tissue growth. As commonly recognized, sustained increase in cell proliferation may also lead to the promotion of growth of preinitiated cells and subsequently to tumorigenesis. Although increased cell proliferation was noted in short-term studies, the data were not adequate to support this hypothesized MOA since there was no significant increase in cell proliferation in tissues obtained from the subchronic NTP (1998) study. Therefore, cell proliferation didn't seem to be sustained for a sufficient duration to adequately explain the late onset of tumors. Furthermore, key precursor events linked to cell proliferation, such as apoptosis, were not identified; other information, including inhibition of gap junction intercellular communication, was considered too limited to establish a MOA (U.S. EPA, 2012). Fenner-Crisp et al. (2011b) also had similar conclusions that the available data on cell proliferation, apoptosis, and genotoxicity are inadequate to support a MOA for the THF-induced rat liver tumor. The European RAC was of the opinion that the liver tumors were in the highly sensitive B6C3F1 mouse strain and that the MOA for these tumors has not been elucidated (ECHA, 2010).

SOURCES OF EXPOSURE

Potential exposures to humans are primarily from anthropogenic sources, mainly through inhalation or dermal contact. Nonoccupational exposures may occur via inhalation and oral routes from environmental (air and water) or food contamination as well as from dermal exposure through contact of THF-containing products (NTP, 1998; HSDB, 2011).

Since THF is used as a stabilizer in chlorinated solvents, such as 1,1,1-trichloroethane or trichloroethylene, THF is believed to be present at sites that are contaminated by chlorinated solvents as well as in groundwater from different states at concentrations that, in some cases, may exceed the water quality criteria and guidelines (Isaacson et al., 2006).

INDUSTRIAL HYGIENE

Exposure Limits

Occupational Safety and Health Administration (OSHA) permissible exposure limits (PEL)s: 200 ppm (590 mg/m³) as an 8-h time-weighted average (TWA) and 250 ppm (735 mg/m³) as a 15-min TWA short-term exposure limit (STEL)

The National Institute for Occupational Safety and Health (NIOSH) has not issued recommended exposure limits (RELS) for tetrahydrofuran; however, the NIOSH concurs with OSHA's above PELs

American Conference of Governmental Industrial Hygienists (ACGIH): Threshold limit value (TLV) 200 ppm (590 mg/m³) as a TWA for a normal 8-h workday and a 40-h workweek; STEL 250 ppm (737 mg/m³) for periods not to exceed 15 min

For additional information on exposure limits and acronyms, see OSHA Guideline for Tetrahydrofuran, U.S. Department of Labor; available from: <http://www.osha.gov/SLTC/healthguidelines/tetrahydrofuran/recognition.html>.

Respiratory and Personal Protection Respirators must be worn if the ambient concentration of THF exceeds prescribed exposure limits. Respirators may be used (1) before engineering controls have been installed, (2) during work operations such as maintenance or repair activities that involve unknown exposures, (3) during operations that require entry into tanks or closed vessels, and (4) during emergency situations. If the use of respirators is necessary, the only respirators permitted are those that have been approved by NIOSH and the Mine Safety and Health Administration (MSHA). For additional information on protective clothing and recommended respiratory protection (based on NIOSH), see OSHA Guideline for Tetrahydrofuran, U.S. Department of Labor; available from: <http://www.osha.gov/SLTC/healthguidelines/tetrahydrofuran/recognition.html>.

MEDICAL MANAGEMENT

Information on medical management may be found in HSDB (2011) or in MSDS issued by manufacturers.

PERCHLOROETHYLENE (TETRACHLOROETHYLENE)

DAVID G. DODGE AND JULIE E. GOODMAN

Target organ(s): Nervous system, kidney, liver, reproductive, and developmental

Occupational exposure limits:

OSHA PEL: 100 ppm (8-h TWA); 200 ppm (ceiling)

NIOSH REL: Minimize workplace exposure concentrations (carcinogen)

ACGIH: 25 ppm (170 mg/m³; TLV-TWA); 100 ppm (685 mg/m³; TLV-STEL)

Reference values:

US EPA: RfD: 0.006 mg/kg/day; RfC: 0.04 mg/m³

ATSDR: Inhalation MRL: 0.2 ppm (acute); 0.04 ppm (chronic); oral MRL: 0.05 mg/kg/day (acute)

Health Canada: TDI: 0.014 mg/kg/day

BACKGROUND AND USES

Tetrachloroethylene (PCE; CASRN 127-18-4) is also known as perchloroethylene, tetrachloroethene, and 1,1,2,2-tetrachloroethene and is also commonly abbreviated to PER or PERC. Tetrachloroethylene is a volatile, chlorinated organic hydrocarbon that is widely used as a solvent in the dry-cleaning and textile-processing industries and as an agent for degreasing metal parts. It is an environmental contaminant that has been detected in the air, groundwater, surface waters, and soil (NRC, 2010).

PHYSICAL AND CHEMICAL PROPERTIES

The molecular formula of PCE is C₂Cl₄. Tetrachloroethylene is a clear, colorless, nonflammable liquid with an ethereal odor. Physical and chemical properties include:

Molecular weight: 165.8

Density (g/ml) at 20 °C: 1.62

Boiling point (°C): 121

Vapor pressure (mmHg) at 25 °C: 18.47

Water solubility (mg/l) at 25 °C: 150

Henry's law constant (atm·m³/mol) at 25 °C: 1.8 × 10⁻²

Log K_{ow}: 3.4

MAMMALIAN TOXICOLOGY

Acute Effects

In humans, acute accidental inhalation of high concentrations of PCE has induced central nervous system (CNS) depression, dizziness, fatigue, headache, loss of coordination, unconsciousness, narcosis, liver damage, and some deaths (WHO, 2006). Effects on vision in humans have been reported at exposures as low as 50 parts per million (ppm) (ATSDR, 1997). Human data on acute PCE ingestion at high concentrations are limited, though neurological effects have been observed at 108 mg/kg/day (ATSDR, 1997).

In laboratory rodents, acute inhalation and oral toxicity are low. Lethal concentration 50 (LC₅₀) values are above 20,000 mg/m³ and oral LD₅₀ values are in excess of 2 g/kg

body weight (WHO, 2006). Central nervous system depression is the major overt sign in treated animals. Liver and kidney toxicity also have been observed. Tetrachloroethylene is irritating to the skin in humans and rabbits. Slight, transient eye irritation was reported by volunteers exposed at about 520 mg/m³ vapor (WHO, 2006).

Chronic Effects

Cancer A number of epidemiology studies in human populations exposed to PCE have been conducted, principally in laundry and dry-cleaning workers and populations exposed to chlorinated solvents in drinking water. The results have been inconsistent with regard to cancer (few cancer sites were positive in more than one study) (United States Environmental Protection Agency, 2012). In experimental animals, PCE has been associated with mouse liver tumors (hepatocellular adenomas and carcinomas) in both sexes in two lifetime inhalation bioassays of different rodent strains (JISA, 1993; NTP, 1986); mouse liver tumors were also reported in both sexes in an oral bioassay (NCI, 1977). Tetrachloroethylene was associated with rat mononuclear cell leukemia (MNCL) in two studies (JISA, 1993; NTP, 1986). Tumors reported in single inhalation bioassays include kidney and testicular interstitial cell tumors in male F344 rats (NTP, 1986), brain gliomas in male and female F344 rats (NTP, 1986), and hemangiomas or hemangiosarcomas in male Crj:BDFl mice (JISA, 1993).

Noncancer Neurotoxicity is a key effect evaluated in studies of occupational PCE exposure. Occupational exposures have rarely been linked to clinically significant neurological illness, so researchers have instead examined more subtle endpoints (Bukowski, 2011). The most sensitive of these endpoints appear to involve visual/spatial and color perception. For example, studies have demonstrated color vision decrements at a *lowest-observed-adverse-effect level* (LOAEL) of 42 mg/m³ (Cavallari et al., 1994) and changes in cognitive and visuospatial function at a LOAEL of 156 mg/m³ (Echeverria et al., 1995), both in dry-cleaning workers. Other noncancer effects of PCE identified in humans are inconclusive. Limited and/or inconsistent findings include toxicity to the kidney (i.e., chronic kidney disease), liver (i.e., some biomarker changes indicative of liver toxicity), immune and hematologic systems (i.e., some changes in cell counts), and on reproduction (e.g., spontaneous abortions) and development (e.g., oral clefts).

As with humans, neurotoxic effects of PCE have also been characterized in experimental animal studies (US EPA, 2012). Effects on vision, visuospatial function, and reaction time, as well as brain weight changes have been observed, though exposure concentrations are much higher than those experienced by humans environmentally or occupationally. For example, in rats, changes in flash-evoked potential responses were observed at subchronic PCE inhalation

exposures of 800 ppm, but not 200 ppm (Mattsson et al., 1998) and reduction in rat brain weight, DNA, and protein were observed following subchronic PCE inhalation exposures of 600 ppm, but not 300 ppm (Wang et al., 1993).

Adverse effects on the kidney have been reported in studies of rodents exposed to high concentrations of PCE by inhalation and oral exposures (US EPA, 2012). Specific nephrotoxic effects in animals include increased kidney-to-body weight ratios, hyaline droplet formation, glomerular "nephrosis," karyomegaly (enlarged nuclei), cast (cylindrical structures formed from cells and protein released from the kidney) formation, and other lesions or indicators of renal toxicity. These findings support a LOAEL of 200 ppm and a no-observed-adverse-effect level (NOAEL) of 50 ppm (US EPA, 2012).

Liver toxicity has been reported in multiple animal species by inhalation and oral exposures to PCE (US EPA, 2012). The effects are characterized by increased liver weight, fatty changes, necrosis, inflammatory cell infiltration, triglyceride increases, and proliferation. Subchronic and chronic LOAELs for liver toxicity in animals include 9 ppm for increased liver weight (Kjellstrand et al., 1984, as cited in US EPA, 2012) and 50 ppm for liver necrotic foci (JISA, 1993), respectively.

The database of experimental animal studies for PCE also includes assessments of reproductive and fertility outcomes in rats and mice following inhalation exposures; assessments of developmental toxicity in rats, mice, and rabbits following inhalation exposures during gestation; and assessments of developmental neurotoxicity in rats following pre- and/or postnatal inhalation exposures of the offspring (US EPA, 2012). According to US EPA, (2012) and supported by (NRC, 2010), the overall animal developmental and reproductive toxicity inhalation NOAEL is 100 ppm based on Tinston (1994, as cited in US EPA, 2012; NRC, 2010). In this study, increased mortality and decreased body weight of the offspring were observed at 300 ppm. Both maternal toxicity and decreases in pup viability occurred at 1000 ppm.

The available data from experimental studies assessing immunotoxic and hematological responses in animals are limited.

Agency Evaluations United States Environmental Protection Agency (2012) classified PCE as "likely to be carcinogenic in humans by all routes of exposure," though noting that "the epidemiologic literature on cancers provides limited evidence that tetrachloroethylene is carcinogenic in humans." United States Environmental Protection Agency (2012) based its cancer risk estimation for PCE on data from animal studies because it found no available epidemiology studies of cancer that were suitable for dose-response modeling. United States Environmental Protection Agency (2012) found that mode of action (MOA) data are lacking or limited for all candidate animal cancer endpoints for PCE. Because an MOA for PCE could not be established, US EPA defaulted to using a linear, no-threshold approach to estimate the low

exposure risk. Quantitative estimates of carcinogenic risk from both oral and inhalation exposures are based on the male mouse hepatocellular tumor data from the Japan Industrial Safety Association (JISA) (JISA, 1993) bioassay (US EPA, 2012). The International Agency for Research on Cancer (IARC) classified PCE as “probably carcinogenic to humans (Group 2A)” based on the limited evidence in humans and sufficient evidence in animals (Guha et al., 2012). The American Conference of Governmental Industrial Hygienists (ACGIH) (ACGIH, 2012) classifies PCE as an A3 carcinogen, meaning it is a confirmed animal carcinogen (at high doses) with unknown relevance to humans.

United States Environmental Protection Agency’s (2012) chronic oral reference dose (RfD) for PCE is 0.006 mg/kg/d and its chronic inhalation reference concentration (RfC) is 0.04 mg/m³. Both were derived from PCE exposure levels associated with measures of neurotoxicity in studies of occupationally exposed adults. In general, neurological effects were found to be associated with the lowest PCE exposures, and thus reference values based on neurotoxic effects are protective against other noncancer effects that occur at higher concentrations (US EPA, 2012; NRC, 2010). The Agency for Toxic Substances and Disease Registry’s (ATSDR’s) acute and chronic inhalation minimal risk levels (MRLs) are 0.2 and 0.04 ppm, respectively; both are based on neurological effects in occupationally exposed adults (ATSDR, 1997, 2013). The acute oral MRL is 0.05 mg/kg/d, based on developmental neurotoxicity in mice.

Mechanism(s) of Action

An understanding of PCE toxicokinetics is critical, for some effects, to both the qualitative and quantitative assessment of human health risks from PCE exposure because the active agent(s) for a number of endpoints are thought to be metabolites (Lash and Parker, 2001; Clewell et al., 2005; Chiu et al., 2007; NRC, 2010). Metabolism of PCE occurs through two main irreversible pathways: oxidation and glutathione (GSH) conjugation. Oxidative metabolism is thought to predominate in the liver, and the primary stable metabolite of the oxidative pathway is trichloroacetic acid (TCA) (US EPA, 2012). It is generally believed that the PCE-induced liver tumors in mice occur via the formation of metabolites in the oxidative pathway, with particular focus on TCA (US EPA, 2012). The observed species differences in liver tumor formation in response to PCE exposure could be explained by differences in the rates of oxidative metabolite formation (Lash et al., 1998; Lash and Parker, 2001). Given a similar exposure to PCE, humans are not capable of generating the same amounts of reactive oxidative metabolites as compared to rodents. A number of metabolic products can be formed in the conjugative pathway, including S-trichlorovinyl-L-cysteine (TCVC) and mercapturate N-acetyl trichlorovinyl cysteine (NAcTCVC). Tetrachloroethylene-induced kidney tumors

in rats are generally believed to involve metabolites from GSH conjugation (US EPA, 2012; NRC, 2010). Estimates of the extent of GSH conjugation in mice, rats, and humans are far more uncertain, especially in humans (Chiu and Ginsberg, 2011). Even less clear is the metabolite(s) contributing to the development of MNCL, brain gliomas, or testicular interstitial cell tumors in exposed rats and hemangiosarcomas in exposed mice and how metabolic differences may impact species sensitivity (Chiu and Ginsberg, 2011; US EPA, 2012). According to US EPA (2012), no mechanistic hypotheses have been advanced for the human cancers suggested to be increased with PCE exposure in epidemiology studies.

Genotoxic effects of PCE have been extensively investigated in human populations and in a variety of mammalian and nonmammalian test systems. Overall, there is no confirmed evidence that PCE has genotoxic or mutagenic activity in intact organisms (Lash and Parker, 2001; NRC, 2010). United States Environmental Protection Agency (2012) acknowledged that PCE has largely yielded negative results in standard genotoxicity assays, but it concluded nonetheless that “the hypothesis that mutagenicity contributes to the tetrachloroethylene carcinogenesis cannot be ruled out for one or more target organs, although the specific metabolic species or mechanistic effects are not known.”

The potential neurotoxic mechanisms of PCE were reviewed by Bale et al. (2011). In contrast to PCE metabolites being the active agent(s) for a number of endpoints, *in vitro* studies with PCE support the theory that the parent compound interacts with discrete targets in the brain to cause neurotoxicity. It is less clear if there are key metabolites that are also involved in these changes. Based on animal toxicity and mechanistic studies, the authors suggest that PCE interacts directly with several different classes of neuronal receptors by generally inhibiting excitatory receptors/channels and potentiating the function of inhibitory receptors/channels. With regard to the visual effects of PCE, there are no associated mechanistic studies to indicate what receptor systems may be involved. The authors suggest that there may be some similarities in neurological mechanisms of PCE between animals and humans, but that it is difficult to ascertain given there is limited mechanistic information in humans.

Chemical Pathology

In experimental animals, several effects on brain pathology, including DNA- and RNA-level changes, changes in neurotransmitter levels, and changes in brain fatty acid composition have been observed in the range of 37–800 ppm (US EPA, 2012).

Pathological changes in the kidney have been observed in studies of rodents following relatively high subchronic (400–800 ppm) or chronic PCE exposures (100–200 ppm) via inhalation and oral administration. These include karyomegaly (enlarged nuclei) in proximal tubules, hyaline

droplet formation, glomerular nephrosis, and cast formation (US EPA, 2012).

Pathological changes in the liver have been reported in multiple animal species by inhalation and oral exposures to PCE. The effects are characterized by increased liver weight, fatty changes, necrosis, and inflammatory cell infiltration. The LOAEL for the inhalation studies is 9 ppm for increased liver weight and morphological changes. The LOAEL for pathological changes in liver from oral administration is 100 mg/kg/d (US EPA, 2012).

SOURCES OF EXPOSURE

Atmospheric releases of PCE can occur due to evaporative losses during dry cleaning. Other atmospheric emissions may result during manufacture, from use in metal degreasing, in production of fluorocarbons and other chemicals, in the textile industry, and in miscellaneous solvent-associated applications (WHO, 2006). Tetrachloroethylene may also be disposed of to land and surface water (WHO, 2006).

Tetrachloroethylene has been detected in groundwater and surface water, air, soil, food, and breast milk (US EPA, 2012).

Occupational

Workers with potential exposure to PCE include those with occupations in the dry-cleaning industry, metal industries (cleaning machinery parts and degreasing activities), chemical-production industries that make or use PCE, and other industries with solvent-associated applications (WHO, 2006). Mean PCE concentrations inside dry-cleaning facilities have been on the decline since the 1960s, but have still been found to range from 20 to 70 mg/m³ in the United States and Nordic countries in recent decades (US EPA, 2012).

Environmental

The most important routes of exposure to PCE for the general population include inhalation of ambient air and ingestion via drinking water. Dermal exposure is not thought to be a major route of exposure for most people (WHO, 2006; US EPA, 2012). Ambient PCE concentrations vary from source to source and with proximity to source. Median PCE concentrations in outdoor air across the United States have been estimated at about 0.3 µg/m³ for urban areas and 0.1 µg/m³ for rural areas. Near points of use, such as dry cleaners or industrial facilities, indoor exposure to PCE is more significant than outdoor exposure, and groundwater and surface water concentrations can be considerably higher than average (US EPA, 2012).

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration's (OSHA) permissible exposure limits (PELs) for PCE are

100 ppm as a time-weighted average (TWA), 200 ppm as a ceiling (for 5 min in any 3-h period), and 300 ppm as a maximum peak. The National Institute for Occupational Safety and Health (NIOSH) (NIOSH, 2011) does not provide a quantitative exposure limit for PCE, but instead states to minimize workplace exposure concentrations, which is consistent with their old policy for potential occupational carcinogens. Under the new policy, NIOSH will develop quantitative recommended exposure limits (RELs) that are based on risk evaluations using human and/or animal health effects data, and on an assessment of what levels can be feasibly achieved by engineering controls and measured by analytical techniques. The ACGIH (2012) threshold limit value (TLV)-TWA for PCE is 25 ppm (170 mg/m³) to provide a margin of safety to minimize potential discomfort and subjective complaints (e.g., headache, dizziness, sleepiness, incoordination that may occur from prolonged exposure at 100–200 ppm); its TLV—short-term exposure limit (STEL) is 100 ppm (685 mg/m³) to minimize the risk of anesthetic-like effects.

In some occupational settings, it is possible to substitute an agent less hazardous than PCE. In other settings, it may be possible to eliminate hazards by increasing ventilation (ATSDR, 2008). Personal protective equipment (PPE), including aprons, gloves, goggles, and respirators approved for use with organic chemicals, are used to help workers avoid PCE exposure (OSHA, 2005). All containers of liquid PCE should be capped; rags soaked with PCE should be stored in sealed containers (ATSDR, 2008). High levels of exposure can occur during cleanup of contaminated equipment and spills. Workers must wear respirators equipped with filters or cartridges specifically designed for organic vapors when elevated PCE exposures are anticipated (OSHA, 2005; NIOSH and IPSC, 2005).

MEDICAL MANAGEMENT

For persons with PCE toxicity, the level of exposure either must be reduced or the source eliminated. There is no antidote for PCE poisoning. Treatment consists of support of respiratory and cardiovascular functions (ATSDR, 2011). Victims exposed only to PCE vapor who have no eye or skin irritation do not need decontamination. Others may require removing contaminated clothing, washing of exposed skin and hair with mild soap and water, and/or irrigation of exposed eyes with copious amounts of tepid water or saline for at least 15 min (ATSDR, 2011; NIOSH and IPSC, 2005). In cases of ingestion, emesis should not be induced. Instead, a slurry of activated charcoal should be administered if the victim is alert, asymptomatic, and has a gag reflex. Follow-up laboratory evaluation of hepatic and renal function should be arranged for severely exposed patients. Neurologic examination for post-hypoxic injury is recommended in cases of CNS or respiratory

depression. Patients who have skin burns or corneal lesions should be reexamined within 24 h (ATSDR, 2011).

TRICHLOROETHYLENE

DAVID G. DODGE AND JULIE E. GOODMAN

Target organ(s): Central nervous system, kidney, liver, immune system, male reproductive system, developing embryo/fetus

Occupational exposure limits:

OSHA PEL: 100 ppm (8-h TWA); 200 ppm (ceiling)

NIOSH REL: 25 ppm (as a 10-h TWA)

ACGIH: 10 ppm (54 mg/m³; TLV-TWA); 25 ppm (135 mg/m³; TLV-STEL)

Reference values:

US EPA: RfD: 0.0005 mg/kg/day; RfC: 0.0004 ppm (0.002 mg/m³)

ATSDR: Oral MRL: 0.0005 mg/kg/day (chronic); Inhalation MRL: 0.0004 ppm (chronic)

Health Canada: TDI: 0.00146 mg/kg/day

BACKGROUND AND USES

Trichloroethylene (TCE; CASRN 79-01-6) is also known as trichloroethene, acetylene trichloride, 1-chloro-2,2-dichloroethylene, and ethylene trichloride, and it is also commonly abbreviated to TRI. It is a volatile, chlorinated organic hydrocarbon that is widely used for degreasing metals and as a hydrofluorocarbon (HFC-134a) intermediate (ATSDR, 2013). It is also used in adhesives, paint-stripping formulations, paints, lacquers, and varnishes. In the 1930s, TCE was introduced for use in dry cleaning, but this practice was largely discontinued in the 1950s when TCE was replaced by tetrachloroethylene (PCE). It has a number of

other past uses in cosmetics, drugs, foods, and pesticides (US EPA, 2011). It is an environmental contaminant that has been detected in air, groundwater, surface waters, and soil (US EPA, 2011; NRC, 2006).

PHYSICAL AND CHEMICAL PROPERTIES

The molecular formula of TCE is C₂HCl₃. It is a clear, colorless, nonflammable (at room temperature) liquid with chloroform-like odor (ATSDR, 2011). Physical and chemical properties include:

Molecular weight: 131.40

Density (g/ml) at 20 °C: 1.46

Boiling point (°C): 87

Vapor pressure (mmHg) at 25 °C: 69.8

Water solubility (mg/l) at 25 °C: 1280

Henry's law constant (atm·m³/mol) at 25 °C: 9.85 × 10⁻³

Log K_{ow}: 2.61

MAMMALIAN TOXICOLOGY

Acute Effects

In humans, acute inhalation of TCE has been reported to cause headache, fatigue, and drowsiness at 200 parts per million (ppm), decreased depth perception and motor skills at 1000 ppm; and unconsciousness at 3000 ppm (Stewart et al., 1970; Vernon and Ferguson, 1969; Longley and Jones, 1963). Deaths have also been reported in situations of

accidental exposure to unusually high levels of TCE vapors in the workplace or during TCE's use as an anesthetic (DeFalque, 1961). There have been a few reports of acute renal dysfunction in workers exposed to TCE, such as acute renal failure; these are limited by having poor or no exposure data and co-exposure to other chemicals. Human data on acute TCE ingestion at high concentrations are limited, although case studies have reported arrhythmias and heart attacks after ingestion of between 20 and 500 ml TCE (Dhuner et al. 1957; Morreale, 1976; ATSDR, 1997). Acute ingestion of smaller amounts (2 tablespoons to 16 ounces) of TCE has resulted in muscle weakness, vomiting, unconsciousness, and deliriousness, but patients recovered within 2 weeks after cessation of exposure (Morreale, 1976; ATSDR, 1997; Todd, 1954). Dermal exposure to pure TCE for several hours reportedly has caused severe exfoliative dermatitis, rashes, and other skin irritation (Gob and Ng, 1988).

In laboratory rodents, lethal concentration 50 (LC_{50}) values are reported to be between 6400 (in mice) and 12,500 ppm (in rats) after a 4-h exposure (Kylin et al., 1962; Siegel et al., 1971). Oral lethal dose 50 (LD_{50}) values have been reported as 2402 mg/kg/day in mice and 7208 mg/kg/day in rats (Tucker et al., 1982; Smyth et al., 1969). Respiratory effects in rodents after acute inhalation exposure include vacuolation and other morphological changes in Clara cells at 100–500 ppm and nasal irritation at 376 ppm (Giovanetti et al., 1998; Odum et al., 1992; ATSDR, 2013). Neurological effects have been reported in animals after acute inhalation exposure, including decreased brain ribonucleic acid (RNA) and hyperactivity at 200 ppm; decreased wakefulness at 1000 ppm; and lethargy, auditory effects, and anesthesia at concentrations of at least 3000 ppm. Transient ataxia was reported in rats after an acute oral exposure of 633 mg/kg/day (Savolainen et al., 1977; Arito et al., 1993; Adams et al., 1951; Narotsky et al., 1995). Kidney effects have been observed in rodents exposed via acute inhalation exposure of 1000 ppm or higher and oral exposures as low as 50 mg/kg/day (Chakrabarti and Tuchweber, 1988; Berman et al., 1995). Increased liver weight and other hepatic effects (e.g., hepatocellular hypertrophy) have been reported in rodents after an inhalation exposure of 1000 ppm and oral exposures of 1000–2479 mg/kg/day (Ramdhane et al., 2008; NTP, 1985). In rats, decreased fetal weight and incomplete skeletal ossification were reported after an inhalation exposure of 1800 ppm TCE from gestation days 0–20 (Dorfmueller et al., 1979). Dermal exposure to undiluted TCE caused erythema, edema, and increased epidermal thickness in guinea pigs (Anderson et al., 1986).

Chronic Effects

Cancer A large body of epidemiology data is available on TCE and possible cancer outcomes. For example, U.S. EPA

(Environmental Protection Agency) conducted a systematic review of 76 epidemiology studies on TCE and cancer (Chiu et al., 2013). Conclusions from reviews and meta-analyses of these data have varied widely, in part, due to differences in the qualitative evolution of the studies (e.g., strengths and weaknesses in exposure assessment or consideration of potential confounding factors) (see, e.g., Scott and Jinot, 2011; Kelsh et al., 2010; US EPA, 2011; Alexander et al., 2007). Modest increases in kidney cancer from high TCE exposure (mostly occupational) have received the most support generally with some, but lesser, support for non-Hodgkin lymphoma (NHL) and liver cancer because of issues of inconsistent findings, potential publication bias, weaker exposure-response results, and/or small numbers of cases. In experimental animals, it is well established that high doses of TCE in certain strains of rats and mice can cause a variety of cancers (Chiu et al., 2013; Jollow et al., 2009). The type and incidence of tumors depend on the species, strain, and sex under study (Jollow et al., 2009). Malignant liver tumor formation appears to be limited to Swiss and B6C3F1 mice and occur with greater frequency in males than females; numerous strains of rats have showed no elevated incidence of liver tumors after TCE exposure. Low incidence rates of kidney cancer occur in some strains of rats but not in mice or hamsters exposed chronically to high doses of TCE by inhalation or gavage. Lung tumors have been reported in mice but not in rats or hamsters and only after inhalation exposure. Although less well characterized and reported infrequently and/or inconsistently, TCE has been reported to induce lymphohematopoietic cancers in rats and mice and testicular tumors upon inhalation and ingestion in rats (Chiu et al., 2013).

Noncancer Based on the available epidemiology data and experimental and mechanistic studies, TCE poses potential noncancer toxicity to the central nervous system (CNS), kidney, liver, immune system, male reproductive system, and developing fetus. The evidence for TCE toxicity to the respiratory tract and female reproductive system is more limited (US EPA, 2011).

Human and animal studies have associated TCE exposure with effects on several neurological domains. The strongest neurological evidence of human toxicological hazard, based on human and experimental studies, is for changes in trigeminal nerve function or morphology and impairment of vestibular function (e.g., with symptoms such as headaches, dizziness, and nausea). Trigeminal nerve function has been recognized as a sensitive human neurological effect of TCE, with an inhalation lowest observed adverse effect level (LOAEL) of 14 ppm (adjusted to continuous exposure from mean cumulative exposure of 704 ppm-years) (Ruijten et al., 1991; US EPA, 2011). Less, more limited evidence exists for delayed motor function; changes in auditory, visual, and cognitive function or performance; and neurodevelopmental outcomes (US EPA, 2011).

Trichloroethylene causes nephrotoxicity in the form of tubular toxicity in male and female rats and mice following oral or inhalation exposure. Toxic nephrosis, for example, was identified in mice at a LOAEL of 360 mg/kg/day (adjusted for continuous exposure) (NCI, 1976, as cited in US EPA, 2011). There are few human data pertaining to TCE-related noncancer kidney toxicity; however, several available studies reported elevated excretion of urinary proteins, considered nonspecific markers of nephrotoxicity, among TCE-exposed subjects compared to unexposed controls (US EPA, 2011).

Effects of TCE on the liver in rodents include hepatomegaly, increased serum bile acids, small transient increases in deoxyribonucleic acid (DNA) synthesis, cytomegaly in the form of swollen or enlarged hepatocytes, increased nuclear size (probably reflecting polyploidization), and proliferation of peroxisomes. Mice appear to be more sensitive to these effects than other laboratory animal species. Hepatomegaly appears to be the most sensitive indicator of toxicity for the liver; Buben and O'Flaherty (1985) reported increased liver:body weight ratios at all tested doses in mice, ranging from 100 to 3200 mg/kg/day. There are a few human studies on liver toxicity and TCE exposure; some have reported TCE exposure to be associated with significant changes in serum liver function tests—used widely in clinical settings, in part, to identify patients with liver disease—and plasma or serum bile acids (US EPA, 2011).

Human and laboratory animal studies of TCE and immune-related effects provide evidence that TCE exposure increases the risk of autoimmune disease and a specific type of generalized hypersensitivity skin disorder, with more limited evidence for immunosuppression (Chiu et al., 2013). Available human studies do not provide adequate exposure information for dose-response analysis. Among the more sensitive immune-related effects in animals are a decrease in thymus weight and an increase in early markers for autoimmune disease at a LOAEL of 0.35 mg/kg/day TCE in mice (Keil et al., 2009, as cited in US EPA, 2011 and ATSDR, 2013).

A number of human and laboratory animal studies suggest that TCE exposure has the potential for male reproductive toxicity. Human studies have reported TCE exposure to be associated with increased sperm density and decreased sperm quality, altered sexual drive or function, or altered serum endocrine levels. For example, Chia et al. (1996, as cited in US EPA, 2011 and ATSDR, 2013) identified decreased normal sperm morphology and hyperzoospermia in an occupational study in which men using TCE for electronics degreasing had a mean TCE exposure of 29.6 ppm. Several laboratory animal studies that reported effects on sperm, libido/copulatory behavior, and serum hormone levels (US EPA, 2011) provide evidence of similar effects on male reproductive toxicity.

Congenital malformations—particularly cardiac defects—have been associated with exposures to TCE and/or its

metabolites, though these findings have been inconsistent in humans and rodents, and interpretation of these data have been controversial (NRC, 2006; Chiu et al., 2013). Other TCE-related developmental outcomes observed in humans and experimental animals include embryonic or fetal mortality, prenatal growth inhibition, and neurological and immunological functional deficits (Chiu et al., 2013). By far, the most sensitive developmental effect identified was heart malformations in the rat, with a LOAEL of 0.048 mg/kg/day TCE in drinking water (NOAEL of 0.00045 mg/kg/day) (Johnson et al., 2003). This study, however, and its use by U.S. EPA to support its noncancer reference values for TCE (see Section 3.2.3), has been criticized for having a number of limitations, such as certain study design flaws and absence of a dose-response relationship (e.g., Watson et al., 2006; Kimmel et al., 2010).

Agency Evaluations US EPA (2011) classified TCE as carcinogenic in humans by all routes of exposure based on what it characterized as convincing evidence of a causal association between TCE exposure in humans and kidney cancer. US EPA (2011) based its cancer risk estimation for TCE (both inhalation and oral) on human kidney cancer risks reported by Charbotel et al. (2006) and adjusted for potential risk for NHL and liver cancer. US EPA (2011) used linear low dose extrapolation to estimate the exposure-response relationship at low environmental exposure levels from higher occupational exposures; this was based on its conclusion that a mutagenic mode of action is operative for TCE-induced kidney tumors. The International Agency for Research on Cancer (IARC) classified TCE as carcinogenic to humans (Group 1) based on sufficient evidence in both humans and animals (Guha et al., 2012). The American Conference of Governmental Industrial Hygienists (ACGIH) (ACGIH, 2007) classifies TCE as an A2 suspected human carcinogen based on epidemiology studies of TCE.

US EPA's (2011) chronic oral reference dose (RfD) for TCE is 0.0005 mg/kg/day based on the critical effects of heart malformations (rats), adult immunological effects (mice), developmental immunotoxicity (mice), and toxic nephropathy (rats), all from oral studies. Its chronic inhalation reference concentration (RfC) is 0.0004 ppm (0.002 mg/m³) based on route-to-route extrapolated results from oral studies for the critical effects of heart malformations (rats) and immunotoxicity (mice). In general, the critical effects were found to be associated with the lowest TCE exposures; thus, reference values based on these effects are protective against other noncancer effects that occur at higher concentrations (US EPA, 2011). The Agency for Toxic Substances and Disease Registry (ATSDR) adopted US EPA's (2011) chronic RfD and RfC as its chronic oral and inhalation minimal risk levels (MRLs), respectively (ATSDR, 2013).

Mechanism(s) of Action

An understanding of TCE toxicokinetics is critical, for some effects, to both the qualitative and quantitative assessment of human health risks from TCE exposure, because specific metabolites or metabolic pathways are associated with a number of endpoints of observed toxicity (Chiu et al., 2009). Key scientific issues for characterizing these hazards include identifying the metabolites responsible for the effects, elucidating the mode of action, and understanding the relevance of animal data for humans (NRC, 2006). Metabolism of TCE occurs through two main irreversible pathways: oxidation and glutathione (GSH) conjugation (Chiu et al., 2013). Products of the initial oxidation or conjugation step are further metabolized to a number of other metabolites (US EPA, 2011; Chiu et al., 2009). Trichloroethylene liver effects are thought to result from oxidative metabolites, whereas kidney effects generally are associated with metabolites resulting from GSH conjugation (Chiu et al., 2013; Kim et al., 2009; Evans et al., 2009). The identity of TCE metabolites involved in the induction of other effects of TCE is less clear (Chiu et al., 2013). Oxidative metabolism is thought to predominate in the liver, especially after oral exposure and, to some degree, in the respiratory tract after inhalation exposure, especially in mice (Jollow et al., 2009). The primary metabolites of the oxidative pathway that are thought to be toxicologically active are chloral hydrate, trichloroacetic acid (TCA), and dichloroacetic acid (DCA) (Chiu et al., 2013). Mice, on an average, have a greater capacity to oxidize TCE than rats or humans (Chiu et al., 2009). A number of metabolic products can be formed in the conjugative pathway, including dichlorovinyl glutathione (DCVG), S-dichlorovinyl-L-cysteine (DCVC), and mercapturate N-acetyl dichlorovinyl cysteine (NAcDCVC) (Chiu et al., 2009). Estimates of the kinetics and relative extent of GSH conjugation in mice, rats, and humans are complex and uncertain (Kim et al., 2009; Hack et al., 2006; Chiu et al., 2009).

Trichloroethylene and many of its known metabolites have been studied to varying degrees for their genotoxic potential. US EPA (2011) concluded, based on positive genotoxicity data for TCE metabolites derived from GSH conjugation (in particular DCVC), that a mutagenic mode of action is operative in TCE-induced kidney tumors. There are differing opinions, however, with regard to this conclusion (e.g., Lock and Reed, 2006). US EPA (2011) found that data are insufficient to conclude that a mutagenic mode of action is operative in TCE-induced liver tumors.

The potential neurotoxic mechanisms of TCE were reviewed by Bale et al. (2011). In contrast to TCE metabolites being the active agent(s) for a number of endpoints, *in vitro* studies with TCE support the theory that the parent compound interacts with discrete targets in the brain to cause neurotoxicity. It is less clear if there are key metabolites that

are also involved in these changes. Based on animal toxicity and mechanistic studies, the authors suggest that TCE interacts directly with several different classes of neuronal receptors by generally inhibiting excitatory receptors/channels and potentiating the function of inhibitory receptors/channels. With regard to the trigeminal nerve effects of TCE, it has been hypothesized that interaction with sodium channels and the myelin sheath on peripheral neurons are the operative mechanisms. The authors suggest that there may be some similarities in neurological mechanisms of TCE between animals and humans, but they are difficult to ascertain given the limited mechanistic information in humans.

Chemical Pathology

A number of pathological changes have been observed in experimental animals after oral and inhalation exposure to TCE, including changes in the brain, kidney, liver, reproductive system, and developing organism. Some examples of these findings and the exposure levels at which they have occurred are presented below.

Several effects on brain pathology, including trigeminal nerve changes (e.g., changes in fiber diameter and myelin thickness) and decreased dopaminergic neurons in rats with subchronic exposures of 1000 mg/kg/day or more, have occurred in experimental animals after oral exposure (Barret et al., 1992).

Pathological changes in the kidney have been observed in studies of rodents following subchronic (≥ 737 mg/kg/day oral or ≥ 75 ppm inhalation) or chronic (≥ 500 – $1,100$ mg/kg-day oral) TCE exposures. These effects include karyomegaly (enlarged nuclei) in renal tubule epithelial cells, increased kidney weight, nephrosis, and cytomegaly (NTP, 1985; NTP, 1988; Kjellstrand et al., 1983).

Pathological changes in the liver have been reported in rodents after inhalation and oral exposure to TCE. Effects include slight hepatocellular necrosis, centrilobular hypertrophy, enlargement and loss of vacuolization in hepatocytes, and peroxisome proliferation, with effects at lower levels in mice (≥ 400 mg/kg/day oral or ≥ 75 ppm inhalation) (Ramdhane et al., 2008; Elcombe, 1985; Stott et al., 1982).

SOURCES OF EXPOSURE

Trichloroethylene is widely used as a degreasing agent, and it is a common environmental contaminant at Superfund sites and many industry and government facilities, including certain manufacturing operations (e.g., aircraft, spacecraft) (NRC, 2006). Most TCE used in the United States is released to the atmosphere, primarily from vapor-degreasing operations. Releases into the air also occur at treatment and

disposal facilities, water treatment facilities, and landfills (US EPA, 2011). It can be found in soils and surface water as a result of direct discharges and in groundwater due to leaching from disposal operations (NRC, 2006; US EPA, 2011). Other sources of TCE include a number of consumer products, such as adhesives, paint-stripping formulations, and varnishes (US EPA, 2011). Trichloroethylene has a multitude of past uses, such as in dry cleaning (discontinued by the mid-1950s); as a food extractant, such as in the decaffeination of coffee (U.S. EPA banned the use of TCE as a food additive in 1977); as a carrier solvent for the active ingredients of insecticides and fungicides; and as an analgesic and anesthetic (Bakke et al., 2007; US EPA, 2011). Releases of TCE from non-anthropogenic activities are negligible (US EPA, 2011).

Occupational

The majority of data regarding worker exposure to TCE derives from degreasing operations, which is the primary industrial use of TCE (Bakke et al., 2007). Occupational exposure to TCE also has been identified in silk screening, taxidermy, and electronics cleaning (US EPA, 2011). In combination with the vapor source, the size and ventilation of the workroom are the main determinants of exposure intensity (US EPA, 2011). Bakke et al. (2007) reported that the arithmetic mean of industrial hygiene measurements of TCE in a variety of industries with TCE sources across several decades (mostly the 1950s, 1960s, and 1980s) was 38.2 ppm (210 mg/m^3). The highest air levels were reported in vapor degreasing (arithmetic mean of 44.6 ppm [240 mg/m^3]). Based on the development of a database of occupational air measurement data covering the years 1940–1998, Hein et al. (2010) predicted arithmetic mean exposure intensity levels for TCE ranging from 0.21 to 3700 ppm (1.1–20,000 mg/m^3) with a median of 30 ppm (160 mg/m^3). Occupational exposure to TCE has likely declined since the 1950s and 1960s due to decreased usage, better release controls, and improvements in worker protection (US EPA, 2011).

Environmental

Because of the pervasiveness of TCE in the environment, most people are likely to have some exposure via one or more pathway such as inhalation of outdoor/indoor air, ingestion of drinking water, or ingestion of food (US EPA, 2011). A substantial amount of air and groundwater data have been collected; less has been collected from other media. TCE has been detected in indoor and outdoor air throughout the United States, with the highest atmospheric levels in areas concentrated with industry and population (US EPA, 2011). U.S. EPA reported that annual mean TCE concentrations in air at approximately 300 locations across the United States between 1998 and 2008 were between 0.01 and 0.3 parts per

billion (ppb) (US EPA, 2011b). Indoor air can become contaminated by vapor intrusion from contaminated groundwater, the presence of certain consumer products, and volatilization from contaminated water supplies (NRC, 2006). Trichloroethylene is the most frequently reported organic contaminant in groundwater; between 9 and 34% of the drinking water supply sources tested in the United States may have some TCE contamination, though generally at low levels (i.e., less than maximum contaminant levels) (NRC, 2006; US EPA, 2011). It also has been detected in a variety of foods and breast milk (NHANES III, 1997). Approximately 10% of nonoccupationally exposed persons in the United States have detectable levels of TCE in blood (US EPA, 2011).

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for TCE is 100 ppm as a time-weighted average (TWA), 200 ppm as a ceiling concentration, and 300 ppm as a maximum peak above the ceiling concentration (for 5 min in any 2-h period). The National Institute for Occupational Safety and Health (NIOSH) considers TCE to be a potential occupational carcinogen and recommends a recommended exposure limit (REL) of 2 ppm (as a 60-min ceiling) during the usage of TCE as an anesthetic agent and 25 ppm (as a 10-h TWA) during all other exposures (CDC, 2013). The ACGIH (2012) threshold limit value—time-weighted average (TLV—TWA) for TCE is 10 ppm (54 mg/m^3) to provide a margin of safety to minimize potential discomfort and subjective complaints (e.g., headache, dizziness, sleepiness, lack of coordination that may occur from prolonged exposure) and to prevent cognitive decrements and renal toxicity; its threshold limit value—short-term exposure limit (TLV—STEL) is 25 ppm (135 mg/m^3) to minimize the risk of anesthetic-like effects and irritation.

In addition to maintaining exposure at or below permissible limits, OSHA requires employers of workers occupationally exposed to TCE to protect employees through the use of engineering controls and proper work practices. NIOSH's (1988) occupational safety and health guideline for TCE states that workers using TCE as a cleaning solvent or degreaser should have local process enclosures (e.g., covers), local exhaust ventilation, and personal protective equipment (e.g., aprons, gloves, goggles, and respirators). NIOSH also notes that workers should be required to shower following a work shift, prior to putting on street clothes, and that clean work clothes should be provided daily. Workers not wearing protective equipment and clothing should be restricted from areas of spills or leaks until the completion of cleanup (NIOSH, 1988).

MEDICAL MANAGEMENT

For persons with TCE toxicity, the level of exposure either must be reduced (e.g., by removal from the contaminated environment) or the source must be eliminated. There is no antidote for TCE poisoning. Treatment consists of support for respiratory and cardiovascular functions (ATSDR, 2007, 2011). Victims exposed to TCE vapor only do not pose secondary contamination risks to rescuers. Victims whose clothing or skin is contaminated with liquid TCE can contaminate response personnel secondarily by direct contact or off-gassing of vapor. If TCE penetrates the clothes, they should be removed immediately and the exposed skin and hair should be flushed with water and washed with mild soap and water (ATSDR, 2011; NIOSH, 2010). If TCE gets into the eyes of workers, flush them immediately with plain water or saline for 15–20 min (ATSDR, 2011; NIOSH, 2010). In cases of ingestion, emesis should not be induced. Instead, a slurry of activated charcoal should be administered if the victim is alert, asymptomatic, and has a gag reflex. Although the efficacy of activated charcoal has not been demonstrated for TCE, it may be of assistance, particularly in cases of mixed ingestion (ATSDR, 2011). In cases of respiratory compromise, airway and respiration should be secured via endotracheal intubation. Patients who have bronchospasm may be treated with aerosolized bronchodilators. However, the use of sympathomimetic agents such as epinephrine and isoproterenol could precipitate fatal dysrhythmias and should be avoided (ATSDR, 2011).

The diagnosis of acute TCE toxicity is primarily clinical, based on symptoms of CNS disruption or respiratory distress. However, laboratory testing is useful for monitoring the patient and evaluating complications. Routine laboratory studies for all exposed patients include complete blood count (CBC) and glucose and electrolyte determinations. Additional studies for patients exposed to TCE include hepatic and renal function tests (ATSDR, 2011). Hospitalization should be considered for patients who have had significant inhalation exposure (e.g., with loss of consciousness) or ingested significant amounts of TCE. Development of cardiac dysrhythmia may be delayed for 12–24 h after exposure. Patients who have not experienced alterations in mental status or cardiac dysrhythmia or those who had mild symptoms initially and are asymptomatic 12–24 h later may be discharged. Neurologic examination for post-hypoxic injury is recommended in cases of severe exposure (ATSDR, 2011).

ACRYLONITRILE

JASON M. FRITZ AND APRIL M. LUKE

Target organ(s): CNS, respiratory system, eyes, skin, mucous membranes, reproductive system, alimentary canal

Occupational exposure limits: OSHA PEL: TWA 2 ppm (4.3 mg/m³), STEL: 10 ppm (22 mg/m³); NIOSH REL: 1 ppm (2.2 mg/m³), STEL: 10 ppm (22 mg/m³); ACGIH: TLV: 2 ppm (4.3 mg/m³)

Reference values: USEPA RfC: 0.002 mg/m³; USEPA oral cancer slope factor: 0.54 per mg/kg/day; USEPA inhalation unit risk: 0.068 per mg/m³ (1991); ATSDR acute oral MRL: 0.1 mg/kg/day; ATSDR chronic oral MRL: 0.04 mg/kg/day; ATSDR acute inhalation MRL: 0.2 mg/m³ (1990); CalEPA chronic inhalation REL: 0.005 mg/m³ (2001); CalEPA inhalation risk unit: 0.29 per mg/m³; CalEPA oral slope factor: 1 per mg/kg/day (2009).

Risk phrases: 45, 11, 23/24/25, 37/38, 41, 43, 51/53

May cause cancer; highly flammable; toxic by inhalation, in contact with skin, and if swallowed; irritating to respiratory system and skin; risk of serious damage to eyes; may cause sensitization by skin contact; toxic to aquatic organisms, may cause long-term adverse effects in the aquatic environment

Globally Harmonized System of Classification and Labeling of Chemicals (GHS, Rev.4):

Pictograms—

Signal word—danger

Hazard statements: H225, H301, H311, H315, H317, H318, H331, H335, H2250, H411

Highly flammable liquid and vapor; toxic if swallowed; toxic in contact with skin; causes skin irritation; may cause an allergic skin reaction; causes serious eye damage; toxic if inhaled; may cause respiratory irritation; may cause cancer; toxic to aquatic life with long-lasting effects.

Precautionary statements: P201, P210, P260, P280, P284, P302 + P350, P305 + P351 + P338, P310.

Obtain special instructions before use. Keep away from heat/sparks/open flames/hot surfaces. No smoking. Do not breathe dust/fume/gas/mist/vapors/spray. Wear protective gloves/eye protection/face protection. Wear respiratory protection. *If on skin:* Gently wash with plenty of soap and water. *If in eyes:* Rinse cautiously with water for several minutes. Remove contact lenses, if present and easy to do. Continue rinsing. Immediately call a *poison center* or doctor/physician.

BACKGROUND, USES, AND GENERAL SOURCES OF EXPOSURE

Acrylonitrile (AN; CASRN 107-13-1) is a three-carbon alkene with a nitrile substituent group on carbon 1. Synonyms for acrylonitrile include: acritet; acrylnitriil; acrylon; carbacryl; cyanoethene; cyanoethylene; Fumigrain; propenenitrile and 2-propenenitrile; Ventox; and vinyl cyanide. Acrylonitrile is regulated by the U.S. Environmental

Protection Agency (USEPA) under the Clean Air Act as a hazardous air pollutant (USEPA, 1995, 2000), and occupational exposure limits have been promulgated by various health agencies (see Section "Industrial Hygiene").

Acrylonitrile is used in the production of acrylic (>85% AN) and modacrylic fibers (35–85% AN), which are both primarily used to manufacture clothing, carpet, and upholstery (IARC, 1999). Acrylonitrile is also extensively utilized to produce thermoplastics, created by mass polymerization or batch emulsion (acrylonitrile-butadiene styrene [ABS] and acrylonitrile-styrene trimer [SAN] resins), and the adiponitrile and nitrile rubbers used to create nylon. In industrial processes, acrylonitrile is an intermediate in the production of chemicals such as acrylamide, and in the synthesis of antioxidants, pharmaceuticals, dyes, and carbon fibers. Acrylonitrile is also used in surface coatings and adhesives, as well as for processes requiring the introduction of a cyanoethyl group into a molecule (HSDB, 2013). Acrylonitrile is one of the volatile organic compounds (VOC) emitted by biomass combustion (Christian et al., 2004; Warneke et al., 2011; Yokelson et al., 2007), is also present in cigarette smoke (IARC, 1999), and is found in medical equipment such as dialysis tubing (Mulvihill et al., 1992) and nitrile-butadiene rubber gloves (Wakui et al., 2001). Historically, consumer products made from acrylonitrile-based thermoplastics have included piping, refrigerator liners, carpet, automotive panels, desk-top telephones, luggage, children's building blocks and other toys, mobile homes, and housewares (ATSDR, 1990; USEPA, 1994a, 1994b). Acrylonitrile can be released by off-gassing from thermoplastics, which liberate small quantities of acrylonitrile monomer from ABS plastic in enclosed areas (WHO, 2002). Thermoplastics, including ABS, are also common feedstock used in the newly emerging field of three-dimensional printing, which is currently being employed in a variety of industrial, consumer, and biomedical research applications (Nguyen et al., 2012). Exposure could also occur from migration of residual monomer in polymeric products via contact with food or water, and was previously identified in margarine (ATSDR, 1990). However, acrylonitrile leaching from food or beverage containers is unlikely to be a significant source of exposure as modern food packaging is typically not made with acrylonitrile-based plastics, and acrylonitrile was not detected in U.S. foods tested from 1991 to 2004 (FDA, 2006). Acrylonitrile-containing fumigants were used for stored grain (fumigrain) up until the 1970s, and have been historically used as residential de-lousing agents (Ventox) (ATSDR, 1990; Grunske, 1949).

Acrylonitrile is a high production volume chemical. From 1987 to 1995 annual production volume increased from 2 to 3 billion pounds in the United States alone (ATSDR, 1990; NTP, 2011; WHO, 2002), while 2012 production levels are in the range of 3–5 billion pounds (USEPA, 2012).

TABLE 73.1 Chemical and Physical Properties of Acrylonitrile

Characteristic	Information
Chemical formula	C ₃ H ₃ N
Molecular weight	53.063
Melting point	-83 °C
Boiling point	77.4 °C
Density	0.806 g/ml at 20 °C
Log octanol/water partition coefficient (log K _{OW} , mean [range])	0.25 [-0.92–1.2]
Log organic carbon/water partition coefficient (log K _{OC})	-0.07
Vapor pressure	100 mmHg at 22.8 °C
Henry's law constant	8.8 × 10 ⁻⁵ atm·m ³ /mol
Water solubility	7.9 × 10 ⁴ mg/l
Flashpoint	-1 °C (closed cap)
Explosion limits	3–17%
Odor threshold	47 mg/m ³ (air)
Conversion factors	1 ppm = 2.17 mg/m ³ 1 mg/m ³ = 0.46 ppm

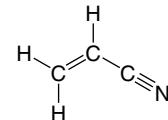

FIGURE 73.1 Chemical structure of acrylonitrile.

PHYSICAL AND CHEMICAL PROPERTIES

Acrylonitrile is a colorless liquid with a pungent onion- or garlic-like odor. It is soluble in water and miscible with most organic solvents. At room temperature, acrylonitrile is flammable and volatile, with cyanide gas formed explosively upon vapor reaction. The chemical structure of acrylonitrile is diagrammed in Figure 73.1, and select chemical and physical properties are presented in Table 73.1 (ATSDR, 1990; IPCS, 1983).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Monitoring data for acrylonitrile in water and soil are limited. Acrylonitrile is soluble in water but will evaporate rapidly. In the atmosphere, acrylonitrile has a half-life of 55–96 h (range = 4–198) and is readily oxidized to formaldehyde, formic acid, formyl cyanide, and hydrogen cyanide. In soil, acrylonitrile may degrade due to microbe metabolism, although this occurs more slowly, with a soil half-life of 170 h (range = 30–552); bacterial decomposition in water occurs at a rate similar to that in soil, in the absence of evaporation. In the absence of bacterial metabolism or

evaporation, acrylonitrile has a half-life of >13 years. Acrylonitrile is not anticipated to bioaccumulate in either plants or animals, given the mean log K_{ow} of 0.25 (range -0.92 to 1.2), and log bioconcentration factor (log BCF) of 0 estimated from water solubility (USEPA, 1994b; WHO, 2002).

ECOTOXICOLOGY

The calculated 96-h acute toxicity limit (96-h LC₅₀) for fish is 9.3–18.1 mg/l; the 48 h value (48 h LC₅₀) for aquatic invertebrates is 7.6–8.7 mg/l. The chronic (30 day) median tolerance limit (TLm) for fathead minnows (*Pimephales promelas*), bluegill sunfish (*Lepomis macrochirus*) and guppies (*Lebistes reticulatus*) is 2.6 mg/l; the corresponding 21-day tolerance limit for reproduction in the freshwater water flea (*Daphnia magna*) is 0.71 mg/l (Hadley, 1994; USEPA, 2000). The 96 h growth inhibiting concentration (96 h EC₅₀) for duckweed (*Lemna minor*), a freshwater aquatic plant, is 1.4 mg/l (USEPA, 1994b; WHO, 2002).

MAMMALIAN TOXICOLOGY AND CHEMICAL PATHOLOGY

Acute Effects

In industrial settings, acute exposure to acrylonitrile occurs through dermal or inhalation routes, and such exposures have been associated with human health effects. Reports in the 1940s of workers in synthetic rubber manufacturing plants, who were exposed to acrylonitrile at concentrations between 16 and 100 parts per million (ppm) (34–217 mg/m³) for 20–45 min, included complaints of dull headache, fullness in the chest, irritation of mucous membranes (e.g., eye, nose, throat), mild jaundice associated with low grade anemia, nausea, vomiting, fatigue, and subjective feelings of apprehension and nervous irritability (Wilson et al., 1948). A case report of a man accidentally sprayed with acrylonitrile in the face, eyes, and body reported symptoms of dizziness, flushing, and nausea with vomiting as well as erythema, mild conjunctivitis, and tachycardia (Vogel and Kirkendall, 1984). Chen et al. (1999) reported on 144 acute acrylonitrile poisoning cases that occurred in industrial settings in China between 1977 and 1994. Although reliable data on exposure levels were limited, 60 cases involved exposures between 18 and 258 ppm (39–560 mg/m³) and the remaining cases may have involved exposures >461 ppm (1000 mg/m³). Symptoms of dizziness, headache, feebleness, and chest tightness were reported in all cases. Other frequently reported symptoms included dyspnea, abdominal pain, pallor, congestion of pharynx, vomiting, and sore throat. Dermal exposure has been associated with skin irritation, erythema, painful itching, blistering, and allergic dermatitis (Bakker et al., 1991; Wilson et al., 1948; Zeller et al., 1969).

Chronic Effects

Noncancer

Humans Most of the information on chronic acrylonitrile exposure comes from occupational studies of Chinese and Japanese workers. Increases in subjective symptoms, deficits in tests of neurobehavior, and increased adverse reproductive outcomes have been reported with chronic acrylonitrile exposure in occupational settings.

Occupational studies from chemical factory workers in China and Japan reported an increase in the prevalence of subjective symptoms in acrylonitrile-exposed workers (Chen et al., 2000; Dong et al., 2000; Kaneko and Omae, 1992; Muto et al., 1992). A broad range of subjective symptoms were reported. General information on the study populations and their exposures from representative occupational studies are listed in Table 73.2.

Neurobehavioral performance was evaluated in workers from the acrylonitrile-monomer department or the acrylic fibers department of a Chinese plant using a WHO-recommended neurobehavioral core test battery (NCTB) (Rongzhu et al., 2005). Investigators reported significant deficits in tests of negative mood (e.g., anger, confusion, depression, fatigue, and tension), attention and response speed, auditory memory, and motor steadiness with acrylonitrile exposure. Significant effects were not observed on scores of manual dexterity or perceptual motor speed. Short-term area sampling indicated a geometric mean acrylonitrile concentration of 0.11 ppm (0.2 mg/m³) for the monomer department and 0.91 ppm (2 mg/m³) for the acrylic fibers department. A cross-sectional health questionnaire study of Japanese acrylic fiber workers reported an increased prevalence of neurosis in acrylonitrile-exposed workers (using the Japanese version of the Cornell Medical index), although the increase was not statistically significant compared to unexposed workers (Kaneko and Omae, 1992). An average employment duration of the exposed workers was 5.6–8.6 years and exposure concentrations ranged from 1.8 ppm (4 mg/m³) to 14.1 ppm (31 mg/m³).

The following reproductive effects have been noted among female acrylonitrile workers: total birth defects, still births, premature delivery, pregnancy complications, and sterility (Collins et al., 2003). Increased incidences of adverse reproductive outcomes (e.g., stillbirths, spontaneous abortions, birth defects, sterility) were also reported in female spouses of male acrylonitrile workers. Reported area measurements of acrylonitrile from these studies ranged from 0.4 ppm (0.9 mg/m³) to 42.9 ppm (93 mg/m³); personal sample measurements were not available. Xu et al. (2003) reported decreased sperm count and significant increase in DNA damage and/or aneuploidy in sperm from male workers exposed to a mean concentration of 0.37 ppm (0.8 mg/m³) for an average duration of 2.8 years.

TABLE 73.2 Subjective Symptoms Reported in Occupational Studies

Symptoms	Exposure	Study Design and Population
Headache, dizziness, poor memory, choking feeling in chest, loss of appetite	Area samples; average concentration reported: 0.48 ppm (1 mg/m ³)	Cross-sectional study; Chinese male and female workers from an acrylic fiber factory with an average employment duration of 13 years (Chen et al., 2000)
Headaches, dizziness, choking in the chest	Area samples; a 3-year range of concentrations reported: 0.92 ppm (2 mg/m ³)–1.3 ppm (2.8 mg/m ³)	Occupational survey; Chinese male workers from a chemical fiber factory; no information on employment duration was available (Dong et al., 2000)
Headaches, tongue trouble, choking lump in chest, fatigue, general malaise, heavy arms, heavy sweating	Area samples; factories were categorized based on concentrations, category means reported: Low—1.8 ppm (4 mg/m ³) Medium—7.4 ppm (16 mg/m ³) High—14.1 ppm (31 mg/m ³)	Cross-sectional study; Japanese male workers from seven acrylic fiber factories with employment duration ranging from 5.6 to 8.6 years (Kaneko and Omae, 1992)
Heaviness of the stomach, decreased libido, poor memory, irritability	Personal samples; factories were categorized based on concentrations, category means reported: Low—0.19 ppm (0.4 mg/m ³) High—1.13 ppm (2.5 mg/m ³)	Cross-sectional study; Japanese male workers from seven acrylic fiber factories with an average employment duration 17 years (Muto et al., 1992)

Rodents Neurological and reproductive effects have also been observed in rodent studies. Decrement in peripheral nerve function in male Sprague-Dawley rats were associated with inhalation exposure to acrylonitrile at concentrations $\geq 54 \text{ mg/m}^3$ for 24 weeks (Gagnaire et al., 1998). A concentration-dependent deficit in sensory conduction velocity and amplitude of tail nerve sensory action potential were reported. Transient deficits were also observed in tail nerve motor conduction velocity. Furthermore, these effects were consistent with results reported following 12 weeks of oral (gavage) exposure to $> 12.5 \text{ mg/kg/day}$ (Gagnaire et al., 1998).

Measures of reproductive performance (e.g., mating index, fertility index, number of implantation sites per dam, number of resorptions per litter) in rats were largely unaffected by acrylonitrile exposure in two multigenerational reproductive toxicity studies (Friedman and Beliles, 2002; Nemec et al., 2008). Female B6C3F₁ mice exposed to $\geq 10 \text{ mg/kg/day}$ acrylonitrile for 2 years were reported to have an increase in ovarian atrophy and cysts compared to controls (Ghanayem et al., 2002; NTP, 2001). Degenerative changes of the seminiferous tubules associated with a decrease in sperm count were reported in male CD-1 mice exposed to 10 mg/kg/day for 60 days (Tandon et al., 1988). These same effects were not observed in male B6C3F₁ mice exposed to $\geq 5 \text{ mg/kg/day}$ acrylonitrile for 14 weeks or 2 years (Ghanayem et al., 2002; NTP, 2001). Increased malformations (e.g., short tail, short trunk, miss vertebrae) were observed in fetuses of female Sprague-Dawley rats exposed to maternally toxic levels of acrylonitrile by gavage or inhalation (i.e., 65 mg/kg/day and 174 mg/m³) on GD 6–15 (Murray et al., 1978). However, similar malformations were not reported in a separate study where female Sprague-Dawley rats were exposed to acrylonitrile concentrations up to 217 mg/m³ on GD 6–20 (Saillenfait et al., 1993).

Carcinogenicity

Humans The most informative epidemiologic literature pertaining to human cancer risk consists of cohorts from the United States, U.K., Germany, and the Netherlands (Benn and Osborne, 1998; Blair et al., 1998; Swaen et al., 2004; Symons et al., 2008; Thiess et al., 1980), as well a European case-control study (Scélo et al., 2004); together, these reports follow the mortality experience of over 35,000 workers. The results of these and other cohort studies suggest that the association between occupational acrylonitrile exposure and lung cancer mortality is not strong, and statistically significant associations are not consistently evident (IARC, 1999). Cancer of the respiratory system is the endpoint most frequently evaluated as possibly resulting from occupational exposure to acrylonitrile; more specific information regarding lung cancer histological subtype (i.e., small-cell versus non-small cell) is not available. Less information is available relating acrylonitrile exposure to mortality from other cancer types due to the small number of site-specific cancer deaths in individual reports. A meta-analysis of brain cancer incidence from 12 cohort studies found no increased risk in human workers exposed to acrylonitrile (Collins and Strother, 1999).

The U.S. National Cancer Institute (NCI) performed an epidemiology study with the largest population (Blair et al., 1998), although at time of follow-up this cohort was still young (median age 48 years, mean follow-up of 21 years), and had experienced few cancer deaths (88% overall survival). In this 8-plant cohort study that followed over 25,000 acrylonitrile workers, there was a twofold increased risk of dying from lung cancer (relative risk: 2.1, 95% confidence interval (CI) 1.2–3.8), among those with longest exposure duration (≥ 20 years) and highest exposure levels ($\geq 8 \text{ ppm-years}$). The positive confounding effect of smoking on lung

cancer incidence was ruled out using an internal control group of unexposed workers (Blair et al., 1998). While workers in two middle exposure and duration groups (11–19 years since first exposure, exposed to 0.13–0.57 or 0.57–1.5 ppm-years) also experienced a twofold increased lung cancer risk, no trend was apparent across the quintiles of exposure. Despite an association with lung cancer in the highest exposure/longest duration group, no significant association was reported with continuous exposure metrics, consistent with later re-evaluations by other investigators (Marsh et al., 2001; Starr et al., 2004). Smaller cohorts from the U.K. (~2700 workers; Benn and Osborne (1998)) and Germany (~1500 workers; Thiess et al. (1980)) also reported increased lung cancer mortality by stratified analysis, but no specific exposure monitoring was performed, and the possibility of confounding by smoking or exposure to other chemicals was not addressed. A multi-industry case-control study of 3000 lung cancer cases also found that European lung cancer patients were twice as likely to have had occupational acrylonitrile exposure versus controls (odds ratio: 2.2, 95% CI 1.1–4.4), an association that remained even after adjusting for several confounding factors such as smoking or exposure to other potential carcinogens (Scélo et al., 2004). Conversely, Dutch (~2800 workers; Swaen et al. (2004)) and other U.S. cohorts (~2500 workers; Symons et al. (2008)) with 30–40 years mean follow-up reported no significant association between lung cancer mortality and acrylonitrile exposure by any metric at exposures up to 31.5 ppm-years, an exposure level equal to or greater than that experienced by the NCI cohort (Blair et al., 1998).

Rodents The most informative experimental literature pertaining to cancer hazard consists of 2-year rodent bioassays performed in Sprague-Dawley (Johannsen and Levinskas, 2002a; Maltoni et al., 1988; Quast, 2002; Quast et al., 1980) and F344 rats (Bigner et al., 1986; Johannsen and Levinskas, 2002b), as well as B6C3F₁ mice (Ghanayem et al., 2002; NTP, 2001). Acrylonitrile exposure consistently induced more malignant epithelial tumors (i.e., carcinomas) at multiple tissue sites in Sprague-Dawley rats of both sexes following chronic oral or inhalation exposure, as well as in F344 rats of both sexes following chronic oral administration (IARC, 1999; NTP, 2011). Combining results across several studies, carcinogenesis in Sprague-Dawley rats has been evaluated following inhalation exposure to 43–174 mg/m³ (6 h/day, 5 days/week for 2 years), or oral administration (primarily via drinking water) of 0.1–22 mg acrylonitrile/kg/day (7 days/week for 2 years); cancer induction in F344 rats has also been evaluated following similar drinking water concentrations.

Male and female rats of both strains developed significantly more central nervous system (CNS) tumors following chronic oral exposure to acrylonitrile at ≥ 3 mg/kg/day (Bigner et al., 1986; Johannsen and Levinskas, 2002a, 2002b; Quast, 2002), or inhalation exposure at ≥ 43 mg/m³

(Maltoni et al., 1988; Quast et al., 1980) when compared with controls. The CNS tumors were primarily located in the cerebral cortex, and also involved the brain stem, cerebellum, and spinal cord (Bigner et al., 1986; Quast, 2002; Quast et al., 1980). While these tumors were frequently characterized as astrocytomas, recent evaluations of immune cell surface marker expression suggest that these tumors may arise from or involve heterotypic cell fusion with brain microglia and/or macrophage cells, and thus, may be more accurately classified as malignant microgliomas (Kolenda-Roberts et al., 2013; Nagatani et al., 2009). In fact, gliosis in the brain with or without perivascular cuffing was also reported in rats at these exposure levels (Quast, 2002; Quast et al., 1980). A histogenic origin similar to this may contribute to mouse CNS tumors (Huysentruyt and Seyfried, 2010) and human glioblastoma multiforme as well (Pawelek and Chakraborty, 2008; Zheng et al., 2012).

The National Toxicology Program (NTP) conducted an evaluation of chronic toxicity and carcinogenesis in B6C3F₁ mice of both sexes exposed to acrylonitrile via gavage at 2.5, 10, or 20 mg/kg/day (Ghanayem et al., 2002; NTP, 2001), and concluded that there was “clear evidence of carcinogenic activity” based on treatment-related increases in forestomach and harderian gland tumor incidence in both sexes. While acrylonitrile exposure induced tumorigenesis in multiple organs in both rats and mice, the only sensitive tissue common to both rodent species was the forestomach. Increased squamous cell papilloma or carcinoma incidence was observed in conjunction with increased forestomach hyperplasia following oral administration in Sprague-Dawley and F344 rats, as well as in B6C3F₁ mice. While the extent of forestomach tumor induction was similar between Sprague-Dawley rats and B6C3F₁ mice administered ≥ 10 mg/kg/day, the hyperplastic response was diminished in mice compared to the robust hyperplasia induced in rats (Ghanayem et al., 2002; Johannsen and Levinskas, 2002a; NTP, 2001; Quast, 2002).

Acrylonitrile exposure induces adenoma and carcinoma formation in the harderian gland of mice at ≥ 3 mg/kg/day and the Zymbal gland of rats at ≥ 1 (F344) or 5 (Sprague-Dawley) mg/kg/day. Papillomas or carcinomas of the tongue and intestinal carcinomas were reported in both male and female Sprague-Dawley rats orally exposed to ≥ 10 mg/kg/day and males exposed via inhalation to 174 mg/m³. In female Sprague-Dawley rats, the incidence of benign (adenomas, fibromas, fibroadenomas, or adenofibromas) and malignant mammary gland tumors was not consistently elevated when combined; when considered separately, however, malignant carcinoma incidence was elevated following acrylonitrile exposure (Johannsen and Levinskas, 2002a, 2002b; Quast, 2002; Quast et al., 1980). In female mice, the incidence of benign or malignant granulosa cell tumors increased slightly and only at 10 mg/kg/day, an effect which may have been treatment related (Ghanayem et al., 2002; NTP, 2001).

While lung cancer has been associated with acrylonitrile exposure in some human workers, the evidence for acrylonitrile-induced lung tumors in rodents is more limited. Acrylonitrile does not induce lung tumors in rats. In female mice, acrylonitrile induced twice as many lung adenomas or carcinomas when administered at 10 mg/kg/day versus controls (Ghanayem et al., 2002; NTP, 2001). Although lung tumor incidence was not statistically significantly elevated at the highest dose evaluated, a significant dose-response trend ($p=0.029$) was observed (Ghanayem et al., 2002; NTP, 2001). Lung tumor incidence was not significantly elevated in male mice at any dose evaluated, and the incidence of non-neoplastic lung lesions was not elevated in either sex.

Inhalation exposure has only been evaluated in rats, where carcinomas of the nasal turbinate epithelium were observed in two female Sprague-Dawley rats exposed to 174 mg/m³, and were not observed in rats administered acrylonitrile via drinking water at any dose (Quast, 2002; Quast et al., 1980). The incidence of inflammatory or degenerative lesions of the nasal epithelium (e.g., respiratory epithelial hyperplasia, squamous metaplasia, erosion of the mucous lining) was also elevated in both male and female rats exposed to ≥ 43 mg/m³, while similar lesions were not induced following oral exposure (Johannsen and Levinskas, 2002a, 2002b; Nemec et al., 2008). See Table 73.3 for an overview of

rodent tumorigenesis as a function of species, strain, sex, and acrylonitrile exposure level.

Some evidence suggests an association between *in utero* exposure and increased susceptibility to acrylonitrile-induced tumor incidence in Sprague-Dawley rats. Lifetime inhalation exposure to 130 mg/m³ acrylonitrile beginning *in utero* at GD12 increased CNS tumor incidence in female offspring when compared to adult dams (Maltoni et al., 1988). A similar observation regarding increased CNS and Zymbal gland incidence was reported in female pups exposed to acrylonitrile trans-placentally *in utero* throughout gestation via orally exposed dams; both dams exposed as adults and *in utero*-exposed pups were orally administered 40 mg/kg/day acrylonitrile for up to 11 months (Friedman and Beliles, 2002).

Hypothesized Modes of Action

Acrylonitrile can be oxidized via cytochrome P450 2E1 (CYP2E1) to 2-cyanoethylene oxide, which can be hydrolyzed to cyanide as one of several possible downstream products of eukaryotic metabolism. Alternatively, glutathione conjugation or sulphydryl reaction with the parent acrylonitrile compound will circumvent this metabolic route (NTP, 2001; Thier et al., 2000). Cyanide can be detected

TABLE 73.3 Rodent Tissue Tumorigenesis as a Function of Acrylonitrile Exposure

Oral Administration (mg/kg/day) ^a

^aDoses in drinking water converted to mg/kg/day by study authors or using study-reported mean rat weights, when presented. Daily intake doses are approximate as results are combined from several studies across multiple investigators; reported daily doses were generally $\pm 20\%$ of presented values. Treatment was administered 7 day/week for approximately 2 years. Empty fields represent exposure levels not evaluated; fields with “—” represent exposures evaluated that failed to elicit treatment-related tumorigenesis by pair-wise comparison as reported by study authors.

^bMale = M, female = F.

^cTissues listed with statistically significantly elevated tumor incidence following acrylonitrile exposure, or otherwise described as biologically relevant and treatment-related by study authors. Abbreviated as follows: central nervous system (cn), mammary gland carcinoma (mg), zymbal gland (zg), forestomach (fs), tongue (tg), non-forestomach gastrointestinal tract (gi), harderian gland (hg), lung (lu), ovaries (ov), and nasal turbinete carcinoma (nc). In high-dose groups, tissue abbreviations in *italics* represent tumor incidences that were elevated above controls but not in a statistically significant manner, possibly due to higher mortality rate observed.

^dRodents were exposed for approximately 6 h/day, 5 days/week for 2 years or throughout natural lifespan.

^eIncludes data for pups exposed starting from GD12 *in utero*, and continued throughout natural lifespan; adult-only exposed males or nulliparous females were not evaluated.

in the blood and tissues of rodents experimentally administered acrylonitrile, and in the blood and urine of workers with reported dermal or inhalation acrylonitrile exposure (IARC, 1999; Kedderis et al., 1993; Major et al., 1998; Thier et al., 1999). Consistent with this observed cyanide release *in vivo*, acute exposure to acrylonitrile when used as a residential fumigant resulted in classic symptoms of cyanosis, leading to convulsions and death in exposed children (Grunskie, 1949). In adults, acrylonitrile intoxication resulting from accidental overexposure can be attenuated by rapid administration of N-acetylcysteine with sodium thiosulfate, highlighting the importance of cysteine conjugation in acrylonitrile detoxification (Thier et al., 1999).

While conjugation with the free sulfhydryl groups present in therapeutic interventions can alleviate acrylonitrile toxicity by preventing cyanide generation, direct reactivity with endogenous substrates, such as reduced thiol groups in cellular proteins, contributes to the pathology observed in laboratory animals acutely exposed to lethal acrylonitrile concentrations. Seizures following initial exposure to high acrylonitrile levels were possibly mediated by cyanide release, leading to inhibition of blood oxygenation, oxidative metabolism, and mitochondrial respiration. However, the severe clonic convulsions preceding death were more likely due to acrylonitrile-protein adduction versus cyanide effects (Benz and Nerland, 2005). Brain ATP levels were not significantly decreased in rats administered an acutely toxic acrylonitrile dose, suggesting that death did not result from acute inhibition of brain metabolic activity (Campian and Benz, 2008). Furthermore, inhibiting metabolism of acrylonitrile to 2-cyanoethylene oxide by blocking CYP2E1 activity did not prevent the death of rats following acute high dose acrylonitrile administration, suggesting that acrylonitrile adduction of blood hemoglobin or other proteins may drive acute lethality (Benz and Nerland, 2005; Benz et al., 1997). Acrylonitrile exposure can be monitored by evaluating the blood levels of several such adduct species, including *N*-(2-cyanoethyl) valine-hemoglobin (Benz et al., 1997; Thier et al., 2002).

Acrylonitrile exhibits genotoxic potential and directly alkylates DNA in biochemical assays (Solomon and Segal, 1985), processes that may play a role in the mode of action for acrylonitrile carcinogenicity. However, a consistent mutagenic response in bacterial or mammalian bioassays is only observed in the presence of cytochrome P450 activity, suggesting that oxidative metabolism is a required step in acrylonitrile-induced carcinogenesis. Following bioactivation, acrylonitrile is mutagenic in *Escherichia coli* or *Salmonella* systems sensitive to point mutations, as well as in yeast and mammalian bioassays evaluating clastogenic or aneuploid endpoints *in vitro* (IARC, 1999); forward mutations are induced in human and rodent lymphocytes *in vitro*, and likewise in mouse splenocytes *in vivo* (Ghanayem and Hoffler, 2007). Induction of chromosomal aberrations (CA), sister-chromatid exchanges (SCE) and micronuclei

(MN) in rodent cells is less consistently observed *in vivo*, with changes of low magnitude reported either as negative (IARC, 1999; NTP, 2011), inconclusive (Morita et al., 1997), or positive (Fahmy, 1999; Wakata et al., 1998). Early evaluations of CAs and SCEs in acrylonitrile-exposed workers were similarly negative (Thiess and Fleig, 1978) or inconclusive (Borba et al., 1996), while more recent examinations report some MN induction in buccal mucosa and peripheral blood cells (Fan et al., 2006), and sperm aneuploidy detected by fluorescent *in situ* hybridization (Xu et al., 2003). In addition to genotoxicity, acrylonitrile exhibits the potential to induce oxidative stress in various cell types *in vitro* (Esmat et al., 2007; Jacob and Ahmed, 2003; Kamendulis et al., 1999), and in the CNS of rats *in vivo* (Whysner et al., 1998). Furthermore, Pu et al. (2009) reported increased levels of oxidative DNA damage in the brains of rats that correlated with the increased rat brain tumor incidence previously observed by Quast (2002) following chronic acrylonitrile exposure at similar doses.

Although acrylonitrile (or bioactive metabolites) adducts proteins, potentially suppresses both oxygen transport to and utilization in respiring tissues, displays genotoxic potential in a variety of assays and rodent tissues, and induces DNA oxidation in the rodent CNS, no comprehensive toxicity pathway has been established for any of the cancer or noncancer health effects associated with chronic acrylonitrile exposure.

POTENTIAL EXPOSURES

Historically, all environmental exposures were thought to be the result of anthropogenic release into air, water, land or groundwater, as there are no known chemical reactions that could lead to *in situ* acrylonitrile formation in the atmosphere (Grosjean, 1990). More recently, however, acrylonitrile has been detected in the smoke plume generated from biomass combustion in both controlled laboratory burns of North American biomass samples (Christian et al., 2004; Warneke et al., 2011), and South American Amazon rainforest fire emissions monitored by aircraft-mounted instrumentation (Yokelson et al., 2007), suggesting that acrylonitrile is a byproduct of natural biomass combustion. Acrylonitrile is rapidly absorbed into human systemic circulation following ingestion, inhalation, or dermal contact (IARC, 1999; WHO, 2002).

General Population

For the general public, air is likely to be the principal medium of acrylonitrile exposure, although exposure to low levels of acrylonitrile could result from direct contact with acrylic products (ATSDR, 1990; WHO, 2002). Inhalation exposure to acrylonitrile is most likely to occur among members of the

general population living in the vicinity of regulated emission sources such as acrylic fiber or chemical manufacturing plants, waste sites (ATSDR, 1990), downwind of rubber production facilities (WHO, 2002), or near major populations centers (USEPA, 1994b, 2005), although the specific emission sources that contribute to urban acrylonitrile levels remain unclear. In addition to anthropogenic sources, smoke generated by combustion of plant biomass (e.g., forest, brush, or grass fires) contains numerous VOCs, including acrylonitrile (Christian et al., 2004; Warneke et al., 2011), which has a sufficiently long half-life in the atmosphere such that it could be dispersed with other combustion products as dictated by prevailing weather conditions, and could contribute to exposure in both urban and rural populations (Karl et al., 2003). Smokers are further exposed to acrylonitrile that is present in the vapor phase of sidestream smoke at 99 µg/U.S. cigarette (Miller et al., 1998) and mainstream smoke at a concentration of 3–19 µg/cigarette, depending on country of origin, brand, and nicotine yield (IARC, 1999; Laugesen and Fowles, 2005). Consequently, indoor air in the residences of smokers could be another source of potential exposure (to both smokers and nonsmokers), as acrylonitrile levels were reported to be 0.5–1.2 µg/m³, similar to or higher than the U.S. mean urban ambient air levels of 0.7 µg/m³, and several orders of magnitude higher than the nationwide mean estimates of 0.001 µg/m³ (Kelly et al., 1993; Nazaroff and Singer, 2004; USEPA, 1996, 2005). Fetal exposure in any environment could occur through transplacental absorption, which has been reported in rodents and observed in pregnant human smokers (Tavares et al., 1996). Precise environmental acrylonitrile concentrations are often difficult to ascertain with a high degree of certainty, as measurements are frequently below the detection level achieved by current technology (McCarthy et al., 2009; Yokelson et al., 2007).

Occupational

Inhalation exposure to acrylonitrile may occur during its manufacture and production and in factories where it is

used to create other products, where exposure levels can be the highest (ATSDR, 1990; WHO, 2002). Occupational levels of acrylonitrile exposure are likely to be several orders of magnitude greater than those experienced by the general population, as typical workplace air concentrations are reported to range from 0.1 to 4 mg/m³ (ATSDR, 1990; IARC, 1999). Occupations with potential for exposure include acrylic resin, rubber, synthetic fiber, and textile manufacturers; synthetic organic chemists; and pesticide workers. The primary routes of acrylonitrile exposure in these and other occupational environments are inhalation and possibly dermal. From 1983 to 1996 the estimated number of U.S. workers potentially exposed to acrylonitrile increased by more than 50%, from 51,000 to 80,000, corresponding with increased acrylonitrile production and consumption during the same time frame (Boiano and Hull, 2001; NIOSH, 1990).

INDUSTRIAL HYGIENE

The American Conference of Governmental Industrial Hygienists (ACGIH) classifies acrylonitrile as a class A3 carcinogen (confirmed animal carcinogen with unknown relevance to humans) (ACGIH, 2001). The National Institute of Occupational Safety and Health (NIOSH) recommends that acrylonitrile be controlled and handled as a potential human carcinogen (NIOSH, 1988). Table 73.4 lists the permissible and recommended exposure limits for acrylonitrile.

The Occupational Safety and Health Administration (OSHA) recommends that engineering and workplace controls to be put into effect to limit employee exposure to acrylonitrile, and when these controls are insufficient to reduce exposure to or below the permissible exposure limit (PEL), employees must be supplied with respiratory protection. Recommendations on respiratory protection for workers exposed to acrylonitrile are listed in Table 73.5.

TABLE 73.4 Permissible and Recommended Occupational Exposure Limits for Acrylonitrile

Organization	Exposure Limit	Concentration	Exposure Period
Occupational Safety and Health Administration (OSHA, 2001)	PEL	2 ppm (4.3 mg/m ³)	TWA for an 8 h workday
	STEL	10 ppm (22 mg/m ³)	Up to 15 min
National Institute of Occupational Safety and Health (NIOSH, 1988)	REL	1 ppm (2.2 mg/m ³)	TWA for a 10 h workday and a 40 h workweek
	STEL	10 ppm (22 mg/m ³)	Up to 15 min
American Conference of Governmental Industrial Hygienists (ACGIH, 2001)	IDLH	85 ppm (184.5 mg/m ³)	NA
	TLV	2 ppm (4.3 mg/m ³)	TWA for an 8 h workday and a 40 h workweek

IDLH—Immediate Danger to Life and Health; PEL—permissible exposure limit; REL—recommended exposure limit; STEL—short-term exposure limit; TLV—threshold limit value; TWA—time weighted average; NA—not applicable.

TABLE 73.5 Recommended Respiratory Protection for Workers Exposed to Acrylonitrile

Condition/airborne concentration	Respiratory protection
Up to 20 ppm ($10 \times$ PEL)	A respirator with half-mask facepiece that is either: supplied-air; or equipped with organic vapor cartridges.
Up to 100 ppm ($50 \times$ PEL)	A respirator with full facepiece that is either: supplied-air; equipped with organic vapor cartridges; equipped with chin style, organic vapor gas mask; equipped with front- or back-mounted, organic vapor gas mask; or a self-contained breathing apparatus.
Up to 4000 ppm ($2000 \times$ PEL)	A supplied-air respirator with full facepiece, helmet, suit, or hood operated in positive-pressure mode.
Above 4000 ppm or unknown concentration	A respirator with full facepiece that is either: supplied-air and auxiliary self-contained breathing apparatus operated in positive-pressure mode; or self-contained breathing apparatus operated in positive-pressure mode
Firefighting	A self-contained breathing apparatus with full facepiece operated in positive-pressure mode.
Escape	Any organic vapor respirator or self-contained breathing apparatus.

MEDICAL MANAGEMENT

Guidance regarding the medical management for acute acrylonitrile exposure can be found on the Hazardous Substances Data Bank and in the Medical Management Guidelines developed by Agency for Toxic Substances and Disease Registry (ATSDR) (ATSDR, 2013). General standards of care to be taken are as follows: (1) seek immediate medical help; (2) if the victim's clothing is contaminated with acrylonitrile, remove the contaminated clothing and move the victim to fresh air; (3) administer oxygen as needed, and if the victim is not breathing on their own, perform artificial respiration; (4) if the patient is unconscious, administer a cyanide antidote until the victim improves or medical response arrives; (5) do not induce vomiting following ingestion and administer a slurry of activated charcoal if the victim is not symptomatic; (6) flush exposed skin for 2–3 min and wash with mild soap; and (7) flush exposed eyes with water for at least 15 min.

RISK ASSESSMENTS

The regulatory levels and recommended values determined for acrylonitrile by various government agencies and organizations are listed below, and summarized in Table 73.6.

Agency for Toxic Substances and Disease Registry

The ATSDR developed acute values for inhalation and oral routes of exposure and a chronic value for oral exposure (ATSDR, 1990). The acute inhalation minimal risk level (MRL) for acrylonitrile was determined as 0.1 ppm (0.2 mg/m^3) based on the lack of significant neurological symptoms or other overt effects in acutely exposed human volunteers. The acute oral MRL was determined to be 0.1 mg/kg/day based on developmental effects in rats. The chronic oral MRL of 0.04 mg/kg/day was based on hematological effects in rats.

TABLE 73.6 Regulatory Standards Determined by Government Agencies and Organizations

Organization	Route	Standard	End Point	Value
ATSDR (1990)	Inhalation	Acute MRL	Lack of neurological symptoms in humans	0.2 mg/m^3
	Oral	Acute MRL	Developmental effects in rats	0.1 mg/kg/day
USEPA (1991)	Inhalation	Chronic MRL	Hematological effects in rats	0.04 mg/kg/day
		Chronic RfC	Nasal epithelium pathology in rats	0.002 mg/m^3
CalEPA (2001, 2009)	Oral	Unit Risk	Respiratory cancer in humans	$0.068 (\text{mg/m}^3)^{-1}$
		Slope Factor	Tumors in rodents	$0.54 (\text{mg/kg/day})^{-1}$
NICNAS (2000)	Inhalation	Chronic REL	Nasal epithelium pathology in rats	0.005 mg/m^3
		Unit Risk	Respiratory cancer in humans	$0.29 (\text{mg/m}^3)^{-1}$
ECJRC (2004)	Oral	Slope Factor	Respiratory cancer in humans	$1 (\text{mg/kg/day})^{-1}$
		Chronic OEL	Category 2 carcinogen	4.3 mg/m^3
WHO (2002)	Inhalation	Chronic OEL	Category 2 carcinogen	$0.5\text{--}45 \text{ mg/m}^3$
		Unit Risk	CNS tumors in female rats	$0.0083 (\text{mg/m}^3)^{-1}$
Health Canada (2000)	Inhalation	TC ₀₅ LCL	CNS tumors in female rats	4.5 mg/m^3
		TD ₀₅ LCL	CNS tumors in female rats	1.4 mg/kg/day

For definition of terms and abbreviations, refer to the relevant agency in the section "Risk Assessments".

TABLE 73.7 Interim Acute Exposure Guideline Levels (AEGLs) for Acrylonitrile

AN Exposure Duration	AEGL1 (Non-disabling)	AEGL2 (Disabling)	AEGL3 (Lethal)
10 min	4.6 ppm (10 mg/m ³)	290 ppm (629 mg/m ³)	480 ppm (1042 mg/m ³)
30 min	4.6 ppm (10 mg/m ³)	110 ppm (239 mg/m ³)	180 ppm (391 mg/m ³)
1 h	4.6 ppm (10 mg/m ³)	57 ppm (124 mg/m ³)	100 ppm (217 mg/m ³)
4 h	4.6 ppm (10 mg/m ³)	16 ppm (35 mg/m ³)	35 ppm (76 mg/m ³)
8 h	4.6 ppm (10 mg/m ³)	8.6 ppm (19 mg/m ³)	19 ppm (41 mg/m ³)

U.S. Environmental Protection Agency

The reference concentration (RfC) developed by the USEPA for acrylonitrile is 0.002 mg/m³ based on degeneration and inflammation of nasal epithelium in rats (USEPA, 1991). No reference dose has been established. The USEPA classifies acrylonitrile as a B1 carcinogen (*probable human carcinogen*, based on limited evidence of carcinogenicity in humans). USEPA derived an inhalation unit risk of 0.068 (mg/m³)⁻¹ based on respiratory cancer in exposed workers and an oral slope factor of 0.54 (mg/kg/day)⁻¹ based on tumors in rodents (USEPA, 1991).

California Environmental Protection Agency

California EPA (CalEPA) developed a chronic inhalation value as well as cancer values for both inhalation and oral routes of exposure (CalEPA, 2001, 2009). The chronic inhalation REL was determined to be 0.0002 ppm (0.005 mg/m³) based on degeneration and inflammation of nasal epithelium in rats. The cancer inhalation unit risk of 0.29 (mg/m³)⁻¹ and cancer slope factor of 1 (mg/kg/day)⁻¹ are based on increased risk of lung cancer in exposed workers.

Australian National Industrial Chemical Notifications and Assessment Scheme

The Australian National Industrial Chemical Notifications and Assessment Scheme (NICNAS) set an occupational exposure limit (OEL) for acrylonitrile of 2 ppm (4.3 mg/m³) TWA for an 8 h work day and classified acrylonitrile as a Category 2 carcinogen (*may cause cancer*) (NICNAS, 2000).

European Union Risk Assessment Report

The European Union risk assessment classifies acrylonitrile as a Category 2 carcinogen (*may cause cancer*) and reports international < OELs ranging from 0.23 ppm (0.5 mg/m³) to 20.36 ppm (45 mg/m³) (ECJRC, 2004).

World Health Organization

The World Health Organization (WHO) derived an inhalation cancer unit risk of 0.0083 (mg/m³)⁻¹ based on increased CNS tumors in female rats (WHO, 2002).

Health Canada

Health Canada developed a tumorigenic concentration at the 5% level (95% lower CL) [TC₀₅(LCL)] for inhalation exposure and a tumorigenic dose at the 5% level (95% lower confidence limit) [TD₀₅(LCL)] oral exposure (Health Canada, 2000). The TC₀₅(LCL) of 4.5 mg/m³ and the TD₀₅(LCL) of 1.4 mg/kg/day were based on CNS tumors in female rats.

International Agency for Research on Cancer

The International Agency for Research on Cancer (IARC) classified acrylonitrile as Group 2B (*possibly carcinogenic to humans*) based on inadequate evidence in humans and sufficient evidence of carcinogenicity in experimental animals (IARC, 1999).

National Toxicology Program

The National Toxicology Program (NTP) classified acrylonitrile as *reasonably anticipated to be a human carcinogen*, based on sufficient evidence of carcinogenicity in experimental animals (NTP, 2011).

National Advisory Committee on Acute Exposure Guideline Levels

The National Advisory Committee established interim acute exposure guideline levels (AEGLs) for acrylonitrile, which are presented in Table 73.7 (USEPA, 2009).

SECTION V

ORGANIC HIGH POLYMERS, MONOMERS, AND POLYMER ADDITIVES

SECTION EDITOR: RAYMOND D. HARBISON

74

INTRODUCTION

RAYMOND D. HARBISON

Over the past four decades the plastics and related chemical industries have experienced pronounced growth. Few aspects of daily living have not been touched in some way by the use of plastics. Superior plastic substitutes for wood, metal, and glass have found their way into medical uses, food packaging, textiles, construction, and even aircraft. The burgeoning use of plastics also has had a significant impact on waste disposal practices in areas where these materials now make up a major portion of the waste volume in landfills.

What is more, the phthalate esters, compounds used in the manufacture of plastics, have become one of the most widely found classes of laboratory and environmental contaminants. These compounds appear regularly in soil and groundwater samples taken from monitoring wells near municipal and industrial landfills. They are also found as fugitive contaminants in analytical laboratories and hospital intravenous systems, where they leach from plastic tubings. As such, they have become a source of growing concern about exposure, both in occupational and in secondary environmental settings.

Plastics and related organic high polymers, regardless of their ultimate use, are similar to the extent that they are based on the structural repetition of smaller units, called *monomers*, and they often contain added substances, which are not actually part of the polymer itself. The toxic phenomena associated with high polymers may be related to their unreacted or underreacted constituents, to various auxiliary substances, or to degradation products. It is uncommon for a fully reacted or “cured” polymer to cause illness because most of these materials have a high degree of biological inertness and insolubility.

Plastics are usually defined as high molecular weight materials that are quite soft during manufacturing and can

be molded by heat or pressure, but they turn solid and permanently deform in the finished state. The term *elastomers* is applied to polymers, such as natural and synthetic rubbers, which can be stretched easily yet return to their original dimensions when the stressing force is removed.

Elasticity is thus a capacity to be reversibly deformed. Linear macromolecules with high longitudinal mechanical strength and lateral flexibility can be used to form synthetic fibers for textile uses.

HAZARDS FOLLOWING COMBUSTION

As noted previously, in their fully polymerized, or hardened, commercial form, plastics pose few if any health hazards. However, with thermal decomposition in a fire, the resultant by-products of combustion may give rise to the potential for both acute and chronic exposure to a diverse group of compounds (Table 74.1). The gases and fine-grained particulates that evolve during combustion can be extremely complex, varying greatly in their composition and concentration in direct relationship to the temperature of combustion, the composition of the source plastic, and the amount of material involved. Although these types of exposure may occur on a limited basis at the time of plastics manufacture, they are far more common for firefighters and for occupants of buildings that had previously been involved in a fire. This is a major contemporary concern for fire departments that stems from the increasing substitution of plastics for wood, metal, and natural fiber in manufactured items found in homes, commercial structures, and vehicles.

The principal toxicological concerns associated with combustion of plastics are that some of the products of thermal

TABLE 74.1 Possible Adverse Health Effects of Thermal Destruction of Plastics

Parent Plastic Categories	Adverse Health Effects
Thermosets	
Amino resin	MMI, RI
Epoxies	MMI, RI
Phenolics	MMI, RI, SA
Polyurethanes	MMI, RI, SA
Polyesters	MMI, RI
Silicones	MMI, RI
Thermoplastics	
Acetates and acrylics	MMI, RI
Fluoroplastics	MMI, RI
Polyvinyl chloride	MMI, RI, SA, PC
Polycarbonates	MMI, RI, SA
Polyethylene	MMI, RI
Polypropylene	MMI, RI
Polystyrene	MMI, RI, SA, PC
Polyvinylidene chloride	MMI, RI, SA, PC

MMI, mucous membrane irritant; RI, respiratory irritant; SA, systemic effects; PC, potential carcinogenic compounds.

decomposition may cause respiratory irritation and systemic effects, and some may also be carcinogenic. Although the extent and concentration of combustion by-products cannot be predicted with certainty, this can be a serious problem, particularly in large, poorly ventilated commercial structures.

The list of thermal degradation products that potentially could be liberated at the time of combustion includes compounds that can cause severe mucous membrane and respiratory effects. Other more exotic and possibly more toxic or

carcinogenic compounds may be generated as a result of the special additives or coloring agents (e.g., metals and halides) added to the plastic formulation at the time of manufacture. In view of these conditions, it is often difficult to predict the toxicological effects and the presenting signs and symptoms likely to result from excessive exposure to smoke and fumes from the combustion of plastics. Furthermore, predicting the long-term health effects of exposure to the thermal degradation products of combustible plastics is problematic. Exposure to these products may cause acute, short-term symptoms that last 6–24 h. Complaints may include eye, nose, throat, and respiratory irritation, which may be accompanied by headache, intermittent cough, and production of excess mucus. In some individuals these signs and symptoms may progress to cough, chest tightness, flulike symptoms, and a marked respiratory sensitivity to the odor of smoke that lasts 2–8 weeks. The complex nature of such fire-related exposure makes it difficult to determine to what extent the health effects observed are caused by the combustion of plastics and related synthetic materials.

INDUSTRIAL HYGIENE, HEALTH, AND SAFETY STANDARDS

For the most part, no industrial hygiene, health, or safety standards have been published for plastics and related high organic polymers. In their reacted, or finished form, these materials pose few if any health hazards; the exceptions, however, are those noted for combustion by-products and materials leached from the finished polymer. The predominant concerns are the parent materials, the additives, and the related chemicals used to manufacture the product.

75

PLASTICS

MAREK BANASIK

The term *resin* has an imprecise meaning in the plastics industry and may be used interchangeably with the term *plastic*. In some applications, resins are short-chain uncured polymers that are subjected to further polymerization and hardening. In other applications, resins are granular, fully cured thermoplastics that can be heated for extrusion, molding, or calendering. The principal plastics may be divided into two groups. The *thermosets* cannot be reformed or melted after the initial “cure” and generally are obtained by polycondensation. The *thermoplastics* can be reheated and reshaped repeatedly and usually are produced by polymerization.

THERMOSETTING RESINS

Amino Resins

The amino resins are formed by the condensation of aldehydes with amines and are almost entirely based on the urea-formaldehyde and melamine-formaldehyde condensation products. They are typically used for electrical switch housings, knobs, molded dinnerware, adhesives, plywood glues, coatings, and industrial laminates. Crease-resistant garments are produced by pressing textiles impregnated with suitable amino resins into the desired shape. Hexamethylene-tetramine, known as “hexa”, is used as a stabilizer in amino resin systems to prevent premature hardening. It decomposes to form formaldehyde [Chemical Abstracts Service Registry Number (CASRN): 50-00-0] and is a possible source of irritating and sensitizing skin reactions, but it has not been a major problem in the plastics or explosives industries. Acetic acid accelerators also do not present unusual problems.

Cured, finished amino resins have not been identified as a source of occupational illness. The component of principal

toxicological interest is formaldehyde, which is present during the production of the resin and in incompletely cured products. Formaldehyde is released as a gas from urea-formaldehyde foams and during heating of other polymers. Its effects are discussed in the section on aldehydes. Workers involved in the production of urea-formaldehyde resins have described some adverse health effects, most notably irritation of the respiratory tract, likely related to the strong odor and irritant properties of formaldehyde.

Urea-formaldehyde resins can be produced in three ways: as molding powders, as adhesives, or as foams. The manufacturing protocol differs depending on the particular type of resin being produced. Melamine-formaldehyde resins are easier to manufacture and are considered more water, heat, and stain resistant than polymers that contain urea. There have been many reported cases of contact dermatitis associated with the production and handling of urea- and melamine-formaldehyde resins, but these dermatitides have been found to be an outcome of exposure to unreacted formaldehyde monomer (Schwartz, 1945; Shellow and Altman, 1966). Some studies have shown cases of allergic contact dermatitis caused by formaldehyde resins that showed no response to skin patch tests with formaldehyde (Fowler et al., 1992). Respiratory effects may occur from exposure to formaldehyde, causing a sensitization reaction similar to occupational asthma. In addition, irritation of the eyes and nose may be a response during exposure to urea-formaldehyde dusts (Vale and Rycroft, 1988).

Epoxy Resins

Cured epoxy resins have an outstanding resistance to heat and chemicals and find wide use in reinforced plastics, coatings, adhesives, casting, “potting,” and encapsulation. The typical resin is prepared by condensation of epichlorohydrin with a diphenol in the presence of a curing agent. Epoxy resins are cured by cross-linking agents known as “hardeners,” such as the polyamines (e.g., diethylenetriamine, triethylenetetramine, and piperazine) or the acid anhydrides and polybasic acids (e.g., phthalic anhydride and adipic acid). Catalysts perform a similar curing action but they do not themselves act as cross-linking agents. Common catalysts include various polyamides, monoethylamine, and tertiary amines, such as triethylamine and benzyl dimethylamine. Diluents (e.g., phenyl, allyl, and butyl glycidyl ether; styrene oxide; styrene; and other epoxides) may be used to reduce the viscosity of uncured resin systems.

Industrial exposure most commonly occurs during the production of epoxy resins. However, this is not the only opportunity for contact. Epoxy resins are often used in paints, leading to industrial as well as household exposure. They are also a component in concrete and flooring material, pipe and crack fixatives, and fiberglass. Inhalation of chemical vapors and airborne dusts related to epoxy resins is the major opportunity for contact.

Epichlorohydrin, bisphenol A (BPA), and liquid epoxy resins are skin irritants and sensitizers, as are the reactive diluent ethers and the related epoxy compounds. Epichlorohydrin is described in the section on chlorinated hydrocarbons. It has been pointed out that the epoxy group may be associated with radiomimetic effects that presumably reflect biological alkylation (Kotin and Falk, 1963). There is no evidence, however, that these substances are comparable to the nitrogen mustards in this regard or that there is an industrial hazard related to this action.

Polymerization of epoxy resins in some cases has been known to cause adverse health effects. Six workers in Japan were clinically noted to have developed a systemic sclerosis marked by skin sclerosis and muscle weakness after a short exposure (Yamakage et al., 1980). The causative agent is suspected to be an amine involved in the production of the polymer. Cases of allergic contact dermatitis involving low molecular weight monomers and oligomers of epoxy resins

have been reported and confirmed with patch testing (Fregett and Thorgeirsson, 1977). These cases have been reported for almost every industrial use of epoxy resin, from its production to its use as a fiberglass coating (Holness and Nethercott, 1989; van Putten et al., 1984). These allergic reactions are the result of a sensitizing reaction capable of recurrence even with minute future exposure. Recent reports indicate that these lower molecular weight compounds are more likely to cause allergic contact dermatitis (Holmes et al., 1993).

Industrial health problems most frequently arise from the exposure to aliphatic polyamine hardeners, which can cause severe primary irritative dermatitis, as well as hypersensitivity dermatitis and asthmatic reactions. These amines are strongly alkaline (pH 13–14) and can cause chemical burns of the skin. Cutaneous amine reactions include erythema, intolerable itching, and severe facial swelling. Blistering may occur, with weeping of serous fluid, crusting, and scaling. An apparently hypersensitive state may recur as an extreme reaction upon reexposure to amines. Cases have been recorded of persons with previous amine dermatitis, who experienced a dramatic return of symptoms upon reexposure. Highly sensitive persons may also react to cured resins containing small amounts of unreacted amine hardeners.

A notable hardener used for epoxy resins is hexahydrophthalic anhydride. This reactive compound has been reported as an eye and mucous membrane irritant and is known to cause occupational asthma and hemorrhagic rhinitis (Grammer et al., 1993; Moller et al., 1985; Venables, 1989). Like many acid anhydrides with a low molecular weight, hexahydrophthalic anhydride can act as a hapten, and thus produce a variety of sensitizing effects. Studies have indicated an IgE-mediated mechanism for this chemical (Welinder et al., 1994). Once in the body, hexahydrophthalic anhydride is metabolized to hexahydrophthalic acid, which is then excreted in the urine. This acid can be measured using gas chromatography as a means of biological monitoring (Jönsson and Skarping, 1991). However, because the rate of elimination is rather fast (2–4 h), exposure can be determined only for recent contact (Jönsson and Skerfving, 1993).

Though pulmonary reactions in the modern plastics industry are most commonly associated with components of polyurethane (PUR) systems, amine hardeners for epoxy resins do cause bronchospasm and coughing episodes, which may persist for several days after cessation of exposure. Repeated attacks of acute amine-induced respiratory disease are often associated with increased responsiveness to these compounds because faint traces of amine vapors in the air have been sufficient to trigger the return of intense symptoms in persons with a history of amine-induced asthmatic conditions. Cases of asthma in workers involved in the curing process of epoxy resins have demonstrated reactions caused by phthalic acid anhydride, trimellitic acid anhydride, and triethylenetetramine (Fawcett et al., 1977).

Acid anhydrides and polyamide hardeners and catalysts are contact irritants, but industrial problems related to their use have been uncommon. Diluents such as xylene or the ketones do not sensitize but may defat the skin with repeated contact. Glass fibers, which have many uses, are mechanically irritating and cause pruritus, and they may be released when inert laminates or other forms are cut or tooled. Sawing, machining, and other manipulation of solid, cured resins that produce heat may give rise to degradation products that contain free amines or unreacted epichlorohydrin.

The carcinogenicity of epoxy resins is difficult to determine because of the array of compounds used. An updated study by Cowles et al. (1994) examined the mortality of employees at a resin-manufacturing facility. An unexpected increase in pancreatic cancer was observed, although no causative agent or process was identified. Occupational exposure at this facility included polypropylene, epoxy resins, polystyrene, and polyethylene.

Prevention of problems from epoxy exposure is based on the meticulous cleanliness of work areas. Mixing of resin and hardener and application of the liquid formulations should be done with appropriate ventilation. Material that is spilled on the skin should be removed promptly with soap and water. Organic solvents used for this purpose tend to spread contamination and irritate the skin. The use of gloves for skin protection is essential. Choosing gloves of the proper material is of great concern. An inappropriate glove can lead to exposure because different gloves are impervious to different chemicals (Holmes et al., 1993; Pegum, 1979).

Phenolics

The modern plastics industry is based on Leo Hendrik Baekeland's discovery in 1909 of phenol-formaldehyde (PF) thermosetting materials. The term *phenolic resin* now encompasses a variety of similar products made by polycondensation of phenols with aldehydes. The "phenols" used for this purpose include phenol, cresol, xylol, p-t-butylphenol, and resorcinol. The aldehydes involved include formaldehyde, paraformaldehyde, and furfural. Alkaline catalysts include hexamethylenetetramine, ammonia, and various other amines. The uses of phenolic resins are similar to those of the amino resins, which have similar structures and properties. Large quantities of PF resins (CASRN: 9003-35-4) are used in bonded brake linings and clutch facings and as bonding agents for foundry sand models. Increases in use among certain industries, such as the aerospace and marine markets, can be attributed to the easy to produce, low viscosity liquid phenolics.

These resins are manufactured from two different processes, depending on the molecular weight desired. For lower molecular weights, an alkaline catalyst and simple heat curing are used to make a resol-type resin. Higher molecular

weight resins, called novolaks, require an acid catalyst, and the addition of hexa aids in cross-linking. Resols are favored for their resistance to cracking, and novolaks are better suited for molding purposes and long-term storage. Phenolic resins in general are good electrical insulators and are resistant to chemical and biological degradation.

Dermatitis are important industrial health effects. Resins in this group have been associated with skin allergies after occupational exposure (Foussereau et al., 1976). More recent studies have shown a positive skin patch test among workers exposed to PF resin (Kieć-Swierczyńska and Szymczak, 1995). Phenol is a potent primary irritant, and resorcinol, furfural, and formaldehyde are both irritants and sensitizers. Furfural (CASRN: 98-01-1) is a photosensitizer that is found in various foods and beverages. In some applications, cashew nut shell oil has been used as a phenolic component in resin formulation. This oil is chemically related to poison ivy resins, but the oil used in industry usually is treated to render it safe for handling. Nevertheless, persons highly sensitive to Rhus-type oleoresins may be reactive. Workers who handle finely divided molding powder may be exposed to dusts that are irritating to the skin and that sometimes cause allergic dermatitis. These resins have also been shown to cause respiratory effects. Pulmonary function testing of workers exposed to PF resin fumes demonstrated airway obstruction (Schoenberg and Mitchell, 1975).

Degradation products from PFs resins are a moderate hazard. Large amounts of carbon monoxide (CO) are produced by PF resin fires, making a potentially hazardous smoke. However, these plastics are good fire retardants and do not produce large amounts of smoke.

Polyesters and Alkyds

Materials of the polyester and alkyds group are essential to reinforced plastic technology. Reinforcement is generally provided by glass fiber textiles, and the typical structure consists of laminations of polyester and textile. Polyester

resins can be saturated or unsaturated depending on the reactants used. A saturated resin will be produced from a polycondensation reaction of a carboxylic acid and an alcohol. For example, the polyester Dacron® (polyethylene terephthalate; CASRN: 25038-59-9) is formed from a reaction of methyl terephthalate and ethylene glycol. Terephthalic acid is perhaps the most commercially important acid used. It is present in most high molecular weight polyester films as polyethylene terephthalate and polybutylene terephthalate (CASRN: 24968-12-5). Saturated resins are important in the boat and automobile industries and are also used in many household furnishings, such as shower stalls.

Manufacturing an unsaturated resin requires the use of a dibasic acid, such as phthalate or maleic anhydride, and a glycol. These are low molecular weight resins that are strong and translucent. Addition of different chemicals to this resin can change its properties to best suit its intended use. Flexibility, solubility, and chemical resistance are some of the changeable characteristics of these polymers. The unsaturated resins generally are nontoxic, but contact dermatitis and skin allergy have occasionally been reported, although one of these reported exposures was not related to an occupational exposure (Lidén et al., 1984; MacFarlane et al., 1986). Poor industrial hygiene while manufacturing these resins was reported to have resulted in several cases of contact dermatitis in one plant (Lim et al., 1970). These polymers are also used in the fiberglass boat industry and are found in furniture and other products that do not require the more expensive saturated resins.

Alkyd resins are similar to polyesters but differ in that they are treated with a triglyceride oil or fatty acid to make them more useful in the coating industry. They are primarily used as a component of paints, varnishes, and lacquers. The toxicity of these compounds is not very noteworthy because industrial standards for the components and co-products of the manufacturing processes are sufficient to protect against harmful exposure to the finished product. Phthalic anhydride (CASRN: 85-44-9) is used in many alkyd resins and is a known irritant and sensitizer. Exposure to compounds such as this is more of a health concern than the actual resin itself.

In a cross-linking step, polyesters are dissolved in styrene and stabilized with an inhibitor, such as hydroquinone, to form a viscous, syrup-like liquid that does not solidify readily. When gelation is desired, a catalyst is added, usually peroxide (e.g., benzoyl peroxide or methyl ethyl ketone peroxide). Promoters or accelerators (dimethylaniline or cobalt salts) may also be added to accelerate this cross-linking solidification. These resins are insoluble in water but are soluble in some organic solvents and complex phenols. Though styrene generally is the reactive solvent and cross-linking group between the polyester macromolecules, other equivalent compounds may be used for special purposes. Methyl methacrylate (MMA) increases resistance

to weathering, diallyl phthalate retards polymerization of the uncatalyzed syrup, and triallyl cyanurate increases resistance to elevated temperatures. A wide range of exposures can occur during polyester manufacturing, and proper caution should be observed in the various processes to limit exposure. Polyesters themselves do not cause skin or respiratory tract irritation or sensitization. Health concerns will most likely target styrene exposure, which is covered in the section on polystyrene.

The acid phthalates can cause burns when they come in contact with damp skin. The dusts are irritating to the eyes and upper airway, but there is no important systemic toxicity. Organic peroxides are highly irritating to epithelial tissues and are flammable oxidizing agents. There is also an evidence that benzoyl and methyl ethyl ketone peroxides are skin sensitizers, as are dimethylaniline and cobalt naphthenate. Dimethylaniline can cause most of the effects of aniline. Although the allyl group has well-known toxic properties, serious occupational hazards have not been associated with diallyl phthalate and triallyl cyanurate, both of which are irritants. Polyester dusts produced by grinding operations can result in cough, dyspnea, and eye and throat irritation in exposed workers, who may also show marked reduction in expiratory flow rates (Zuskin et al., 1979). Generally, however, industrial health problems from the polyester group are uncommon, except for the direct effects of styrene, and most of them may be attributed to the mechanical effects of glass fibers on the skin.

Polyurethane

Polyurethane resins and foams (CASRN: 9009-54-5) are two important industrial polymers. They can be produced as rigid, semirigid, or elastic foams or resins, which give PUR many versatile commercial uses. Polyurethane can be found in furniture, bedding material, automotive sealing material, adhesives, carpet, packaging material and coatings, and many other products. It is favored industrially

because of its resistance to oil, light, and solvents, in addition to its strength and flexibility. These polymers are formed by polyaddition reactions between a diisocyanate and a polyhydroxyl compound, such as a polyol. In foams, carbon dioxide (CO_2) production is used to give rise to bubbles. Blowing and foaming agents may be used to duplicate this process. Exposure to PUR is of limited concern; the diisocyanate reactant is the main occupational health concern.

Health effects directly associated with PUR exposure are not well documented in humans. Idiomatic responses, such as thrombocytopenia, are uncommon but have been the subject of some case reports (Michelson, 1991). The main route of exposure to these dusts is inhalation, related to airborne particles and spraying of PUR coatings. Dust inhalation studies in animals have not shown a carcinogenic effect, but have demonstrated typical respiratory effects, such as pneumonitis and infiltration of macrophages (Thyssen et al., 1978). Workers exposed to dusts have reported reddening of the eyes and lacrimation (Hosein and Farkas, 1981). The hazards associated with these dusts are considered to be limited, and occupational exposure during production usually is within recommended exposure guidelines.

Industrial fires involving PUR should be managed with caution. The main degradation product at lower fire temperatures is CO, but hydrogen cyanide (HCN) is released in small amounts. At higher temperatures (600–800 °C, 1,112–1,472 °F), HCN becomes a major constituent of the smoke. Pulmonary irritation and edema can occur from exposure to lesser concentrations of these chemicals.

More hazardous than the dusts are the two most common diisocyanates used, toluene diisocyanate (TDI) and methylene diphenyl diisocyanate (MDI), which are discussed later in this section. Others of importance that may also be used are isophorone diisocyanate, hexamethylene diisocyanate, and naphthalene diisocyanate.

TDI Toluene diisocyanate is the most important chemical in the formation of PURs. It can exist in two forms, 2,4-TDI (CASRN: 584-84-9) and 2,6-TDI (CASRN: 91-08-7). Though the chemical properties vary slightly between the two isomers, the commercial mixture of 80:20 of 2,4-TDI:2,6-TDI (CASRN: 26471-62-5) is more prevalent in industry and shall be referred to unless otherwise specified. The monomer is a colorless to pale yellow liquid with a sharp, pungent odor. Soluble in organic solvents, TDI is insoluble in water but is highly reactive with water and other hydrogen-rich compounds. It has a vapor pressure of 0.04 mmHg at 20 °C (68 °F) and a relative vapor density of 6.0 (air = 1) Toluene diisocyanate has not been found to occur naturally and is used in many applications of PUR. Polyurethane resin and flexible foams account for about 90% of all TDI used.

MDI A white to pale yellow solid, MDI (4,4'-diphenylmethane diisocyanate; CASRN: 101-68-8) is a compound with a larger molecular weight and thus a lower vapor pressure than TDI. At 0.000005 mmHg (at 20 °C), the vapor pressure assures lower airborne concentrations of MDI than TDI. It is slightly soluble in water at 0.2% by weight and may self-polymerize at 232.2 °C (*ca.* 450 °F). Like TDI, MDI has not been found to occur in nature. The applications for MDI include coatings and lacquers, and it is used primarily to make the more rigid foams and an alternative product, polyisocyanate foam. These rigid foams provide excellent insulation properties in construction and packaging materials.

Industrial Hygiene Toluene diisocyanate is formed in two ways: as a reaction with phosgene and toluedenediamine or by carbonylation of dinitrotoluene followed by thermal conversion. To form PUR, TDI is reacted with a polyol, interacted with urea groups, and cross-linked with water as a mediator. It can also be formed with a polyol to form isocyanate end-groups, and then cross-linked. The expected route of exposure to TDI is inhalation, with dermal contact less common. Airborne concentrations of TDI have been found in the production and processing of PUR and can also be detected in emissions from processing facilities. High performance liquid chromatography and gas chromatography are capable of detecting TDI in the air. Postproduction products of PUR can contain unreacted monomer, and methods have been developed to identify these residues. The exposure guidelines set for TDI exposure are low; the United States (US) National Institute for Occupational Safety and Health (NIOSH) recommends the lowest possible exposure, and the US Occupational Safety and Health Administration (OSHA) has set a permissible exposure limit (PEL) of 0.02 parts per million (ppm) (0.14 mg/m³) (NIOSH, 1994). The American Conference of Governmental Industrial Hygienists (ACGIH) has set a ceiling of 0.02 ppm and a threshold limit value (TLV) time-weighted average (TWA) of 0.005 ppm (0.036 mg/m³) (ACGIH, 1995).

The production of MDI involves phosgenation of methylene dianiline that produces a mixture from which MDI can be distilled. The major routes of exposure to MDI are inhalation and dermal contact, particularly during spraying or heating. Occupational levels of MDI can be measured best with simultaneously used liquid absorbers rather than other solvent free-sampling techniques (Andersson et al., 1983). The OSHA has set its PEL for MDI at 0.02 ppm (0.2 mg/m³), and NIOSH and ACGIH have set both the recommended exposure limit (REL) and the TLV at 0.005 ppm (0.05 mg/m³) TWA (ACGIH, 1995; NIOSH, 1994).

Occupational protection from TDI and other diisocyanates depends on the setting in which exposure is likely to occur. When higher exposures are likely, such as when the resin temperature exceeds 70 °C (158 °F), suits that offer respiratory protection are recommended. Heating of PURs causes

evaporation and release of isocyanates; therefore processing at high temperatures should be conducted in a sealed system or in exhaust-ventilated areas.

Acute and Chronic Effects Exposure to high concentrations of inhaled TDI over a short period causes mostly irritation effects. Eye irritation and lacrimation are likely symptoms of exposure of the eyes to TDI vapor. Inflammatory changes have been noted in the mucous membranes of the respiratory tract and stomach at lower concentrations of 0.05 ppm and 0.1 ppm (Brugsch and Elkins, 1963). Systemic effects, such as headaches, nausea, and central nervous system (CNS) effects, have also been reported (Le Quesne et al., 1976).

The chronic effects of TDI occur mainly through inhalation and are manifested in the respiratory system. The unique feature of this chemical is its ability to act as a sensitizing agent in many individuals. One of the leading causes of occupational asthma, TDI is responsible for a reaction in 5–10% of exposed workers (Bernstein, 1982). Another complication involving the sensitization mechanism is extrinsic alveolitis, reported less frequently (Vandenplas et al., 1993). Both of these diseases are believed to have a latency period. A wide range of other pulmonary diseases have also been linked to TDI exposure. Loss of forced expiratory volume (FEV1) is a significant finding in some epidemiological studies (Jones et al., 1992; Wegman et al., 1982). Hypersensitivity pneumonitis and hemorrhagic pneumonia have been linked to TDI (Charles et al., 1976; Patterson et al., 1990). These obstructive airway diseases and related tissue insults are characterized by inflammation due to exposure.

Occupationally related asthma is the most common adverse outcome and is frequently reported. Unlike other industrial sensitization reactions, TDI-induced asthma can take many years to resolve. Once sensitized, workers have been known to require daily care and complete separation from TDI. Some workers react to small amounts of TDI as long as 12 years later (Banks et al., 1990; Lozewicz et al., 1987; Moller et al., 1986). This persistent sensitivity to TDI is remarkable, making transfer to another work site or complete removal necessary for the protection of the employee. Though rare, deaths from TDI-induced asthma attacks have occurred, and appropriate measures should be taken to minimize this risk (Fabbri et al., 1988).

Methylene diphenyl diisocyanate long was thought to be of low toxicity because of its low vapor pressure, and MDI-related diseases have been documented separately from TDI disorders. Diminished values for peak expiratory flow rate have been demonstrated in workers exposed to both isocyanates, together and alone (Burge et al., 1979). Asthmatic responses, extrinsic alveolitis, pneumonitis, and airway obstruction can be linked to MDI as well to TDI (Baur et al., 1984; Vandenplas et al., 1993). Some clinicians have reported findings of acute respiratory disorder,

rhinoconjunctivitis, and fever associated with chronic exposure to MDI (Littorin et al., 1994).

A number of epidemiological studies have found no association between exposure to TDI, MDI, and other isocyanates and an increased incidence of cancer in the manufacturing industry (Hagmar et al., 1993; Sorahan and Pope, 1993). Animal studies have shown both positive associations and nonassociations (IARC, 1986; Loeser, 1983).

Mechanism of Action The mechanism by which TDI and MDI cause occupational asthma has been studied. An IgE-mediated mechanism has been suggested, but studies have indicated the presence of this mediator in lower numbers of affected workers than expected (Patterson et al., 1987). An IgG-mediated response has been found to be likely for TDI (Cartier et al., 1989). The most likely cause for late asthmatic responses is an inflammatory reaction (Vandenplas et al., 1993). In general, isocyanates act as haptens. A study in guinea pigs provides an *in vitro* model for evaluating the mechanism of action of isocyanates; it demonstrates direct bronchial smooth muscle-induced contractions mediated through a capsaicin-sensitive primary afferent nerve (Mapp et al., 1991).

Pulmonary injury in mice produced by exposure to isocyanates was reported to cause squamous metaplasia of the epithelium (Buckley et al., 1984). Carcinogenicity in animals is suspected with TDI exposure because of its reactive product, diaminotoluene (TDA), which is formed when TDI comes in contact with water. Diaminotoluene is a suspected human carcinogen. Similar to TDI, MDI is degraded to 4,4'-diaminodiphenylmethane, which is also a suspected human carcinogen.

Diagnosis and Treatment Occupational asthma can be defined in a variety of ways. Primarily, it is a small airway sensitization that is reversible and can be induced by either an allergic (e.g., antigen) or nonallergic response in predisposed and many atopic individuals. Isocyanate-induced asthma is diagnosed by using different methods to arrive at an acceptable clinical conclusion. The patient history has been shown to be a better method of ruling out isocyanate asthma than predicting it (Vandenplas et al., 1993). A decrease in the FEV₁ and peak expiratory flow may be a good indicator of occupational asthma (Burge et al., 1979; Diem et al., 1982). Bronchial hyperresponsiveness to histamine or methacholine, although not present in all individuals, can demonstrate a sensitization reaction. These initial tests are nonspecific and do not indicate isocyanates exclusively as the primary cause of the condition. Additional pulmonary function tests, along with exposure data, would be required to identify isocyanates as the cause of occupational asthma. Workers with a diagnosis of occupational asthma should follow general treatment procedures. Removal from exposure usually results in

improvement. However, repeated exposure may cause reactions.

Primary treatment for acute effects entails removing the worker from the exposure area and flushing skin or eyes with water. Clinical evaluation should be completed immediately thereafter.

Biomonitoring Diaminotoluene is a decomposition product of TDI. Though 2,6-diaminotoluene dihydrochloride can also be formed, TDA is the main degradation product. It has been shown that measurement of plasma concentrations of TDA can be used to monitor worker exposure to TDI (Persson et al., 1993). No quantitative correlation between TDA urine levels and actual exposure has been found. For MDI, a method for monitoring dermal exposure has been developed using capillary gas chromatographic measurements of 4,4'-diaminodiphenylmethane in hydrolyzed serum and urine (Tiljander et al., 1989).

Silicones

Silicones are composed of chains of alternate atoms of oxygen and silicon, otherwise known as a siloxane link. Various organic groups can be attached to the silicon atoms, and the amount of cross-linkage between chains by these groups determines whether the polymer will be hard, elastomeric, or fluid. The fully reacted polymers are remarkably inert and therefore are useful in medical applications such as heart valves, prostheses, heart-lung machines, and artificial kidneys. Major industrial uses are in lubricants, encapsulations, dielectric laminates, and “non-stick” release compounds.

The biological properties of the silicone intermediates have been studied. Of the silicones, the chlorosilanes are corrosive to mucous membranes, but the ethoxysilanes are less so. Various metallic soaps, acetic acid, and toluene solvents may be used in the final applications of silicones.

Polydimethylsiloxane The polydimethylsiloxane (CASRN: 63148-62-9) materials are excellent examples of silicones because of their chemical properties and widespread industrial use. They can be manufactured as gels, resins, fluids, or elastomers, depending on the cross-linking characteristics. Toxicity testing using polydimethylsiloxane compounds on animals has found little, if any, harmful effects associated with

chronic exposure. These tests include oral dosing and teratogenicity testing (Cutler et al., 1974; Kennedy et al., 1976). Human health effects associated with silicone implants have been reported. Polydimethylsiloxane is the most prevalent silicone used medically and has been incorporated into many prostheses, including breast implants. A recent epidemiological study of women with and without silicone implants revealed no association between silicone breast implants and connective tissue diseases (Sánchez-Guerrero et al., 1995). Occupational exposure to comparable amounts of silicone is highly unlikely. The manufacture of these silicone compounds has not been linked to adverse health effects except for acute minor eye irritation.

THERMOPLASTICS

Acetal Resins

Acetal resins (CASRN: 9002-81-7), also known as polyoxyethylene and polyformaldehyde, are polymers of pure formaldehyde with unusually good mechanical properties. They are resistant to elongation and impact and replace light metals in many uses. The finished polymer has not been related to adverse health effects in humans or animals. They can be thermally degraded, for example, in an overheated molding machine, to produce formaldehyde gas, with its well-recognized irritant and sensitizing properties.

Acrylics

Acrylic plastics, such as Lucite® and Plexiglas®, are made from methyl and ethyl acrylate and methacrylate. Poly(methyl methacrylate) (CASRN: 9011-14-7) is the most common and best representative of this group of plastics. These substances are respiratory and cutaneous irritants, the acrylates more so than the methacrylates. Studies have shown sensitization reactions to a number of different components of photopolymerizing plates in the printing industry. Contact dermatitis from dermal exposure to uncured plates is not uncommon (Pedersen et al., 1983).

Acrylic paints are composed of a water emulsion of acrylic polymers that have no known biological hazards with occupational exposure or intended environmental use. Aside from paints and coatings, these polymers are also used in food contact items and medical implants because of their low bioavailability.

MMA Methyl methacrylate (CASRN: 80-62-6) is an important monomer and polymer with many industrial applications. As a monomer, MMA has many uses, including latex paints, lacquers, sealants, adhesives, acrylic fiber production, and surface coating resins for paper and leather. The largest application for MMA is in the acrylic sheeting industry. The polymer of MMA is widely used in dental and orthodontic devices and as cement in many orthopedic surgical procedures. Methyl methacrylate is an entirely synthetic chemical. At room temperature, it is a colorless liquid with a fruity, acrid odor. It is slightly soluble in water, 1.5% by weight, and is much more soluble in organic solvents, such as ethanol and acetone. Methyl methacrylate has a vapor pressure of 29.3 mmHg at 20 °C (68 °F) and a relative vapor density of 3.45 (air = 1). When exposed to light, heat, or ionizing radiation, MMA is likely to undergo polymerization.

Industrial Hygiene Methyl methacrylate is mainly produced industrially in two distinct processes, beginning with the chemical isobutylene. In the first process, isobutylene is oxidized to methacrylic acid with nitric acid and subsequently undergoes an esterification process with methanol. The second process involves ammoniation of isobutylene, then hydrolyzation with sulfuric acid and a reaction with methanol to form the final product. Exposure to MMA industrially most often occurs through inhalation, usually in the production of products containing MMA rather than in the production of MMA itself. A study in one US polystyrene production facility revealed that highest concentrations of airborne MMA are at the batch reactors and the unloading dock (Samimi and Falbo, 1982). It is also liberated when acrylic plastics are cut with a CO₂ laser (IARC, 1994). A second important route of MMA exposure is through the skin. This type of exposure is most notable in hospitals and dental clinics where dermal contact with prostheses and devices containing residual amounts of the monomer occur. Gloves offer some protection but are not completely reliable, since many have been shown to be permeable to MMA (Waegemaekers et al., 1983). Respirators are an effective means of controlling inhalation exposure.

Exposure guidelines set by the ACGIH, NIOSH, and OSHA are all identical. Airborne levels of MMA are limited to a TLV, REL, and PEL of 100 ppm (410 mg/m³) (ACGIH, 1995; NIOSH, 1994).

Acute and Chronic Effects Methyl methacrylate-induced acute toxicity can occur through cutaneous and respiratory

exposure routes. Methyl methacrylate has been characterized as a skin and respiratory irritant at low concentrations. At high concentrations systemic injury to other organs may occur, such as the kidneys and heart.

Chronic exposure to MMA can lead to a variety of responses, depending mostly on the exposure route and concentration. As a sensitizing agent, MMA may cause contact dermatitis after dermal exposure (Farli et al., 1990) and an asthmatic condition or other respiratory effects after inhalation (Pickering et al., 1986). There have been several cases of neurological disturbances reported following prolonged dermal exposure to MMA among dental technicians and hygienists. Symptoms described have included numbness, pain, and whitening of the fingers, as well as isolated cases of peripheral neuropathy and loss of motor function (Donaghy et al., 1991; Rajaniemi and Tola, 1985). There have been no reports of adverse reproductive effects in humans, and rodent assays have been either inconclusive or have shown no adverse developmental effects (Solomon et al., 1993).

The carcinogenicity of MMA has been evaluated in both animal studies and human epidemiological studies. Though some report increases in colorectal cancers, these results are considered insignificant, with most studies showing no significant increase, if any is seen at all (Collins et al., 1989; Walker et al., 1991). After review of the literature, the International Agency for Research on Cancer (IARC) has classified this chemical as a Group 3 compound, not classifiable as to its carcinogenicity (IARC, 1994).

Management of signs and symptoms from excessive exposure to MMA is the most likely treatment because the range of effects varies depending on the route of exposure.

Target Organs and Mechanism of Action The target organ for excessive exposure to MMA depends on the route of exposure. Inhalation of the compound is most detrimental to the lungs, the major site of tissue insult. Skin effects are most common from dermal exposure, with some systemic effects occurring in the nervous system (Bereznowski, 1994). Regardless of the exposure route, it has been shown in rats that the major metabolic path of MMA is oxidation of the chemical, leading to expiration as CO₂ (Bratt and Hathway, 1977). The study indicates that up to 65% of MMA absorbed is expired within 2 h. More recent studies have determined that MMA is quickly degraded to methacrylic acid by a serum nonspecific carboxylesterase (Bereznowski, 1995). Methacrylic acid is less toxic than MMA. This rapid hydrolysis of MMA is the reason for its low toxicity. Since the blood is the site of detoxification, this action works to limit systemic organ damage.

Biomonitoring Monitoring for MMA exposure is difficult because of its fast hydrolysis and expiration. However, analysis of blood and urine for the presence of methanol was studied and appears to be an effective procedure for

monitoring occupational exposure (Mizunuma et al., 1993). The same study also estimated that only 1.5% of MMA inhaled will be excreted in the urine. Blood analysis for the presence of methacrylic acid could also be a plausible means of biomonitoring. Thus far, however, no studies have indicated this analysis as a reliable test.

1,3-Butadiene One of the many compounds used in the manufacture of plastics and elastomers is 1,3-butadiene (CASRN: 106-99-0), more commonly referred to as simply butadiene. Though butadiene is a component of many polymers, the production of acrylonitrile–butadiene–styrene and acrylonitrile–butadiene copolymers uses 72% of the butadiene produced in the US. Butadiene has also been detected in cigarette smoke, automobile exhaust, and gasoline vapor. Formed mostly from the production of thermogenic resins and rubber, butadiene has not been found to occur naturally. At room temperature, it exists as a colorless, mildly aromatic gas with a potential to explode when mixed with air, making inhalation its primary route of exposure. Butadiene is slightly soluble in water but readily dissolves in organic solvents. The compound has a vapor pressure of 2,100 mmHg at 25 °C (77 °F) and a relative vapor density of 1.87 (air = 1). Once polymerized, it may be considered biologically inert. Occupational exposure is most likely during production and polymerization of the monomer.

Industrial Hygiene Occupational exposure to butadiene occurs mainly in the unloading and loading of crude product and during sampling (Fajen et al., 1990). A study by NIOSH has indicated that in a given year, 65,000 workers may be exposed to butadiene (Fajen et al., 1990). Exposure during processing usually is a consequence of leaks in the seals of equipment. Maintenance of valves, seals, and pumps to prevent leaks and decontamination of equipment, and monitoring of the work area, are valuable for controlling butadiene exposure. A number of studies have shown that without excessive exposure from leaks, occupational exposure is usually well below guidelines set by OSHA and ACGIH, typically below 2 ppm (Bond et al., 1995; Heseltine et al., 1993). The ACGIH has a TLV TWA of 2 ppm (4.4 mg/m³); OSHA has a lower PEL TWA of 1 ppm (2.2 mg/m³) (ACGIH, 1995; IARC, 2008).

Acute and Chronic Effects Because of the relatively rare occurrence of high levels of exposure, the acute effects of butadiene exposure are seldom observed. At extremely high levels of exposure, there have been reports of respiratory tract and eye irritation. At high levels of exposure, butadiene can also produce anesthetic effects. Removal of the person from high levels of exposure will result in disappearance of symptoms.

1,3-Butadiene has been the subject of some controversy and debate concerning its potential as a human carcinogen. Two cohort studies indicate an association between industrial exposure to butadiene and increased mortality among workers from leukemia and lymphohematopoietic cancer (Divine, 1990; Matanoski et al., 1990). However, these studies have been criticized by those who do not support these findings, and conflicting results exist among similar studies (Acquavella and Cowles, 1993). A retrospective study by Cowles et al. (1994) did not demonstrate any increase in cancer among workers exposed to butadiene levels below ceiling values. A study to investigate the association between prostate cancer and butadiene exposure revealed no association between such exposure and prostate cancer deaths (Downs et al., 1987). The evidence in rodent assays is equally questionable. Most studies conclude that while butadiene is a rather potent carcinogen in mice, it is not in rats (Bond et al., 1995; Owen et al., 1987). Therefore the animal data do not support the conclusion that butadiene is a human carcinogen at occupational levels of exposure in compliance with recommended guidelines.

Target Organ or Site The lungs are the target site of the acute effects produced by butadiene. However, chronic exposure studies in laboratory animals have revealed that this compound can affect other sites as well, some of which have been reported in humans. The studies in rodents have identified several sites for tumor induction, with the only similar location in both mice and rats being the mammary gland (Melnick and Kohn, 1995). This site has not been linked to human exposure. The suspected higher incidence of leukemia and lymphomas leads to a conclusion that butadiene may have an effect on bone marrow. It has been reported that butadiene is genotoxic in the bone marrow of mice but not rats (Melnick and Kohn, 1995).

Mechanism of Action Studies in the past have reported that butadiene is a potential mutagen (de Meester et al., 1978). Though itself a mutagen, butadiene metabolites are of greater interest. Butadiene is converted to 1,2-epoxy-3-butene and 3-butene-1,2-diol, both of which have been shown to be carcinogenic (Bond et al., 1995; IARC, 1992, 2008). Studies indicate that mice metabolize 1,2-epoxy-3-butene to 3-butene-1,2-diol, but rats and humans are deficient in this conversion mechanism (Bond et al., 1995). These two compounds have been linked to neoplasms in laboratory animals. However, there is a lack of evidence for the metabolic production of significant amounts of these metabolites in humans at levels of exposure in compliance with recommended guidelines. Both the liver and lungs seem to be important in the detoxification of these compounds. An IARC review of current literature has led to classification of butadiene as “ . . . carcinogenic to humans (Group 1)” (IARC, 2008).

Biomonitoring Biomonitoring exposure to butadiene is possible by measuring urinary metabolites of butadiene and not the actual compound. Two major urinary metabolites can be measured. The product of epoxybutene hydrolysis can be measured, and the product of glutathione conjugate of epoxybutene can be measured as well. The epoxybutene hydrolysis metabolite can be detected in humans who have been exposed to low levels of butadiene (Heseltine et al., 1993). Advances have occurred in recent years that have resulted in other assays. For example, occupationally exposed workers were monitored by analyzing the adducts formed by the reaction of 1,2-epoxy-3-butene with the terminal valine of hemoglobin (Neumann et al., 1995). This has also been reported to be successful in animals and is useful as a biomonitoring tool for workers.

Polystyrene

Polystyrene (CASRN: 9003-53-6) is prepared by the polymerization of styrene under the influence of organic peroxides in solution. Addition of inhibitors such as hydroquinone or butylcatechol prevents the monomer from polymerizing in storage. The properties of the polymer vary depending on the additives involved and the fabrication method. It can be injection molded, blow molded, thermoformed, or extruded. Prepared as a resin in small spheres, polystyrene is a clear, rigid polymer that is relatively stable under most conditions. Hazards associated with the manufacture of polystyrene are associated with the monomer, styrene, and not the actual polystyrene product. Primarily a packaging material, polystyrene is used mostly as a component of a variety of food containers, such as egg cartons and hot/cold vending cups. It is also used in small appliances, medical devices, and toys. Exposure to polystyrene dusts may cause mechanical irritation of the eyes and respiratory tract. Degradation products resulting from fire release styrene at lower temperatures and mostly CO and CO₂ at higher temperatures, with a usually dense smoke being produced.

Styrene Styrene (phenylethene; CASRN: 100-42-5) is manufactured and used in large volumes. It is mainly used in plastics, latex paints and coatings, synthetic rubbers, polyesters, and styrene–alkyd coatings (Collins and Richey, 1992). Packaging is the single largest use, in the form of styrene resins, particularly foams. Unlike other organic monomers, styrene has been identified in trace amounts in the gummy exudate of tree trunks and in the spice cinnamon (Duke, 1985). At room temperature it is a colorless to yellow, oily liquid with a pungent odor. In water styrene has a low solubility of 0.03% by weight, but it is much more soluble in organic solvents, such as benzene and acetone. Styrene is a somewhat viscous liquid, with a vapor pressure of 5 mmHg at 20 °C (68 °F) and a relative vapor

density of 3.6 (air = 1). Styrene is quite reactive and polymerizes rapidly, and if uncontrolled it may cause an explosion (Miller et al., 1994).

Industrial Hygiene Styrene is produced industrially by catalytic dehydrogenation of high purity phenylethene in the vapor phase. It can also be formed as a co-product from a propylene oxide process. In 1993 a study by NIOSH estimated that approximately 1.112 million workers were potentially exposed to styrene. The main route of exposure is through the air, with the highest levels of exposure occurring in the areas of polymerization, manufacturing, and purification (IARC, 1994). The most extensive exposure occurs in the fabrication of boats, tanks, wall panels, and bath and shower units from glass fiber-reinforced polyester composite plastics (Miller et al., 1994). Products with a larger surface area must be made through an open-mold process rather than a press-mold operation. Studies have shown that an open-mold process can lead to a styrene exposure of three times the magnitude of a press-mold process (Lemasters et al., 1985). The OSHA has set the PEL for styrene at 100 ppm TWA, with a 600 ppm 5-min maximum peak in any 3 h; NIOSH has set the REL at 50 ppm TWA, and the ACGIH has set the TLV TWA at 20 ppm (ACGIH, 2001; NIOSH, 1994).

Currently, occupational exposure to styrene is low, with most overexposures occurring as a result of leaks in equipment. Controlling leaks and replacing faulty machinery are the most effective controls for styrene exposure. Studies have indicated that protection of the respiratory system *via* personal respirators is beneficial. Skin protection has a negligible effect on overall exposure but is still necessary for protection against dermatitis (Brooks et al., 1980).

Acute and Chronic Effects The acute effects of excessive exposure to styrene are irritation of the skin, eyes, and airway and depression of the CNS (Härkönen, 1978; Leibman, 1975). High concentration exposures can be hepatotoxic. Disturbances detected in workers include nausea, vomiting, fatigue, and prenarcotic symptoms such as dizziness and drowsiness (Wilson, 1944). *In vitro* studies have found styrene to be acutely cytotoxic to neuronal and nonneuronal cells at high concentrations (Kohn et al., 1995), as well as reducing peroneal nerve conduction velocity (Lilis et al., 1978). The irritant properties of styrene are usually sufficient to protect workers against serious overexposure, but perception of the characteristic odor diminishes with continued exposure.

The chronic effects of styrene have been evaluated, with conflicting reports and studies emerging. A potential confounder of the epidemiological studies involves exposure to other industrial chemicals used during manufacturing, such as benzene and 1,3-butadiene. There have been reported associations between lymphatic and hematopoietic cancers and exposure to styrene (Kolstad et al., 1994; Koveginas et al., 1994). However, other cohort studies do not report an

association between lymphatic and hematopoietic cancers and exposure to styrene (Ott et al., 1980; Wong et al., 1994). Studies examining prostate cancer and styrene exposure did not find any association (Coggon et al., 1987; Hodgson and Jones, 1985). An IARC review of current literature has led to classification of styrene as “*. . . possibly carcinogenic to humans (Group 2B)*”, with recommendations for further study (IARC, 1994). Further, the US National Toxicology Program (NTP) classified styrene as “[r]easonably anticipated to be a human carcinogen” in its Report on Carcinogens (NTP, 2014a).

Other chronic effects of styrene exposure may include chronic respiratory effects of bronchitis, pulmonary changes, and styrene-induced asthmatic-like conditions (Hayes et al., 1991; Moscato et al., 1987). Analysis of electroencephalographic readings from some exposed workers has shown changes in cerebral activities (Matikainen et al., 1993). Changes in personality have been reported, but validation of these results has not been provided (Lindström and Martelin, 1980). Styrene can pass the placental barrier, but no adverse reproductive effects have been associated with exposure to styrene at occupational levels in compliance with guidelines (Brown, 1991).

Workers occupationally exposed to high concentrations of styrene should be removed from the area as soon as possible. Many of the styrene-induced effects are reversible once exposure is discontinued. Treatment of persistent effects should be based on management of the signs and symptoms.

Target Site and Mechanism of Action The amount of styrene absorbed *via* inhalation is about 60–70% (Stewart et al., 1968). Once styrene absorption has occurred, it is rapidly distributed throughout the body. It has been shown in animal studies to cause tumors of the forestomach and hepatocellular tumors in male mice (IARC, 1994). Styrene has also been found to be stored in adipose tissue and released slowly (IARC, 1994).

Both styrene and its metabolite, styrene-7,8-oxide (SO; CASRN: 96-09-3), are able to cross the blood–brain barrier and thus affect the nervous system (Savolainen and Vainio, 1977). This is possible because of the hydrophobic nature of both compounds.

Styrene is biotransformed to SO by a cytochrome P-450-mediated monooxygenase system (Foureman et al., 1989; Leibman, 1975). Styrene-7,8-oxide is subsequently detoxified by two different pathways: enzymatic hydration to phenylethylene glycol, or styrene glycol, *via* microsomal epoxide hydrolase (Oesch et al., 1971) and a conjugation reaction involving glutathione S-transferase detoxification. Further biotransformation of these metabolites yields mandelic acid and phenylglyoxylic acid, which are excreted in the urine. Styrene has also been found to be directly excreted in the urine in small amounts (Periago et al., 1996). Metabolism of styrene also occurs in the heart, kidneys, and lungs, but most styrene is metabolized in the liver (Cantoni et al., 1978).

Genetic changes have been linked to styrene exposure *in vivo* and *in vitro*. One study suggests that low, chronic exposure to styrene may be able to produce more persistent DNA adducts and mutations than acute, short-term exposures (Bastlová et al., 1995). The carcinogenicity of SO has been studied, and results suggest that the metabolite is a carcinogen and responsible for DNA adducts and sister chromatid exchanges (Bastlová et al., 1995; Uusküla et al., 1995). The NTP classified SO as “[r]easonably anticipated to be a human carcinogen” in its Report on Carcinogens (NTP, 2014b).

Biomonitoring The most effective means of monitoring styrene exposure is through measurement of styrene and its metabolites in the urine. The measurement of mandelic acid and phenylglyoxylic acid is most common, but the determination of which metabolite to measure is subjective because both are present. These measurements have been the subject of some controversy because individual differences have been noted as the result of concurrent exposure to other solvents, alcohol consumption, and individual variation of metabolism (Guillemin and Berode, 1988). More recent studies have shown that direct measurement of styrene in urine by gas chromatography is also reliable (Gobba et al., 1993; Periago et al., 1996).

Some studies have also been reported that measure the hemoglobin adducts formed by the SO metabolite in mice and in humans. Though adducts are present in human hemoglobin, their predictive value has not been validated (Severi et al., 1994).

Risk Assessment Many studies have been done on occupational exposure to styrene and adverse health effects in humans. Most research is in agreement that, although a long-term exposure hazard cannot be completely ruled out at this time, any carcinogenic risk is likely to be small (Coggon, 1994).

Cellulose Derivatives (Cellulosics)

Cellulose acetate (CASRN: 9004-35-7), cellulose propionate, and cellulose butyrate, have almost entirely replaced industrial use of cellulose nitrate, a highly flammable source of nitrogen dioxide gas when burned. Modern cellulosics are used in films and coatings in small parts such as knobs, eyeglass frames, and pencil barrels. The properties of these compounds rely primarily on their additive and individual properties, but in general they are insoluble and are especially clear and lustrous. Direct toxicity is not associated with these polymers, but pyrolysis products and their high flammability can cause serious health hazards. An important characteristic of their burning properties is a tendency to smolder. Organic in nature, these polymers are chemically modified from wood and cotton derivatives and thermally degrade to high concentrations of CO₂ and CO. Industrial fires involving these products should be managed with caution. The manufacturing process may involve exposure to solvents and organic acid compounds that may result in skin reactions.

Fluoroplastics

Fluoroplastics vary somewhat in composition and include polytetrafluoroethylene (PTFE), polyfluorinated ethylene propylene, and polyvinylidene fluoride. They are manufactured from a fluorination of a carbon polymer backbone. These materials have high thermal stability, are biologically inert, and can be used for human organ prostheses, as well as for highly resistant insulations, chemical piping, containers, gaskets, and coatings. Their well-known high resistance to heat makes them a useful material in high temperature applications such as boiling and baking. The widely used Teflon® is a variety of fluorocarbon resin.

Polytetrafluoroethylene One of the most notable compounds in this group of polymers is PTFE (CASRN: 9002-84-0). It is produced by a polymerization of tetrafluoroethylene. The general fluoroplastic characteristics of thermal and chemical stability are well demonstrated in this polymer. Animal studies and human evidence do not indicate that these materials are carcinogenic. Most case studies of health effects were a result of exposure to PTFE. Exposure to degradation products is of greatest health concern. Exposure to the dusts of this plastic can be harmful and are regulated as a nuisance dust by most agencies. Pyrolysis products from PTFE first become evident at temperatures above 300 °C (572 °F). These products include tetrafluoroethylene, hydrogen fluoride, silicon tetrafluoride, and an incomplete waxy substance (Okawa and Polakoff, 1974). Hexafluoropropylene and octafluorisobutylene are released at higher temperatures, and the toxic compounds perfluorisobutylene and carbonyl fluoride are evolved above 400 °C (752 °F). All of these compounds are

potentially lethal at high concentrations, with the most toxic degradation product being perfluoroisobutylene. Workers who smoke have been the subject of many reports of "polymer fume fever" as a result of PTFE resin-contaminated cigarettes. The burning ember reaches high enough temperatures [about 875 °C (1,607 °F)] to expose the worker to sufficient toxic pyrolysis products. Illness resulting from exposure to the pyrolysis of fluorohydrocarbons is similar to influenza and was first described by the term "polymer-fume fever" by Harris (1951). Subsequent reports, by Lewis and Kerby (1965) and Wegman and Peters (1974), described the symptoms that appear 4–5 h after exposure to sublimates or thermal decomposition products of fluoroplastics. These consist of chest tightness and dyspnea, followed rapidly by general malaise, aching, weakness, headache, and cough. Chills and fever to 40°C (104°F) follow the onset of symptoms by about 12 h. The acute illness may be alarming and uncomfortable when it is severe, but it is of short duration, subsiding within 48 h.

Acute exposure is the main concern, but some reports indicate that repeated episodes of polymer fume fever may have serious pulmonary effects and long-term cumulative effects (Brubaker, 1977). Pulmonary edema is a rare yet serious outcome.

Harmful worker exposure is not commonly related to the production of the polymers themselves because the reactions are conducted in closed systems. The chemical intermediates include fluorohydrocarbons of the so-called Freon type, which are relatively inert or have only narcotic properties at high concentrations. More active reactants may occur in the polymerization process, and these may be highly corrosive and possibly nephrotoxic, but acute exposures are unlikely.

Worker protection is provided through warnings to the workers, prohibition of smoking in the workplace, hand washing, and attention to airborne dust and heat sources. Adequate ventilation and proper housekeeping should be sufficient to avoid severe exposures. Processing temperatures should be monitored to avoid decomposition product exposure. In the past, biomonitoring of workers involved in the production of fluoroplastics revealed fluoride concentrations in the urine below levels corresponding to a toxic exposure (Polakoff et al., 1974). These early tests led to the conclusion that occupational exposure to these polymers is not a serious threat to workers' health.

Polyamides

Polyamides, such as the nylons, are used in fibers, filaments, castings, and extrusions and can be classified into two families: the diamine-dibasic acid type and the condensed amino acid type. No known toxic effects are associated with the end product of either family, although nylons are not entirely inert biologically. Diamine-dibasic acid nylons are prepared by the reaction of a diamine, such as hexamethylenediamine, with an acid, such as adipic acid or sebaceous acid. The diamine has a primary irritant as well as a sensitizing effect on skin and is irritating to the eyes and upper airway. The dibasic acids are not of a significant health hazard.

Nylons are synthetics produced as a fiber, plastic, or film. They are extensively used industrially and domestically because of their stability, which renders them resistant to solvents and abrasives. Household appliances manufacturing and the automotive industry are the two largest users of nylon. Nylons 6 and 6,6 are two of the most important and widely used polyamides. The formation of nylon 6 (caprolactam; CASRN: 25038-54-4) involves a batch or continuous polymerization process in which caprolactam reacts with water at high temperatures. Nylon-6,6 (CASRN: 32131-17-2) is manufactured by condensing a nylon salt formed from a solution of hexamethylene diammonium and adipic acid. Special-purpose nylons produced include nylon-6,10, nylon-6,12, and nylon-11. Although nylons themselves are not completely biologically inert, the relatively few effects reported may be attributed to monomers and additives. Rare skin reactions to virgin nylon products have been described and have been attributed to residual reactants or to low molecular weight polyamides (Morris, 1960). Dyes and finishes applied to nylon for wearing apparel have also been uncommon causes of contact dermatitis.

Caprolactam Caprolactam (hexahydro-2H-azepin-2-one; CASRN: 105-60-2) is the main component of the synthetic fiber nylon 6. It is a white, crystalline solid with an unpleasant odor. A nonvolatile compound, it has a low vapor pressure of 0.0000008 mmHg and is not found to occur in nature. Caprolactam is 53% soluble in water by weight and is also soluble in organic solvents. Production involves a conversion of cyclohexanone to caprolactam in the presence

of aqueous ammonia. The standards for dust exposure to this chemical are: 5 mg/m³ TLV TWA for ACGIH and 1 mg/m³ REL TWA for NIOSH, with a 15-min short-term exposure limit of 3 mg/m³ (ACGIH, 2001; NIOSH, 1994). For vapor exposure NIOSH is recommending 1 mg/m³ REL TWA and ACGIH 5 mg/m³ TLV TWA.

The toxicity of caprolactam is relatively low. The IARC concluded that “[t]here is evidence suggesting a lack of carcinogenicity of caprolactam in experimental animals” and that it is “... probably not carcinogenic to humans (Group 4)” (IARC, 1999). Fukushima et al. (1991) reported a wide spectrum of carcinogenicity data that demonstrated no link between exposure to caprolactam and cancer. The sites of action for caprolactam are thought to be the eyes, skin, respiratory system, CNS, cardiovascular system, liver, and kidneys. Liver damage was reported in rats as elevated serum alanine aminotransferase levels, but treatment did not cause DNA damage (Kitchin and Brown, 1989). There have been some reported cases of eye and upper airway irritation from exposure to caprolactam vapor (Ferguson and Wheeler, 1973). Uncommon contact dermatitis has been reported, but this is an infrequent outcome (Morris, 1960).

The metabolism of caprolactam in humans has not been described. In rats it has been shown that caprolactam is excreted in the urine as both unchanged caprolactam and as epsilon amino acid (Goldblatt et al., 1954).

The most prominent air contaminant in many typical polycaprolactam nylon operations is derived from eutectic mixtures of diphenyl and diphenyl oxide. This material is heated and pumped under pressure as a heat transfer fluid. In such applications the material may be heated to temperatures as high as 370 °C (698 °F); thus there is a potential for serious burns. Small leaks may give rise to vapors and mists, which reportedly induce nausea. Excessive exposure and poor hygienic conditions have resulted in liver injury and nervous system changes.

Degradation products found in smoke from nylon 6 fires have been identified. Upon combustion of nylon 6, HCN, CO, and CO₂ are produced. Nylons in general can release significant amounts of ammonia gas (Morikawa, 1978). Particular caution should be used when an industrial fire involves these polymers.

Polycarbonates

Polycarbonates are polyesters formed from the polymerization of bisphenol through carbonate linkages. Bisphenol A (4,4'-isopropylidenediphenol; CASRN: 80-05-7) with a phosgene carbonic acid derivative is most commonly used. There are two processes involved in producing these resins, depending on the functionality of the carbonate desired. Polycarbonate resins are amorphous and unusually stable in most solvents. The plastic is used primarily for small mechanical parts such as gears and cams and also in products such as bottles because of its strength and rigidity. Biological effects have not been associated with the finished polymer. Hazards are associated with production of the polymer, and adverse reactions may be associated with exposure to BPA, phosgene, and other co-monomers and additives used during the production of the polymer. Processing fumes of this resin may contain a variety of irritant substances. Procedures for minimizing occupational exposure include adequate ventilation and personal protection.

Bisphenol A is a halogenated, cyclic hydrocarbon that is also used as a fungicide and a component of epoxy resins. It is a white solid that is insoluble in water. Caution should be taken with this compound because it is incompatible with strong oxidizers, strong bases, acid anhydrides, and acid chlorides. The toxicity of this compound is generally low, but after dermal absorption it may affect the liver, spleen, and pancreas. A skin allergy after chronic exposure may occur, and a severe enough acute exposure may even burn the eyes and skin. Biotransformation of this compound in the rat results in metabolites primarily excreted as glucuronide conjugates in urine and as hydroxylated compounds in feces (Knaak and Sullivan, 1966). Recent *in vitro* studies have shown that oxidation of up to 70% of BPA to bisphenol *o*-quinone via a semiquinone intermediate is an important

metabolic pathway (Atkinson and Roy, 1995a). The reactive intermediate is capable of covalently binding to DNA and producing adducts (Atkinson and Roy, 1995b). The characterization of BPA metabolism and its intermediates is not complete, and more studies are necessary. Bisphenol A, like many of the dihydroxyphenols, is structurally similar to synthetic estrogens and has demonstrated estrogenic effects in female rats. Recommendations for occupational hygiene include proper exhaust ventilation and careful washing of clothes and skin that come in contact with BPA.

Polyvinyl Chloride

Polyvinyl chloride (PVC; CASRN: 9002-86-2) is a widely used synthetic polymer made from vinyl chloride monomer (VCM). In industry it is used primarily in floor tiles, ducts, waterproof clothing and upholstery, insulation, piping, packaging, and medical devices. A pure polymer resin of PVC is rigid and somewhat unstable at high temperatures and under exposure to light. A variety of additives are used to increase the elasticity or rigidity, heat stability, and flame resistance, and other fillers and stabilizers are used as well. There are four polymerization processes, which vary in frequency of use. The molecular weight and size of the resin produced depend on the process used. As with most polymers, PVC is generally considered to be biologically inert. Exposures to PVC dusts, degradation products, and additives, and to VCM are the greatest hazards.

PVC Dusts Exposure to PVC dust can occur during many uses of the polymer. Earlier studies have indicated that certain types of PVC dust are capable of causing cell membrane damage (Richards et al., 1975). Epidemiological and animal studies have shown significant increases in pulmonary dysfunction, most often pneumoconiosis associated with PVC dusts. This is not uncommon when chronic exposure to inert dusts occurs. The reaction occurs mostly in the lung tissues, with an inflammatory response leading eventually to fibrosis and granulomatous lesions (Agarwal, 1983). Other clinical symptoms can occur simultaneously with pneumoconiosis, such as systemic sclerosis that is thought to be caused by the presence of nondigestible particles in macrophages (Studnicka et al., 1995). Treatment of

excessive exposure to dusts and the associated signs and symptoms is discussed in a separate section. Occupational exposure to PVC dusts is regulated as a respirable particulate by OSHA and a particle not otherwise specified by ACGIH.

Degradation Products Though PVC does not depolymerize under extreme heat, it will thermally decompose to more reactive and harmful products. The most harmful product detected in the smoke from PVC fires has been hydrogen chloride, at relatively high concentrations (Baxter et al., 1995). Hydrogen chloride is a respiratory irritant that can aggravate asthma and allergic conditions, as well as irritate the mucosal membranes. Other components of PVC smoke include CO and a variety of hydrocarbons. Exposure to this smoke should be avoided.

Vinyl Chloride Monomer Vinyl chloride monomer (chloroethylene; CASRN: 75-01-4) is the main component of polyvinyl chloride. First used as an anesthetic before the 1950s, it is today one of the most widely used monomers in the plastics industry. At room temperature it exists as a colorless, flammable gas with an ethereal odor. The explosive properties of this chemical were the major industrial hazard before the discovery of its biological effects. Slightly soluble in water, VCM is more soluble in organic solvents. It is not known to occur naturally and has a vapor pressure of 2,580 mmHg at 20 °C (68 °F) and a relative vapor density of 2.15 (air = 1). As one of the first recognized occupational carcinogens, the toxicity of VCM has been well characterized.

Industrial Hygiene Vinyl chloride monomer is synthesized by a halogenation process involving ethylene (Budavari, 1989). Thousands of workers every year are potentially exposed to VCM occupationally. Workers involved in the production of PVC and VCM are those most likely to be exposed to the highest levels of vinyl chloride, particularly those involved in the cleaning and maintenance processes (Purchase et al., 1987). Inhalation is by far the most common route of exposure. Today, airborne levels of VCM in well-maintained settings generally are below 1 ppm because of the nature and reputation of the chemical. In the past, exposure to unreacted VCM in the postproduction areas of PVC manufacturing were of some concern, but current washing procedures have brought levels to an almost undetectable amount. Since the association of VCM with hepatic angiosarcoma (ASL), the permissible levels of exposure to vinyl chloride have been reduced. The OSHA has set its PEL TWA at 1 ppm (5 ppm for 15 min). The NIOSH has listed the chemical as an occupational carcinogen, recommending that exposure be reduced to the lowest possible levels (NIOSH, 1994). The ACGIH has set a TLV TWA value of 1 ppm (ACGIH, 2001).

Current practices in most industrial settings have maintained low levels of airborne vinyl chloride. High concentrations have a detectable odor, but concentrations

likely to be encountered in the workplace are undetectable by odor. Equipment leaks and accidents are probably the cause of most cases of overexposure. Personal respirators and maintenance are recommended to prevent accidental excessive exposure.

Acute Effects Early reports of the effects of vinyl chloride focused on the acute effects of the compound. At high concentrations VCM has a narcotic effect and depresses the CNS, beginning at levels above 8,000 ppm (Mastromatteo et al., 1960). Cases of workers becoming dizzy or unconscious, or both, have been reported, although few occupational deaths have been associated with VCM. The flammability of the gas, as well as cardiac and circulatory disturbances in patients, was a deterrent for using VCM in surgical procedures (Oster et al., 1947). Vinyl chloride is a liquid at temperatures below -21.7°C (-7.06°F). Dermal contact with the liquid at this temperature causes frostbite-like symptoms.

Chronic Effects and Target Organs Chronic exposure to vinyl chloride has been well documented and may have a wide range of effects on various organs and organ systems. The primary target organ is the liver, with effects also noted in the CNS, the blood and lymphatic system, and the respiratory system. The carcinogenicity of VCM has been extensively studied in recent years.

One of the first occupational disorders associated with vinyl chloride was acroosteolysis and Raynaud's phenomenon in the hands of those who cleaned autoclaves and monomer-manufacturing vessels (Harris and Adams, 1967; Wilson et al., 1967). These reports were among the first to question the moderate toxicity associated with VCM at that time. Systemic sclerosis, affecting the skin and other organs, has also been observed in some workers (Haustein and Ziegler, 1985). Diagnosis of acroosteolysis was accomplished by use of X-rays. A combination of these signs and symptoms led to the development of a diagnosis of "vinyl chloride disease" associated with the industry. Treatment of symptoms and removal of the worker from the VCM environment were helpful in reversing some of the conditions. A study by Simonsen et al. (1994) has identified VCM as a possible neurotoxicant, with only limited evidence in humans.

The most notable and well-known chronic effect of vinyl chloride is the development of ASL. First reported by Creech and Johnson (1974), several epidemiological studies since then have confirmed this association (Smulevich et al., 1988; Wong et al., 1991; Wu et al., 1989). The extremely rare occurrence of this disease in the general population was the most prominent factor in discovering the correlation. Symptoms of this carcinoma include hepatomegaly accompanied by splenomegaly and gastrointestinal bleeding (Heath et al., 1975). Animal studies have confirmed the epidemiological

evidence and identified the mechanism for the development of the cancer (Froment et al., 1994; Viola et al., 1971).

Other cancers have also been linked to vinyl chloride exposure, although none as strongly as ASL. Associations have been reported with other liver cancers and brain and CNS cancers, and weaker and more controversial associations have been reported with lung and blood/lymphatic cancers (Beaumont and Breslow, 1981; Weinman and Chopra, 1987; Wong et al., 1991; Wu et al., 1989). These associations have not been verified at the present time. An evaluation of three teratogenicity studies does not provide any significant evidence that VCM is a cause of birth defects (Hemminki and Vineis, 1985).

Mechanism of Action The primary site for metabolism of vinyl chloride is the liver. As with many other xenobiotics, it is not the VCM that is directly responsible for cell injury. The metabolism of VCM produces reactive intermediates, which, as a result of detoxification, lower intracellular glutathione levels after exposure (Barton et al., 1995). In an early study in rats, Hefner et al. (1975) studied the possibility that VCM is metabolized by the alcohol dehydrogenase pathway to chloroethylene oxide, which spontaneously rearranges to chloroacetaldehyde. There is a similar pathway in humans resulting in an electrophilic epoxide metabolite produced by cytochrome P-450 2E1 (Guengerich et al., 1991). Both of these metabolites produce adducts with DNA and proteins (Fedtke et al., 1990). It is these metabolites and pathways of biotransformation that are most responsible for the carcinogenic activity of vinyl chloride. Studies have suggested that these pathways and metabolites are the cause of cancers, tumors, and lymphatic tissue disorders in humans and animals (Froment et al., 1994; Fucic et al., 1995; Trivers et al., 1995). Although some of the vinyl chloride is expired in air, a larger amount has been observed to be excreted in urine in the form of subsequent polar compounds (Watanabe et al., 1976).

Complications involving Raynaud's phenomenon arise from blood vessel obstruction in the extremities. X-rays demonstrate osteolytic lesions, likened to "bullet holes," in the distal phalanges in conjunction with acroosteolysis (Haustein and Ziegler, 1985). Massive acute poisonings in rodents have identified congestion of the lungs with pulmonary edema and hemorrhages as the main cause of death (Mastromatteo et al., 1960).

Biomonitoring Biomonitoring of radiolabeled ^{14}C has been used to examine the metabolic pathways of VCM and to measure levels exhaled as $^{14}\text{CO}_2$ in expired breath and as urine metabolites. However, these monitoring results would not be useful for assessment of the low exposures likely to occur today. Chromosomal breakage and sister chromatid exchanges have also been evaluated as possible monitoring aids. They may be useful for evaluating immediate exposure

but are less likely to be accurate for long-term monitoring because of DNA repair (Du et al., 1995). Measurements of certain serum antibodies may be useful as subclinical diagnostic tools for assessing ASL and other cancer risks (Trivers et al., 1995).

Risk Assessment A risk assessment for vinyl chloride is possible with a few important assumptions made regarding animal modeling. It would not be entirely correct to assume that the dosimetry and lifetimes of an experimental animal and humans are wholly comparable. Risk assessments made for VCM have produced different results, depending on the assumptions made in the calculations. Extrapolations of past exposures confounded by the long latency period of ASL (as long as 20 years) have led some researchers to predict a relatively high number of ASL cases in the future (Purchase et al., 1987).

Acrylamide

Acrylamide (2-propenamide; CASRN: 79-06-1) is a vinyl monomer produced as a white, crystalline solid. As a monomer, acrylamide is used in the manufacture of certain products such as grout material, adhesives, and biotechnical electrophoretic gels. After polymerization, polyacrylamide is primarily used as a flocculent in water treatment processes and in secondary oil recovery. One of its more favorable qualities is its ability to improve solubility, adhesion, and cross-linking of polymers. The compound is highly soluble in water and less soluble in organic solvents. As a consequence of its high solubility, acrylamide has been detected in potable water supplies. Acrylamide has a low vapor pressure of 0.007 mmHg at 25 °C (77 °F) and a vapor relative density of 2.5 (air = 1). At room temperature it is stable but may spontaneously polymerize upon exposure to ultraviolet light or upon melting. It has not been found to occur in nature.

Industrial Hygiene Acrylamide is produced from a catalytic hydration reaction of acrylonitrile with a copper-based or microbiological catalyst (IARC, 1994). Production of acrylamide may lead to exposure to either or both monomers. Dermal contact is the most probable route of exposure, whereas inhalation is of secondary importance because of its low vapor pressure. Addition of monomer and hand mixing are tasks in which possible dermal contact is high. Workers involved in the manufacturing of acrylamide, its polymer, or products containing the monomer are likely to be exposed. Surprisingly, estimations of exposure by NIOSH conclude that a larger percentage of contact results from the presence of unreacted monomer in polymer-containing products (IARC, 1994). Important factors in exposure are the lack of worker understanding of the hazards of acrylamide and

poor housekeeping and personal hygiene (Cummins et al., 1992). The chronic neurotoxicity associated with acrylamide led to the development of engineering controls, which resulted in low workplace concentrations. The NIOSH and the ACGIH have set similar values for their dermal REL TWA and TLV TWA at 0.03 mg/m³ (ACGIH, 1995; NIOSH, 1994). The OSHA has set its PEL TWA at 0.3 mg/m³.

Industrial monitoring of surface wipe samples and the presence of monomer in the polymer can be achieved with high performance liquid chromatography using water as an eluent (Skelly and Husser, 1978). Air monitoring, although not as important, may also be used with a variety of techniques. Protective clothing and gloves are a necessity for preventing overexposure to acrylamide. Personal respirators may be used for extra protection after protective clothing has been provided.

Acute and Chronic Effects The acute and chronic effects of acrylamide exposure are similar. In some cases a large enough single exposure can result in chronic toxicity. The duration of exposure and total dose determine the severity of toxic effects. These effects, which may be delayed for several hours, include somnolence, confusion, hallucinations, tremors, and possibly seizures with cardiovascular collapse. Recovery may take a few weeks to months, and in some cases prolonged extremity weakness and loss of reflexes may be observed. Visual impairment and eye irritation may result from ocular exposure to fumes or dusts.

Chronic exposure to acrylamide is more common. Such exposure may result in effects related to the peripheral and CNS. Early effects of peripheral neuropathy may include numbness of the hands and feet, peeling skin, loss of reflexes and sensation, muscular atrophy, and loss of vibration sense (Bachmann et al., 1992; He et al., 1989). Abnormalities related to acrylamide exposure have been identified in as much as 32% of the total work force (Myers and Macun, 1991). Weight loss, anorexia, and gastrointestinal upset may be seen as well.

Epidemiological studies of worker populations have not demonstrated an increase in cancer-related mortality despite acrylamide's possible carcinogen status (Collins et al., 1989). In contrast, animal studies provide evidence of exposure-induced cancers of the thyroid gland-follicular epithelium, CNS, mammary gland, scrotal mesothelium, and uterus when acrylamide is ingested (Johnson et al., 1986). Chronic skin application of acrylamide acted as a skin tumor initiator and systemically induced lung adenomas (Bull et al., 1984). A review of present data has prompted the IARC to classify acrylamide as “. . . probably carcinogenic to humans (Group 2A)” (IARC, 1994). The ACGIH has changed its carcinogenic rating from A2 to A3, a change from a suspected human carcinogen to a confirmed animal carcinogen with unknown relevance to humans (ACGIH, 2001).

Diagnosis and Treatment Sites of action identified in humans are the peripheral and CNS, the eyes, and the skin, with the reproductive system being identified in animals. Diagnosis of acrylamide-induced peripheral neuropathy can be made using standard neurological procedures. Documentation of exposure to the compound is essential in concluding that acrylamide is the main cause. The clinical signs described above may be reported by an affected worker to support differential diagnosis. Decreases in vibrotactile thresholds may be quantified using a Vibratron II or similar device (Bachmann et al., 1992). Electroneuromyographic assessment may be made early by measuring decreases in sensory action amplitude, abnormalities in electromyography, and prolongation of the ankle tendon reflex (He et al., 1989).

First, an exposed worker should be removed from the area of exposure. Exposed skin should be thoroughly washed with soap and water. Rashes and other acute effects may appear and should be systematically treated as necessary. Treatment of excessive exposure to acrylamide with pyridoxine, pyruvate, and *N*-acetylcysteine is experimental, and their efficacy has not been established. Neurological manifestations will require time to gradually subside and return to normal.

Mechanism of Action The importance of the dermal route of exposure is likely a result of the ability of acrylamide to be rapidly absorbed. Chemicals that are soluble in both water and organic solvents are generally able to cross the epidermis quickly.

Metabolism of acrylamide is not well reported because further studies are required to fully identify the mechanism involved. It has been reported in some studies that acrylamide is metabolized in the body to a more reactive epoxide intermediate, glycidamide (Bergmark et al., 1991; Calleman et al., 1994). Cytochrome P-450 mixed-function oxidase is the likely enzyme for this reaction, although the results have been conflicting (Abou-Donia et al., 1993). Acrylamide-induced peripheral neuropathy has been the subject of many investigations. Fullerton and Barnes (1966) showed that acrylamide-poisoned rats exhibited degeneration of axis cylinders and myelin sheaths. This retrograde degeneration involved nerves with larger diameters and longer lengths (Spencer and Schaumburg, 1977). A model of acrylamide-induced peripheral nerve damage has been reported that involves giant axonal swelling in which the attack occurs at the nodes rather than the nerve terminal (Tilson, 1981). In more recent studies, fast axonal transport deficiencies were identified as being caused by both acrylamide and glycidamide (Harris et al., 1994). The underlying mechanisms of acrylamide-induced degenerations are likely a combination of these effects.

Biomonitoring Several methods are available for measuring occupational exposure to acrylamide. Both acrylamide and its metabolite, glycidamide, are conjugated with glutathione

and excreted in the urine as mercapturic acid metabolites. Measurement of these metabolites can be used to monitor exposure. Other methods include measurement of plasma levels of acrylamide/glycidamide and the presence of hemoglobin adducts (Bergmark et al., 1993; Calleman et al., 1994). The hemoglobin adducts form by attachment to cysteine residues and the N-terminal valine. Perhaps the most complete means of biomonitoring is demonstrated in a report by Calleman et al. (1994) in which a neurotoxicity index was developed and significantly correlated with levels of mercapturic acid in the urine, hemoglobin adducts of acrylamide, accumulated *in vivo* doses of acrylamide, employment time, and vibration sensitivity.

Polyvinylpyrrolidone

Polyvinylpyrrolidone (PVP; CASRN: 9003-39-8) is a polymer of 1-ethyl-pyrrolidone. This plastic is soluble in water and organic solvents. Typically, it is polymerized with heat or in the presence of a catalyst. The grade of PVP used, classified by its average molecular weight, is known by its K value. A K-12 value, for example, corresponds to a viscosity-average molecular weight of 3,900. Polyvinylpyrrolidone is characterized by very low toxicity and is used in an iodine complex as povidone, an antibacterial solution. It is also used in drugs, food, and cosmetics as a stabilizer or thickening agent. More industrial applications include adhesives, coatings, and cleaners. The material used in the US is PVP rather than shellac, which is used in United Kingdom. Its use in foodstuffs is an indication of the lack of toxicity of this material. Oils and propellants containing PVP have been used in hair sprays.

Some reports of toxicity upon PVP exposure have been published, although these case reports have not been validated. Bergmann et al. (1958) described pulmonary damage that followed exposure to PVP hair sprays and diagnosed the disease as thesaurosis. McLaughlin et al. (1963) reviewed the literature and reported on the 775 chest X-rays of British hairdressers, and Cares (1965) presented the US experience.

These reported cases resembled sarcoid clinically, radiographically, and by histopathological findings. Alternative diagnoses in the literature are interstitial fibrosis and foreign body granulomas. McLaughlin et al. (1963) concluded that it is possible to diagnose thesaurosis by chest X-ray, perhaps because of hair spray particles in the lung, but they could not correlate the quantity of spray inhaled and clinical findings. Their single case of a hairdresser was thought to be an example of unusual hypersensitivity. Gowdy and Wagstaff (1972) described five cases with pulmonary infiltrates on chest X-ray and four with respiratory complaints, all exposed to a variety of aerosols and all cured by discontinuation of exposure. Four biopsies and lung function tests were nonspecific. Furthermore, these investigations surveyed 227 beauty shop operators and found none ill, but 11 with increased bronchovascular markings on chest X-ray. Thesaurosis appears to be chiefly a problem of different diagnoses. When used as a plasma expander, PVP is generally thought to be safe. One reported case of a woman who received massive amounts of PVP injections clinically showed intracellular bone deposits of PVP and demonstrated pathological fractures as a result (Kepes et al., 1993). These types of massive, chronic exposures are unlikely in the workplace but are important in identifying possible long-term effects. Mutagenicity studies have not shown any significant increased frequency of sister chromatid exchanges *in vitro* (Ray et al., 1995).

Others

Additives The polymers previously discussed are modified through the addition of materials that impart specific,

desirable properties to the finished product. These additives, not being large and inert polymeric macromolecules, may have biological characteristics that are greater than those of the basic plastic to which they are added. For the most part, the biological properties of these additives have not been well established. However, the metallic and organometallic compounds do present a known hazard. Exposure to additives tends to be small because they are introduced primarily in the early steps of formulation, and relatively few workers are exposed.

Plasticizers Plasticizers are mixed into polymers to increase flexibility and workability. Phthalate esters account for approximately 2/3rd of the total domestic plasticizer production and include di(2-ethylhexyl)phthalate (CASRN: 117-81-7), diisooctyl phthalate, and dibutyl phthalate. Di(2-ethylhexyl)phthalate is the most commonly used and is of low toxicity, although it may be a factor in pulmonary edema and in producing bronchial asthmatic conditions after excessive inhalation exposure (Roth et al., 1988). Although no such evidence exists in human data, animal studies report testicular toxicity as a result of damage to Sertoli and Leydig cells (Creasy et al., 1988; Jones et al., 1993). It is also characterized as a liver and kidney toxicant in mice after chronic exposure (Ward et al., 1988). Adipate, sebacate, and azelate esters are also commonly used, especially when low temperature flexibility is desired. These esters have low toxicity. Polyester and epoxidized plasticizers are also of low toxicity, and the epoxy materials can be sensitizers.

Phosphate esters, among the first plasticizers to be developed, impart flame resistance to polymers. Tricresyl phosphates have been the most important, and those used as plasticizers are generally free of the ortho isomer, which has prominent neurotoxic properties. Triphenyl phosphate, cresyl diphenyl phosphate, and octyl diphenyl phosphate are also used. Standard operating procedure should be used to ensure purity of materials in this group and the absence of neurotoxic components. The low vapor pressure of the aromatic phosphate esters prevents excessive exposure at ambient temperatures.

Other plasticizers include chlorinated paraffins and chlorinated biphenyls. The latter group is associated with chloracne and liver injury; the paraffins lack this toxicity.

Flame Retardants Flame-retardant properties can be inherent in certain plastics because of high chlorine content or, as in the case of the polycarbonates, because they evolve CO₂ on thermal decomposition. They are required in polymers important in electrical and high temperature applications. Additives of hygienic interest include tricresyl phosphate, chlorinated diphenyls and triphenyls, bromine compounds, halogenated phosphates, and antimony trioxide. Flame-retardant intermediates that are actually incorporated

into the polymer usually contain chlorine or bromine, as discussed in the chapters on flame retardants.

Stabilizers Stabilizers retard the natural degradation of plastics caused by light and heat. Potentially hazardous stabilizers are lead salts or soaps, barium and cadmium compounds, and organotin compounds. Alternative compounds for lead and cadmium are or have been developed and put into use. Ultraviolet absorbers are added to protect polymers against those wave lengths that tend to disrupt bonds in organic material. Typical absorbers used are the benzophenones, benzotriazoles, aryl esters of salicylic acid, benzoic and terephthalic acids, and organonickel compounds. Antioxidants include alkylated phenols and bisphenols, amines, and organic phosphites.

Organic Peroxides Organic peroxides are used to cure polyester resins, to initiate polymerization of vinyl and diene monomers, and to cross-link polymer chains such as polyolefins or silicones. More than 45 organic peroxide compounds are available for industrial use. Although not all peroxides are hazardous, they are, in general, strong oxidizing agents capable of causing skin irritation or burns and severe eye damage. Peroxides on the skin or in the eyes should be removed promptly with large amounts of water. The use of face shields and protective clothing is advisable for those who handle organic peroxides. These compounds tend to be unstable and to undergo spontaneous decomposition. Fires or explosions can result from the contamination or improper storage of organic peroxides.

Inert Fillers and Fibrous Reinforcements Inert fillers and fibrous reinforcements are added to many formulations to improve their mechanical properties, to act as extenders to reduce costs, or to impart special properties to the plastic. The addition of silica, asbestos, talc, mica, glass flakes and fibers, and other materials is common. Some of these substances have inherent biological reactivity that may create an exposure hazard at the time of polymer formulation or when the finished plastic is cut or machined. Under these circumstances, potentially injurious dusts may be generated. Rapid developments within the plastics industry have created high thermal conductivity polymers (beryllia-filled epoxy), antifriction elastomers (molybdenum-disulfide filled), radiation shields (lead-filled polyolefin), and plastics reinforced with exotic fibers (boron, sapphire). Adverse biological effects may be associated with the use of some of these materials.

Foaming Agents Foaming agents may be added to increase the porosity of plastics that normally foam or to create foamed structures from plastics that have no inherent foaming properties. Foaming agents may generate gas by either physical or chemical means. Physical foaming agents are

generally volatile liquids that become gaseous and create cells under the influence of exothermic reactions or externally applied heat. Aliphatic hydrocarbons of a petroleum ether, ligroin, or light spirits type are flammable but do not have prominent toxic properties. Halogenated aliphatic hydrocarbons, such as methyl chloride, methylene chloride, and trichloroethylene, are also used as foaming agents. The aliphatic fluorocarbons are essentially inert.

Chemical "blowing" agents that produce foam are compounds that decompose under the influence of heat to yield a gas, usually nitrogen. A chemical foaming agent used in industry, particularly in PVC and polyolefin resins, is azodicarboxamide (CASRN: 123-77-3). It is manufactured as a fine yellow dust that is insoluble in most organic solvents and water but dissolves readily in dimethyl sulfoxide. This compound, when inhaled as a dust, can result in a nocturnal productive cough and transient decreases in pulmonary function (Ferris et al., 1977). A study of workers exposed to azodicarboxamide during the injection-molding process reported significant associations with several respiratory symptoms, including cough, wheezing, irritation, and signs of chronic bronchitis (Whitehead et al., 1987). Chronic inhalation exposures in some workers have resulted in occupational asthma (Normand et al., 1989; Slovak, 1981). Contact dermatitis hazards are not reported with great frequency but have been reported in isolated cases (Yates and Dixon, 1988). Workplace air concentrations of azodicarboxamide can be measured via filter collection and subsequent chromatography (Ahrenholz and Neumeister, 1987).

Azobisisobutyronitrile (CASRN: 78-67-1), another foaming agent, releases nitrogen gas and a residue of tetramethyl succinic dinitrile that persists in the foam. The latter compound is a convulsant in animals and has been associated with headache, nausea, and other ill-defined systemic complaints in workers. The substitution of other foaming agents has eliminated many of these hazards. Azobisisobutyronitrile may also be used in small amounts for the catalytic polymerization of vinyl plastics. Dinitrosoterephthalamide, also used as a foaming agent, has not been a source of industrial illness.

ELASTOMERS

MAREK BANASIK

BACKGROUND

Elastomeric polymers are frequently constructed of the same monomers that are used in plastics. The proportions, minor constituents, catalysts, and reaction conditions are varied to yield a product with elastic properties. An important distinction between some synthetic elastomers and other macromolecular polymers is that “cured” elastomers can occasionally be a source of hazardous ingredients in the formulation stage. It has been shown that many elastomer polymers can cause occupational contact dermatitis. In the past, workers’ compensation for this type of claim has been highest in the rubber industry (Kilpikari, 1982; Varigos and Dunt, 1981). However, epidemiological studies on mortality among rubber workers exposed to a variety of polymers of different concentrations have shown no increase in deaths associated with cancer or other diseases (Andjelkovich et al., 1977; Delzell et al., 1981). In fact, these studies have shown a decrease in overall mortality among these workers.

POLYETHYLENES

Chlorosulfonated polyethylenes are prepared through the reaction of sulfur dioxide and chlorine with polyethylene dissolved in carbon tetrachloride, and some hazards may be associated with exposure to these ingredients. Hazards have not been identified with human use of the polymer, nor have hazards been identified by animal testing. Chlorosulfonated polyethylenes are used in white sidewall tires, hoses, and tank linings and for other products that must be resistant to heat, oxidation, and ozone. These polymers are cured with metallic oxides. Accelerators include mercaptobenzothiazole, benzothiazolyl disulfide, and dipentamethylenethiuram tetrasulfide, which as a group are known skin sensitizers and may be present in the finished rubbers.

Chlorinated polyethylenes are prepared by substituting chlorine atoms with hydrogen atoms on the ethylene polymer. This rubber may also contain residual monomer and carbon tetrachloride and should be washed thoroughly with water. Skin irritation may occur, especially during processes involving heat. Chlorinated polyethylenes are most commonly used in automobile hoses and other mechanical products.

ETHYLENE-PROPYLENE COPOLYMERS AND TERPOLYMERS

To produce ethylene-propylene copolymer [Chemical Abstracts Service Registry Number (CASRN): 9010-79-1] or terpolymer (CASRN: 25038-37-3), alkenes are reacted under the influence of a coordination catalyst such as vanadium oxychloride or diethylaluminum chloride. The terpolymer of this rubber differs in that it has small amounts of diene, which

aids in establishing curing sites. Peroxides may be used in curing, although incorporation of a third monomer, such as dicyclopentadiene, permits use of conventional sulfur vulcanization. Generally, these elastomers are of low toxicity, although curing compounds that contain sulfur may be released in minute concentrations, and these may cause skin or respiratory irritation. Elastomers of this group are resistant to atmospheric heat and chemical attack and are used in hoses, belts, gaskets, and footwear.

FLUORINATED ELASTOMERS

Copolymers of vinylidene fluoride (CASRN: 75-38-7) and hexafluoropropylene (CASRN: 9011-17-0), chlorotrifluoroethylene (CASRN: 79-38-9), or perfluoropropylene (CASRN: 116-15-4) are highly resistant elastomers used in gaskets, seals, and other applications in industries where high cost materials can be afforded. The elastomers are biologically inert, although extreme heating can produce harmful breakdown products such as hydrogen fluoride, monofluoroacetic acid, and other fluorocarbons. These products can cause a variety of acute and systemic effects. Skin sensitization can occur after extended contact with the polymer. Curing agents include diamines, peroxides, or ionizing radiation.

NEOPRENE

Neoprene rubber, the trade name for polychloroprene-based rubber, is obtained by the emulsion condensation of chloroprene, a derivative of butadiene. The two types of neoprene are distinguished by whether a sulfur or nonsulfur modification process was used. Neoprene is highly resistant to weathering and to oil, as well as to solvents, ozone, oxygen, and heat. It is used primarily in mechanical and automotive products, such as cable sheaths, belts, hoses, seals, and gaskets, and it also is an important additive for some adhesives. As with most rubber products, a sensitized individual can develop contact dermatitis from extended dermal exposure to neoprene (Fowler and Callen, 1988). An occupational exposure to the monomer chloroprene is the most likely contact to result in an industrial hazard.

CHLOROPRENE

Chloroprene (2-chloro-1,3-butadiene; CASRN: 126-99-8) is a flammable, colorless liquid at room temperature with a characteristic ether-like odor. It is slightly soluble in water and more soluble in organic solvents. Its vapor pressure and relative vapor density are 215 mmHg at 25°C and 3.0 (air = 1), respectively. It has not been found to occur naturally. Chloroprene is very unstable and reacts in air with oxygen

and other compounds to form epoxides, peroxides, and other hazardous compounds. This instability and spontaneous formation of different compounds are thought to be the explanation for the variable findings in chloroprene studies.

Industrial Hygiene

The most probable route of chloroprene exposure in an industrial setting is inhalation by workers during manufacture of the compound or during its use. Because chloroprene may be carcinogenic, occupational exposure should be kept at a minimum. The United States (US) National Institute for Occupational Safety and Health recommends a self-contained breathing apparatus or a supplied-air respirator, both with full facepiece and operated in a positive-pressure mode (NIOSH, 1994). The US Occupational Safety and Health Administration has set a permissible exposure limit for chloroprene of 25 parts per million (ppm) (90 mg/m³) time-weighted average (TWA); the American Conference of Governmental Industrial Hygienists has recommended a slightly lower standard threshold limit value of 10 ppm (36 mg/m³) TWA (ACGIH, 1995; NIOSH, 1994). Dual mechanical seals on process pumps and careful attention to leaks in the machinery can keep industrial airborne levels to a minimum.

Acute and Chronic Effects

Chloroprene is a mucous membrane irritant, and an acute exposure can cause a variety of signs and symptoms, depending on the exposure route and dose (Sanotskii, 1976). Signs and symptoms caused by higher concentrations include respiratory tract and eye irritation, central nervous system depression, lacrimation, dermatitis, corneal necrosis, and hair loss from dermal contact (Gooch and Hawn, 1981). The depilatory effects of chloroprene are reversible, and hair regrows after exposure is terminated. Acute exposure studies in animals have shown similar effects, as well as adverse lung and liver effects at high concentrations (Clary et al., 1978). Low level acute exposure has had cumulative effects in rats (Plugge and Jaeger, 1979).

Chronic exposure to chloroprene yields a similar variety of systemic and local effects, including headache, irritability, dizziness, insomnia, respiratory irritation, cardiac palpitations, chest pain, gastrointestinal disorders, and dermatitis. Case reports of a long-term exposure in the rubber industry have described acute sensitizing illnesses associated with eosinophilia (Bascom et al., 1988). Reproductive effects also have been noted, including a decrease in spermatogenesis, sexual impotency, and disruption of the menstrual cycle. The diversity of both chronic and acute effects suggests that because of chloroprene's reactive nature, exposure actually involves to a variety of chemicals and compounds.

Because chloroprene has not been shown to be carcinogenic in humans, the International Agency for Research on

Cancer (IARC) has classified it in Group 3, inadequate evidence of carcinogenicity in both animal and human studies (IARC, 1987). Two epidemiological studies in Eastern Europe indicate an increase in lung and skin cancers among chloroprene workers (Lloyd et al., 1975). However, a US-based study of a similar population did not confirm these findings (Pell, 1978). Mutagenicity assays for chloroprene using bacteria have yielded positive findings, but these tests are not an indication of human carcinogenicity (Bartsch et al., 1975). Similar discrepancies have been seen in animal studies (Dong et al., 1989). These results do not demonstrate a consistent finding suggesting that chloroprene is a carcinogen.

Target Sites

The primary sites of action for chloroprene are the eyes, skin, respiratory system, and reproductive system. However, the route of exposure and reactant products of the chemical upon exposure are the two factors that determine the effects of chloroprene.

POLYISOBUTYLENE

Butyl rubber (CASRN: 9010-85-9) is formed from the polymerization of isobutene (isobutylene) with small amounts of chloroprene, isoprene, or butadiene and may be halogenated. The reaction is carried out in a closed system with an aluminum chloride catalyst. Butyl rubber is highly impervious to gases, which makes it the rubber best suited for inner tubes and tires, air chambers, adhesives, and dielectrics. Isobutene is an anesthetic and asphyxiant gas and can be hazardous in concentrations high enough to produce asphyxia. At these concentrations, explosion is an additional hazard.

POLYISOPRENE

Polyisoprene (CASRN: 9003-31-0) is the polymer known as natural rubber, although it can also be manufactured. The natural rubber latex is harvested from the rubber tree, *Hevea brasiliensis*. This substance has a variety of natural additives, such as proteins and sugars. The polymer from the natural latex is resistant to many solvents and also is easily processed. The synthetic form of this rubber is produced from a pure isoprene solution with a stereospecific isomer to produce the more commonly used *cis*-1,4 isomer. These rubbers are resistant to abrasion and most solvents and are commercially used in automobile tires, adhesives, and a variety of products that come in close contact with the general public. Their use in baby bottle nipples is a good indication of the extremely low toxicity associated with these elastomers.

ISOPRENE

Isoprene (2-methyl-1,3-butadiene; CASRN: 78-79-5) is the monomeric unit of polyisoprene. The structure of this molecule is very similar to that of butadiene, with a simple methyl substitution differentiating the two. Although it is mainly used in the production of polyisoprene, isoprene is also used in styrene-based polymers and in butyl rubber. At room temperature it is a clear, colorless liquid with a faint odor; it is insoluble in water but soluble in acetone and other organic solvents. The vapor pressure of isoprene is 550 mmHg, and it has a relative vapor density of 2.35 (IARC, 1994). Unlike the

chemically similar butadiene, isoprene is found in abundance in nature; for example, it is a component of natural terpenes and also is expired by plants and humans.

Industrial Hygiene

In the past, different production techniques were available to make the isoprene monomer. Currently, the most commonly used process involves the formation of an isoprene by-product from petroleum cracking. Because isoprene is a naturally occurring product and its metabolism is not well characterized, most regulatory agencies have not set standards for an isoprene exposure. Such an exposure can occur in the polymerization process and in the formation of the isoprene-based synthetic rubbers and elastomers.

Acute and Chronic Effects

Inhalation is the major route of exposure to isoprene, with dermal contact and ingestion rarely occurring. Similarities between acute butadiene and isoprene exposure have been reported. At high concentrations, isoprene is a narcotic and asphyxiant, although respiratory irritation occurs at lower levels, which can warn workers to avoid higher concentrations (Dahl et al., 1987). Isoprene has also been noted to affect mucociliary flow rates (Weissbecker et al., 1971).

The chronic effects of isoprene have not been extensively reported, although animal studies have shown isoprene to be carcinogenic. Catarrhal inflammation and loss of sense of smell can occur with increasing length of exposure. A study by Melnick et al. (1994) demonstrated multiple organ neoplasia after a 6-month inhalation study in rats and mice. As a result of these studies, the IARC carcinogenicity classification for isoprene is Group 2B, sufficient animal evidence of carcinogenicity but insufficient human evidence (IARC, 1994).

Target Site and Mechanism of Action

The target organ for acute effects of isoprene is the central nervous system. Isoprene is an anesthetic at high concentrations. It can also result in asphyxia at high concentrations by displacement of breathable air. It is metabolized in rodents by hepatic cytochrome P-450, which results in two major mono-epoxide metabolites (Gervasi and Longo, 1990; Longo et al., 1985). These studies have determined that isoprene binds to the active site of cytochrome P-450 and undergoes an oxidation and hydrolysis step. The metabolites are 3,4-epoxy-3-methyl-1-butene and 3,4-epoxy-2-methyl-1-butene. The latter is the minor metabolite and the only one believed to be further converted to isoprene diepoxide, an animal carcinogen (Gervasi and Longo, 1990). The formation of a carcinogenic metabolite from isoprene exposure must be considered in the assessment of risk, although the rate of

conversion to this metabolite does not appear to be high. The precursor to endogenous isoprene production is believed to be mevalonic acid, a component of cholesterol synthesis (Deneris et al., 1984). Excretion of isoprene through expiration has been measured; isoprene is the main hydrocarbon in breath (Gelmont et al., 1981).

Biomonitoring

Levels of isoprene have been detected in human breath and, more recently, in human blood samples (Cailleux et al., 1992). The correlation between these measurements and occupational exposure has not been established.

POLYSULFIDE RUBBER

Polysulfide elastomers are condensation products of sodium polysulfides and dichloro compounds, such as ethylene dichloride. More complex chlorinated hydrocarbons yield products with improved properties. These elastomers are

highly resistant to oils, solvents, and weathering and are found in coatings, caulking compounds, adhesives, and mechanical components. In most applications of the polysulfide rubbers, occupational health problems are related to contact dermatitis.

POLYURETHANE

The fibers commonly called spandex are polyurethane elastomers, which are biologically inert. They can be substituted without reaction for rubber by people who have become sensitized to auxiliary compounds invariably present in natural and synthetic rubbers. These polymers are noted for their resistance to oil and abrasion and for their mechanical strength. Use of these rubbers in footwear has been blamed for a limited number of cases of contact dermatitis (Grimalt and Romaguera, 1975). All spandex formulations are not identical; many are based on polytetramethylene glycol, 2,4-toluene diisocyanate, other diisocyanates, and hydrazine. The solvent for extrusion is dimethylformamide. The effects of the diisocyanates are well known and were discussed previously. The effects described for these constituents are the primary health problems associated with these elastomers as well.

SILICONE RUBBERS

Industrial medical problems have not been prominent in the preparation or use of silicone rubbers. Benzoyl peroxide may be used as a vulcanizer. These rubbers are most appropriate for use as gaskets and seals because of their flexibility and heat resistance.

STYRENE-BUTADIENE COPOLYMER RUBBERS

Styrene-butadiene rubber (SBR; CASRN: 9003-55-8) is prepared in large quantities for tire treads and other, similar uses. The properties, molecular weight, and percentage of monomer can all be controlled in the polymerization process. Hazards of the SBR industry have been identified and related mostly to the monomers and additives. Contact dermatitis and leukemia have been associated with solvent and additive use but not with the actual polymer itself (Checkoway et al., 1984; Kilpikari, 1982). Epidemiological studies in the industry have not revealed a significant increase in disease or

causes of death (Matanoski and Schwartz, 1987; Meinhardt et al., 1982). The hazards of the butadiene and styrene monomers were discussed previously.

Polybutadiene (CASRN: 9003-17-2) is a homopolymer of butadiene (CASRN: 106-99-0). The catalysts involved in the polymerization process determine the structure and molecular weight of the rubber. It is used in tires and for other products that require abrasion resistance. At times both SBR and polybutadiene are extended with oils. There are underlying hazards associated with the individual oils, some of which are carcinogenic in animals and suspected human carcinogens.

ADDITIVES IN ELASTOMER SYSTEMS

Various substances added to rubber formulations in the course of production may cause skin reactions in people who use the finished products, as well as in industrially exposed workers. The additives generally are similar for natural rubber, nitrile rubber, polybutadiene, neoprene, butyl rubber, and ethylene-propylene copolymers.

Vulcanizers generally contain elemental sulfur, although zinc and magnesium oxides are important in the neoprene cure, and peroxides are used for ethylene-propylene systems. The rate of vulcanization is influenced by accelerators, some of which are potent sensitizers. Common accelerators include benzothiazolyl disulfide, mercaptobenzothiazole, tetraethyl thiuramdisulfide (disulfiram), tetramethyl thiuramdisulfide (thiram), thiocarbamilide, dithiocarbamates (zinc dimethyl, zinc diethyl, zinc dibutyl, lead dimethyl compounds), diphenylguanidine phthalate, hexamethylene tetramine, and lead oxide (litharge).

Besides causing allergic contact dermatitis, the accelerators disulfiram and thiram can produce severe reactions when they are absorbed together with alcohol or paraldehyde. This reaction involves the inhibition of aldehyde dehydrogenase, presumably through the chelation of molybdenum, so that the normal metabolic degradation of aldehydes is inhibited.

Aldehydes consequently accumulate and cause flushing, palpitations, dyspnea, nausea, and hypotension. These reactions do not involve sensitization. Pharmaceutical grade disulfiram is used to produce distaste and intolerance for alcohol in the treatment of alcoholism.

Antioxidants are used to protect rubber against the destructive effects of atmospheric oxygen. The most commonly used antioxidants are monobenzyl ether of hydroquinone (AgeRite Alba), di-(β -naphthyl)-*p*-phenylenediamine, monoctyl and dioctyl diphenylamines, and phenyl alpha and beta naphthylamines.

The monobenzylether of hydroquinone, in addition to being a sensitizer, can cause loss of skin pigment in many individuals, often in the absence of any previous skin reaction. This reaction is most apparent in very dark-skinned persons in whom the response resembles vitiligo. Exposure to this compound has been significantly reduced through modifications in the rubber compounding process. Many of the amine antioxidants are also potent sensitizers.

Pigments and fillers include carbon black, whiting (calcium carbonate), clay, silica, and asbestos. The hazards of the fibrogenic dusts are well established and are discussed

elsewhere. There has been some speculation that polycyclic aromatic carcinogens are adsorbed to carbon black particles handled in industry, but there is no evidence that the pigment contains these materials. However, if there is a suspicion that the carbon black contains hazardous levels of polycyclic hydrocarbons, the material should be analyzed for polycyclic hydrocarbons content.

Some additives may remain, used to arrest the polymerization process to control for elastomer characteristics and molecular weight. Residual impurities remaining after washing can cause some adverse skin reactions, which may be causally associated with the elastomer itself but are the result of the impurities and not the elastomer. Dodecyl mercaptane has been demonstrated by skin patch testing to cause contact dermatitis in association with rubber footwear (Grimalt and Romaguera, 1975).

SYNTHETIC FIBERS

MAREK BANASIK

BACKGROUND

To a great extent, polymeric fiber textiles resemble many of the high molecular weight polymers used in plastics and elastomers. Significant chemical and physical modifications during production provide the properties necessary for fibers and filaments. In general, these polymers are not associated with occupational health hazards. However, industrial exposure to many of the chemicals and additives used with these fibers may pose health hazards. Although the mechanism of carcinogenesis has not been identified, a significant increase in the incidence of a rare colon cancer has been reported among a population of synthetic fiber workers, particularly those who worked in the extrusion departments (Vobecsky et al., 1984). However, this report has not yet been verified. These fibers are manufactured for their use alone or as a component of fiber-reinforced plastics. Fiber-reinforced plastics are extremely strong and can substitute for steel in many applications. Problems may arise as the development of new materials and processes is introduced before health hazards can be adequately identified (Midtgård and Jernes, 1991). Exposure prevention methods, such as shielding, ventilation, and personal protection, are recommended for compounds for which effects are not well characterized. Fibers usually are regulated by the United States Occupational Safety and Health Administration as nuisance dusts. The permissible exposure limits are 15 mg/m³ for total dust and 5 mg/m³ for the respirable fraction. The size of the fibers, including their length and diameter, and the fibers' durability and concentration are the critical determinants of their hazardous nature. Those too large to be respired may cause mechanical irritation to the eyes and skin.

ACETATES

Cellulose acetate rayon is made from the wood pulp of cotton linters treated with glacial acetic acid and acetic anhydride, along with sulfuric acid as a dehydrating agent. Both acetic acid and its anhydride have a pungent odor and are potent lacrimators. The anhydride is a severe skin and eye irritant, and it may occasionally be a sensitizer. This response is presumably the result of its reaction with amino groups of cutaneous protein.

In the production of fibers, the cellulose acetate is dissolved in a solvent for extrusion. In the case of triacetate material, the solvent may be methyl acetate, glacial acetic acid, *N,N*-dimethylformamide, dimethylacetamide, or dimethyl sulfoxide (DMSO). *N,N*-dimethylformamide [Chemical Abstracts Service Registry Number (CASRN): 68-12-2] is a powerful solvent that is irritating to the eyes, mucous membranes, and skin. It can pass through intact skin or can be absorbed from the lungs and gastrointestinal tract. It can be hepatotoxic but is rapidly metabolized by demethylation to monomethylformamide. The presence of this metabolite in urine can serve as an effective bio-monitoring tool (Maxfield et al., 1975). The unpleasant fishy odor serves as a warning and tends to limit exposure. Dimethyl sulfoxide (CASRN: 67-68-5) has been suggested as a vehicle for transporting drugs through the skin. Dermal exposure to DMSO may result in erythema, itching, and burning. For cellulose acetates other than the triacetate, the conventional solvent is acetone.

ACRYLICS

Acrylonitrile (CASRN: 107-13-1) is the chief constituent of acrylic fibers. To improve the dye and working properties of

the material, acrylonitrile frequently is copolymerized with small amounts of other monomers such as acrylates, amides, vinyl esters, and various hydrocarbons (e.g., styrene and isobutene). When the comonomer is vinyl chloride (CASRN: 75-01-4) or vinylidene chloride (CASRN: 75-35-4) and is present in quantities approximately equal to the acrylonitrile, the polymer is said to be a modacrylic, which is extruded in acetone. Acrylics are prepared for extrusion in solvents that may include *N,N*-dimethylformamide, DMSO, strong acids, and concentrated inorganic salt solutions. Although acrylics generally are inert, penetration of the skin by acrylic fibers has been reported to lead to sarcoid-like granulomas (Pimentel, 1977).

NYLON

The polyamides known as nylon are used principally as fibers and, to a lesser extent, resins in the plastics industry. In fiber applications, nylon may be modified by titanium dioxide, a delusterant, by manganese and phosphorus salts as light stabilizers, and by copper salts and acridine compounds as heat stabilizers. These substances are not released from the finished fiber. There have been only scattered reports of ill effects among workers exposed to nylon fiber. For example, sarcoid-like granulomas of the lungs were reported in a woman who was exposed to nylon dust for 20 years in a fiber bag factory (Pimentel, 1977).

ARAMID

Aramid [poly(imino-1,3-phenyleneiminocarbonyl-1,3-phenylene carbonyl)]; CASRN: 24938-60-1] is the most common nylon fiber used, known for its strength and durability. Uses of aramid fibers include protective clothing, tires, conveyor belts, and cables. Animal studies have shown that chronic inhalation exposure to these fibers can produce pulmonary lesions (Lee et al., 1988). More recent studies have found that these lesions are not carcinomas, as originally thought; rather, they are more accurately referred to as proliferative keratin cysts (Carlton, 1994). Clearance of the fibers occurs relatively quickly, as does recovery from injury, as with other carbon fiber exposures (Kelly et al., 1993; Warheit et al., 1992). Aramid fibers are also readily cleared by rat lungs, which reduce residence time (Kelly et al., 1993). Human exposure to aramid fibers is considered to be of minimal risk.

POLYESTERS

Fibers of the polyester group are formed of polyethylene terephthalate (CASRN: 25038-59-9). This polymer is produced from dimethyl terephthalate and ethylene glycol under

the influence of catalysts, which include oxides, carbonates or acetates of zinc, antimony, manganese, cobalt, calcium, or magnesium. The terephthalates have few, if any, biological properties.

POLYURETHANE

The polyurethane fiber, commonly known as spandex, can more accurately be described as an elastomeric fiber because it can be stretched 500–600% larger than its initial state. These fibers are most noted for their quick recovery after being stretched. A spandex fiber usually contains at least 85% polyurethane and is marketed under a wide variety of names. Historically, it was produced to improve the first vulcanized rubber fibers made (Hicks et al., 1965). Vulcanized rubber fibers are highly resistant to abrasion, chemicals, and sunlight. They are used in many applications but are most noticeable in their use in apparels such as brassieres and active wear. When spandex was first introduced, a few cases of allergic contact dermatitis were reported, but these were found to be caused by some trace contaminants rather than the actual fiber. Sensitization to the fiber itself may occur but is considered extremely rare. Mercaptobenzothiazole, thiram, and diphenylguanidine are some of the many accelerators and antioxidants that may have adverse effects with dermal contact (Joseph and Maibach, 1967). Production must be controlled carefully to avoid exposure to the diisocyanates used in polyurethane manufacturing.

RAYON

Rayon (CASRN: 61788-77-0) in its finished form is essentially cellulose and is not inherently toxic. The phases of production that have been hazardous are those that involve opportunities for exposure to carbon disulfide. In the production of rayon, wood pulp is treated with sodium hydroxide to produce alkali cellulose. This material is then reacted with carbon disulfide to produce cellulose xanthate. It is this exposure to carbon disulfide that is the greatest potential hazard. The resulting xanthate crumb, when dissolved in dilute sodium hydroxide to form viscose, is extrudable to form rayon fibers. In modern practice, this process takes place in closed systems. Exposure is possible, but with appropriate ventilation, a significant hazard is not likely to occur.

The biological effects of carbon disulfide are discussed elsewhere, but the health effects noted in the viscose rayon industry are described here. Epidemiological studies have described a variety of health effects associated with this industry. Neuropathy is a well-known effect produced by excessive carbon disulfide exposure and is reported in the rayon industry. The fiber cutting area of a rayon plant has been linked to higher concentrations of airborne carbon disulfide,

leading to occupational exposure and outbreaks of polyneuropathies (Chu et al., 1995). In areas of lower concentrations, lesser effects, such as absentmindedness and difficulties in perception, have been noted (Cassitto et al., 1993).

The nervous system is not the only systemic effect linked to carbon disulfide exposure. One study found male workers experiencing decreased libido and potency, although sperm motility and fertility were not affected (Vanhoorne et al., 1994). Both carbon disulfide and hydrogen disulfide have been the cause of eye irritation, severe enough to cause certain workers to leave their jobs (Vanhoorne et al., 1995). Regardless of the work area involved, exposure to these chemicals must be controlled to prevent work-related illness.

BISPHENOL A (4,4'-ISOPROPYLIDENEDIPHENOL)

JULIE E. GOODMAN, LORENZ R. RHOMBERG, AND MICHAEL K. PETERSON

The following information is for the pure form of bisphenol A (BPA), generally occurring as white to light tan solid flakes, grains, or powder with a mild phenolic odor.

First aid: *Oral exposure:* Amounts that may be ingested accidentally in the workplace are considered to have low toxicity. If swallowed, wash out the mouth with water, provided the person is conscious. Call a physician. Do not induce vomiting unless directed to do so by a medical professional. *Inhalation exposure:* Exposures to vapors are minimal at room temperature due to the low vapor pressure of BPA. Vapor levels sufficient to cause irritation may be generated when BPA is in the molten state. If inhaled, move the person to fresh air. If breathing becomes difficult, call a physician. *Dermal exposure:* A short single acute exposure is not likely to cause significant skin irritation. Prolonged or repeated exposure may cause skin irritation, particularly under conditions of sweating. In case of skin contact, flush with copious amounts of water for at least 15 min. Remove the contaminated clothing and shoes. Call a physician. *Eye exposure:* BPA dust may cause moderate irritation and corneal injury. In case of contact with eyes, flush with copious amounts of water for at least 15 min. Ensure adequate flushing by separating the eyelids with fingers. Call a physician.

Target organ(s): Endocrine system, liver, kidney, bladder.

Occupational exposure limits: In the absence of specific threshold limit values (TLV) and permissible exposure limits (PEL) for BPA, OSHA has an exposure limit for particulates not otherwise regulated (15 mg/m³ for total dust and 5 mg/m³ for the respirable fraction). ACGIH has an exposure guideline for particulates not otherwise

classified of 10 mg/m³ for total dust and 3 mg/m³ for the respirable fraction.

Reference values: (1) Human health: US EPA RfD, EFSA TDI, and ECHA DNEL (oral, general population): 0.05 mg/kg-bw/day; (2) Ecotoxicological: PNEC (freshwater) is 0.018 mg/l, PNEC (marine water) is 0.016 mg/l, PNEC (freshwater sediment) is 2.2 mg/kg sediment dry weight, PNEC (marine water sediment) is 0.44 mg/kg sediment dry weight, and PNEC (soil) is 3.7 mg/kg soil dry weight.

Risk/safety phrases: STOT Single Exp. 3 H335: May cause respiratory irritation. Eye damage 1 H318: Causes serious eye damage. Skin Sens. 1 H317: May cause an allergic skin reaction. Repro. 2 H361: Suspected of damaging fertility or the unborn child.

BACKGROUND AND USES

Bisphenol A (CASRN 80-05-7) is an organic compound used predominantly in the production of products made of polycarbonate plastic and epoxy resins. People are generally exposed to minute levels of BPA, mostly from the ingestion of food or beverages that have been in contact with materials manufactured with BPA. Workers may be exposed to higher levels during the manufacture of the compound. While studies have shown that BPA has weak estrogen-like activity and that it may cause effects at extremely high doses in animals, human exposures are well below the intake levels determined by most government bodies to be without harm (EFSA, 2006).

TABLE 78.1 Physical-Chemical Properties of Bisphenol A (ECB, 2003)

Property	Value	Comments
Form	Solid white flakes or powder	
Melting point	155–157 °C	
Boiling point	360 °C	Decomposition also likely
Density	1.1–1.2 kg/m ³ at 25 °C	
Vapor pressure	5.3 × 10 ⁻⁹ kPa	
Solubility in water	300 mg/l	
Log K _{ow}	3.3–3.5	
Flash point	207 °C	
Autoflammability	532 °C	
Explosive limits	0.012 g/l with O ₂ > 5%	Not an oxidizing agent

BPA was first synthesized in 1891, but it was not used widely until applications in the plastics industry were identified in the 1950s (University of Minnesota, 2008). While the most prominent use of BPA is in the manufacture of polycarbonate plastic and epoxy resins, it is also used in the production and processing of polyvinyl chloride (PVC) and modified polyamide and in the manufacture of carbonless and thermal paper, wood filler, adhesives, printing inks, surface coatings, polyurethane, brake fluid, resin-based dental composites and sealants, flame retardants, paints, and tires (ECB, 2003; EFSA, 2006).

PHYSICAL AND CHEMICAL PROPERTIES

BPA is a white solid at room temperature with a slight phenolic odor and a very low vapor pressure (ECB, 2003). It is mildly soluble in water. It is not considered to be an explosive in the conventional sense but can pose a hazard as a finely powdered material in air (ECB, 2003). It is not considered to be a chemical oxidizer. The physical-chemical properties of BPA are provided in Table 78.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

BPA can be released into the environment during the production, processing, and use of BPA-containing materials, although levels in environmental samples are generally very low or undetectable (ECB, 2003). This is because BPA has low volatility and a short half-life in the atmosphere, is rapidly biodegraded in water, and is not expected to be stable, mobile, or bioavailable from soils (ECB, 2003; Cousins et al., 2002).

Most environmental releases of BPA are during the manufacture of BPA-containing products when residual BPA in wastewater is released from treatment plants into receiving streams (Cousins et al., 2002). BPA's half-life in

soil and water is in the order of 4.5 days while in air it is <1 day (Cousins et al., 2002). It has a low bioconcentration factor and is rapidly metabolized in fish, with a half-life of <1 day (Cousins et al., 2002).

ECOTOXICOLOGY

Numerous ecotoxicity studies have been conducted on BPA because of its prevalence in the environment (Staples et al., 2002). Under the European Union's (EU)'s registered substances database for REACH (Registration, Evaluation, Authorisation and Restriction of Chemicals), the following predicted no effect concentrations (PNECs) have been derived, namely, 0.018 mg/l (freshwater), 0.016 mg/l (marine water), 2.2 mg/kg sediment dry weight (dw) (freshwater sediment), 0.44 mg/kg sediment dw (marine sediment), and 3.7 mg/kg soil dw (ECHA, 2011). When these values are compared to the concentrations of BPA that have been reported in typical surface waters (0.000001–0.00010 mg/l), the likelihood of adverse effects on aquatic ecosystems is negligible (Staples et al., 2002). However, because the aquatic PNECs indicate that species populating this medium are the most sensitive, the sections that follow focus on the relevant acute and chronic aquatic toxicity data.

Acute Effects

Because of BPA's relatively short half-life in water, the primary aquatic toxicity concern relates to high-level acute exposures, which may occur from spills or other accidental releases. Under acute conditions, BPA has been reported to be moderately toxic to water fleas (i.e., *Daphnia magna*) (48-h EC₅₀s ~3.9–16 mg/l) and Mysid shrimp (i.e., *Mysidopsis bahia*) (96-h LC₅₀ ~1.1 mg/l; NOEC = 0.51 mg/l) (ECHA, 2011). The reported LC₅₀s in marine and freshwater fish also indicate a moderate acute toxicity concern with values in the following ranges, that is, approximately 7–15 mg/l (48 h) or 3–10 mg/l (96 h) (ECHA, 2011). Based on the acute aquatic

hazard criteria set forth under EU's implemented version of GHS (Globally Harmonized System, the foregoing values do not meet the criteria for classification and labeling for acute aquatic hazards (ECHA, 2011).

Chronic Effects

There have been a variety of studies on BPA's effects on chronic endpoints, including survival, growth and development, and reproduction. Many of these have been discussed in detail elsewhere (e.g., Staples et al., 2002) and are summarized below.

Staples et al. (2002) evaluated a wide variety of these studies and found that eight survival studies were appropriate for assessing this endpoint. Staples et al. (2002) observed that study duration had little impact on species survival and that, for most species (including four species of fish, an amphibian, and an invertebrate), there were no effects at the highest doses tested, which ranged from 0.10 to 3.16 mg/l.

Staples et al. (2002) summarized multiple studies that evaluated BPA's effects on growth and development. Eight studies evaluating different species of fish and an amphibian species for durations of 28–431 days found that the lowest BPA concentrations that caused effects on these parameters ranged from 1.82 to 11.0 mg/l. No observed effect concentrations ranged from 0.12 to 3.64 mg/l. In aquatic invertebrate studies, growth effects were observed in a copepod, with an EC₁₀ (the effect concentration for 10% of the population tested) of 0.10 mg/l (Andersen et al., 2001), but Staples et al. (2000) concluded that this study was not valid for use in hazard assessment, as few methodological details or results were reported. In a different aquatic invertebrate (*Daphnia magna*), no effects on molting were observed at concentrations up to 3.16 mg/l (the highest concentration tested). In algae, growth effects were reported for freshwater green algae (EC₁₀ of 1.36–1.68 mg/l) and the marine diatom (EC₁₀ of 0.40–0.69 mg/l).

Staples et al. (2002) evaluated reproductive toxicity studies in a variety of aquatic organisms, including fish, amphibians, invertebrates, and algae. In fish studies, which ranged from 14 to 100 days in duration and evaluated multiple generations as well as early life stages, lowest observed effect concentrations ranged from 0.16 to 2.28 mg/l. No adverse effect concentrations were reported in invertebrates up to the highest concentration tested of 3.16 mg/l. Adverse effects on growth were observed in green algae between 0.4 and 1.68 mg/l.

Based on the criteria for long-term aquatic hazards under the EU's GHS, the foregoing values do not support classification and labeling for chronic aquatic hazards (ECHA, 2011).

MAMMALIAN TOXICOLOGY

Standardized studies performed according to internationally validated test guidelines and conducted under good

laboratory practice (GLP) standards have not shown effects from BPA at low doses (Ema et al., 2001; Tyl et al., 2002, 2008). A large number of smaller-scale non-guideline, non-GLP studies have reported an extensive and disparate set of effects in the low-dose range, i.e., <5 mg/kg-bw/day (reviewed in Gray et al., 2004; Goodman et al., 2006, 2009). Often, the effects reported in non-guideline, non-GLP studies are found only at one or two low doses but without effects at higher doses. The effects in question are often intermediary rather than apical endpoints, and their interpretation as indicators of potential frank toxicity is a matter of debate. Critics of the reliance on guideline/GLP studies cite non-guideline, non-GLP studies as evidence that guideline/GLP studies use insensitive strains of animals, fail to uncover subtle endocrine-mediated effects, and err in presuming that a lack of high-dose effects precludes lower-dose effects of concern (vom Saal and Hughes, 2005).

The counterargument is that non-guideline, non-GLP studies are inconsistent among one another (and with the GLP study results), with most examinations of validated endpoints being negative and the reported effects on nonvalidated endpoints being inconsistent and not dose-dependent (Goodman et al., 2009; Hengstler et al., 2011; Sharpe, 2010; Tyl, 2009). Under this view, the reported effects at low doses can be attributed to chance fluctuations and imprecisely defined control states, to which small studies using novel designs are prone. Moreover, many of these studies administered BPA by subcutaneous injection, which obviates the relevance of such studies to human exposures because this route of administration bypasses first-pass metabolism by the liver (Goodman et al., 2009; Hengstler et al., 2011). Though the interpretation of the body of toxicological data for BPA continues to be controversial (Myers et al., 2009a, 2009b; Becker et al., 2009), in reviews and assessments conducted by responsible government bodies around the world, the latter view—that is, the evidence does not support effects below 5 mg/kg—has prevailed, as detailed in the Risk Assessments section.

Acute Effects

In general, BPA has low acute toxicity by the oral and dermal routes, with experimental values exceeding the highest recommended dose levels from the respective test guidelines. For example, the oral LD₅₀ values in laboratory animals such as mice and rats are above 2000 mg/kg-bw, and the dermal LD₅₀ values in rabbits are also above 2000 mg/kg-bw (ECB, 2003). Though no deaths were reported in an acute 6-h inhalation study in rats at 170 mg/m³, minor and transient changes in the nasal epithelium were reported (ECB, 2003).

Animal studies generally report that BPA has low dermal irritation potential (ECB, 2003); however, BPA is classified under the EU's adopted version of GHS as a category 3 single exposure, specific target organ toxicity (STOT) for respiratory irritation (ECHA, 2011). In studies with rabbits, BPA

has been shown to be an eye irritant (ECB, 2003) and has an EU-GHS classification of having the potential to cause serious eye damage (i.e., eye damage 1) (ECHA, 2011).

Most previous studies of BPA's sensitization potential are case reports that are confounded by co-exposure to other chemicals such as epoxy resins. Recent studies do not confirm any skin sensitization up to 30% BPA, and medical surveillance reports from five BPA manufacturing plants also did not identify any workers who had self-reported skin effects or had skin issues observed during the routine 1–3-year medical examinations (ECB, 2003). Notwithstanding the conflicting reports on this endpoint, BPA is classified as a category 1 skin sensitizer (i.e., may cause an allergic skin reaction) by the EU (ECHA, 2011).

Subchronic and Chronic Effects

The estrogenic effects of BPA at high doses are well understood and generally agreed upon by scientists, but there is controversy over BPA's effects at low doses (sometimes called the “low-dose hypothesis”). Because the lowest level at which adverse effects have been reported in guideline/GLP studies is 50 mg/kg-bw/day, studies of BPA at doses an order of magnitude lower than this (i.e., ≤5 mg/kg-bw/day) are considered relevant for addressing possible low-dose effects. Typical human exposures are several orders of magnitude lower than this dose.

When evaluating the relevance of effects reported in animal studies to humans, it is important to consider some of the pharmacokinetic similarities and differences between animals and humans exposed to BPA (reviewed in Hengstler et al., 2011). In all mammals thus far examined, BPA is readily absorbed via oral intake, with substantial first-pass metabolism by the gut wall and liver. Metabolism is generally to the glucuronide or sulfate conjugate, and these appear to be toxicologically inactive. Elimination of the metabolites is via urine in humans and the urine and feces in rodents.

Most of the BPA to which humans are exposed is ingested orally and metabolized in the intestine and liver, then eliminated in urine, so it does not reach the general circulation in appreciable amounts nor does it accumulate in the body after ingestion (Völkel et al., 2002, 2005). Though BPA in rodents is also metabolized in the intestine and liver, there is substantial enterohepatic recirculation after oral exposure (i.e., the chemical is excreted via bile from the liver into the digestive tract, where the glucuronide is cleaved and the aglycone is reabsorbed), the effect of which prolongs the presence of BPA at low levels in the systemic circulation (Kurebayashi et al., 2003). Subcutaneously injected BPA enters the systemic circulation directly, which bypasses hepatic first-pass clearance and results in substantially higher systemic levels of unconjugated BPA. Metabolized or conjugated BPA has little or no known biological or estrogenic activity (Matthews et al., 2001).

Two recent studies by the U.S. Food and Drug Administration (FDA) indicate that both adult and newborn experimental animals have the capacity to metabolize and eliminate BPA from the body; however, there are some species-specific differences. The first study examined this process in rats and found that, after ingesting BPA, adult rats could efficiently and rapidly metabolize and eliminate the chemical, but metabolism in newborn rats was not as efficient. The second study was conducted in monkeys. FDA found that adult monkeys could efficiently metabolize BPA, and that newborn monkeys had the same capacity as adult monkeys to safely metabolize and eliminate BPA (Doerge et al., 2010a, 2010b). Thus, the authors concluded that effects based on doses in rodent studies would overpredict effects in primates.

The majority of low-dose BPA studies have been conducted in rodents. Internal doses in these studies are higher than humans would experience based on the same exposure, and this is particularly true for non-oral exposures.

Reproductive and Developmental Effects Based on hundreds of animal studies with BPA doses ≤5 mg/kg-bw/day, there is an overwhelming preponderance of lack-of-effect findings compared to findings of effect over a wide variety of reproductive and developmental toxicity endpoints (reviewed by Gray et al., 2004; Goodman et al., 2006, 2009; Hengstler et al., 2011; and multiple government agencies, discussed in the regulatory status/rationale section below). The most robust reproductive and developmental BPA evaluations are the multigeneration studies conducted with Sprague-Dawley rats (Ema et al., 2001; Tyl et al., 2002) and CD-1 Swiss mice (Tyl et al., 2008). These studies used a large number of animals with a range of oral doses and examined a wide variety of hormonally sensitive endpoints. Reproductive effects occurred only at the highest tested doses in these studies (EFSA, 2006). Effects at lower doses were observed only sporadically (e.g., in only one generation, with no dose-response pattern) and were not considered to be treatment-related.

Among all other BPA low-dose animal studies, there are some that reported responses at low doses, but no marked or consistently repeatable effects were observed. Reported effects are not consistent between rats and mice, and there are no consistent patterns among dose groups and evaluation times (Nagel et al., 1997; Gupta, 2000; Ashby et al., 1999; Cagen et al., 1999; Toyama et al., 2004; Tyl et al., 2008). The reported effects considered together lack any common pattern consistent with a hormonal mode of action. Regardless, BPA is classified under the EU's GHS as a category 2 reproductive toxicant (i.e., suspected of damaging fertility or the unborn child) (ECHA, 2011).

Neurological Effects During fetal and childhood development, natural hormones can influence brain development and

subsequent behavior, including sexual behavior and other social interactions. Thus, several investigators examined whether low doses of BPA during fetal development can affect subsequent behavior of pups (e.g., Kubo et al., 2003; Schantz and Widholm, 2001). Early studies evaluated a number of endpoints, but interpretation is hampered by a lack of understanding of whether results are applicable to humans. Even so, there is no consistent evidence among these studies that low doses of BPA (i.e., ≤ 5 mg/kg-bw/day) cause adverse effects on behavioral endpoints (e.g., Ema et al., 2001; Palanza et al., 2002; Aloisi et al., 2002).

Because the relevance of these studies to humans is unclear, two recent studies were conducted (one by the U.S. Environmental Protection Agency, EPA) using robust, validated methodologies to assess the effects of low doses of BPA on the developing brain. These studies found no evidence of neurological effects in animals exposed to low doses of BPA (Stump et al., 2010; Ryan et al., 2010).

Immunological Effects The natural interactions between hormones and the immune system led several investigators to study whether BPA is associated with altered immune function. The data are currently insufficient for drawing conclusions about possible immunological effects at low doses, such as those experienced by humans. In light of several guideline/GLP multigenerational studies reporting no pathology indicative of immune system dysfunction at low doses (e.g., Tyl et al., 2002, 2008; Ema et al., 2001), the findings reported from non-guideline, non-GLP studies on immunological effects are unlikely to be indicative of potential human risks.

Carcinogenic and Mutagenic Effects Researchers have examined whether BPA could be carcinogenic via a hormonal mode of action. BPA was first tested for carcinogenicity by the U.S. National Toxicology Program (NTP), which concluded that, “under the conditions of this bioassay, there was no convincing evidence that [BPA] was carcinogenic for F344 rats or B6C3F1 mice of either sex” (NTP, 1982). In these assays, rats and mice were exposed for 103 weeks but not prenatally or during early life.

No government or international organizations classify BPA as a carcinogen. Though it is unclear whether BPA was evaluated for nomination by the NTP or the International Agency for Research on Cancer (IARC) for review of BPA’s carcinogenic potential, this substance is not currently listed as a carcinogen by either agency. EPA’s Integrated Risk Information System (IRIS; US EPA, 1988) developed a health assessment on BPA but did not perform a complete evaluation of its carcinogenic potential. In 2002, a panel of prominent scientists conducted a weight-of-evidence evaluation of potential BPA carcinogenicity and concluded that “BPA is not likely to be carcinogenic to humans,” citing the NTP bioassay as providing “no substantive evidence to indicate that BPA is carcinogenic to rodents” (Haughton et al., 2002).

In the following year, the EU published the results of its risk assessment report on BPA, in which the EU also concluded that BPA does not have carcinogenic potential (ECB, 2003).

In the last decade, several studies have examined the association between BPA and precursor lesions to cancer. While some studies showed associations between BPA and these precursors, none actually reported cancer (although it should be noted that most of these studies did not evaluate animals for their entire lifetime; e.g., Ho et al., 2006; Prins et al., 2008). Other studies evaluated the carcinogenic potential of BPA when co-administered with other chemicals (e.g., Jenkins et al., 2009; Lamartiniere et al., 2011). While some animals developed cancer in these studies, these results are not necessarily applicable to human exposures because BPA was administered via non-oral routes and/or with chemicals known to be carcinogens. Thus, these recent findings are not indicative of BPA being a human carcinogen under relevant conditions of exposure.

Several human studies have evaluated the association between BPA and various health effects, including, for example, premature birth, miscarriages, obesity, polycystic ovarian syndrome, cancer, altered sperm and semen characteristics, and other reproductive endpoints (e.g., Cantonwine et al., 2010; Sugiura-Ogasawara et al., 2005; Takeuchi and Tsutsumi, 2002; Takeuchi et al., 2004; Hiroi et al., 2004; Yang et al., 2006). The majority of these studies have methodological limitations that make their results difficult to interpret, largely because exposures in the general population are quite low and the range of exposures among people is small. The low BPA levels measured often are close to or below laboratory detection limits. Urinary measurements are comprised largely of conjugated, biologically inactive BPA, and blood measurements in most studies are most likely due to contamination and are not reflective of actual exposure (Teeguarden et al., 2011). The majority of human studies are cross-sectional in nature, in which BPA was measured at the same time as the health effect was assessed, so it cannot be known whether past BPA exposures were causally associated with the effect. Overall, the human studies conducted thus far are insufficient to address possible effects at these environmental levels.

Mode of Action

Studies have shown that BPA has estrogen-like or endocrine activity, meaning it can mimic or alter the effects of the body’s natural hormones. While toxicity tests used to develop safety standards for BPA found that the lowest dose at which adverse effects in animals were observed was 50 mg/kg-bw/day, several orders of magnitude higher than human exposures, hormonal effects were only found at much higher doses (Ashby and Odum, 2004). Still, some individual scientists support the so-called “low-dose hypothesis”—that is, at very low doses, BPA may cause adverse

effects that are not observed at higher doses via an endocrine mode of action.

BPA's weak estrogenic activity has been reported since the 1930s, but it was regarded as a safe and effective plasticizer until the publication of a study by a group of investigators led by Frederick vom Saal (vom Saal et al., 1998). In this study, pregnant mice were given oral doses of BPA at 0.002 or 0.020 mg/kg-bw/day from gestation days 11 to 17. When the male offspring were 6 months old, they were reported to have permanently increased preputial glands compared with unexposed mice. Because these effects were not observed at higher doses in other studies, this led to the hypothesis that low doses of BPA could cause effects that high doses would not.

The low-dose hypothesis is inconsistent with the first tenet of toxicology—*the dose makes the poison* (Eaton and Gilbert, 2008; Faustman and Omenn, 2008). Substances generally elicit an increasing level of effect with increasing dose. That is, adverse effects occur only when the dose exceeds a threshold for a certain period of time because at low doses, biochemical or physiological mechanisms inhibit a chemical's adverse effects or the perturbations are too minor to produce a dysfunction. As the magnitude and duration of exposure to a chemical increase beyond the threshold, these protective mechanisms become overwhelmed, and an adverse response appears to a degree that corresponds to the increase in dose. Proponents of the low dose hypothesis suggest that, as the dose of BPA increases, effects occur that would not occur at higher doses. This hypothesis is based on a selective evaluation of studies, however, and not a thorough analysis of the entire toxicological database (see, e.g., reviews conducted by Goodman et al., 2006, 2009; Gray et al., 2004; Hengstler et al., 2011).

SOURCES OF EXPOSURE

Almost all nonoccupational human exposures occur via residues in food or beverages that have been in contact with polycarbonate plastic or with containers lined with epoxy resins, as these products can contain trace amounts of the original compound or additional BPA that may be generated during the breakdown of the product (ECB, 2003; FAO and WHO, 2010). Oral and dermal exposures can also occur from contact with other products made with BPA. Estimates based on urine measurements and pharmacokinetic data suggest BPA intakes generally range from <0.00003 to 0.00161 mg/kg-bw/day.

Though many industries use products that may contain BPA residues, exposures to BPA from these products are generally thought to be negligible because the BPA is incorporated into a matrix (ECB, 2003). Highest occupational exposures likely occur in the BPA manufacturing industry. BPA is generally processed under closed conditions; however,

there are several points where there may be dermal and inhalation exposures to BPA, such as during product sampling and product bagging. BPA concentrations reported in these types of processes ranged from non-detect to 23.3 mg/m³ (8-h time-weighted average, TWA). Recent data submitted by European BPA manufacturers have reported lower concentrations, with 8-h TWAs ranging from non-detect to 3.6 mg/m³ (ECB, 2008).

INDUSTRIAL HYGIENE

Occupational limits for BPA have not been established by the U.S. Occupational Safety and Health Administration (OSHA), the U.S. National Institute for Occupational Safety and Health, or the American Conference of Industrial Hygienists (ACGIH). Rather, BPA is covered generally under the nuisance dust standards of these organizations. For example, OSHA has a permissible exposure limit (PEL) for particulates not otherwise regulated of 15 mg/m³ for total dust and 5 mg/m³ for the respirable fraction, whereas ACGIH has a threshold limit value (TLV) for particulates not otherwise classified of 10 mg/m³ for total dust and 3 mg/m³ for the respirable fraction.

RISK ASSESSMENTS

Several government and international agencies have performed human health risk assessments on BPA. Most of these risk assessments have used a no-observed-adverse-effects level (NOAEL) of 5 mg/kg-bw/day, derived from two multigenerational rodent studies, and a composite uncertainty factor of 500 (i.e., 10 × 10 × 5, for interspecies differences, interindividual variability, and uncertainties in the database on reproductive and developmental toxicity, respectively). Thus far, all of these risk assessments have concluded that exposure to BPA from its current uses poses no human health risks, i.e., either the exposure levels are far below the TDI (tolerable daily intake) or the margins of safety are far above 500 (i.e., estimated exposures are over 500 times lower than the NOAEL).

The same government and international agencies that performed risk assessments on BPA have also undertaken reviews in response to claims of low-dose BPA toxicity (i.e., ≤5 mg/kg-bw/day). Thus far, no such review has concluded that adverse effects reported to occur below the traditionally defined no-effect level are sufficiently plausible to constitute a health threat. Nonetheless, several governments have initiated bans on specific uses of BPA (e.g., in children's feeding bottles in Canada and the EU and all food contact material for children under 3 years of age in Denmark).

Risk assessments conducted by various government and international agencies and the regulatory status of BPA

around the world are described below. While the agencies and countries discussed should be considered to be a comprehensive list, it may not be exhaustive.

In 2001, NTP organized a scientific panel to conduct a peer review of the evidence on low-dose reproductive and developmental effects. The panel determined that “low-dose” effects of BPA were not “conclusively established as a general or reproducible finding” (NTP, 2001). A subpanel focusing specifically on BPA concluded,

[Th]ere is credible evidence that low doses of BPA [bisphenol A] can cause effects on specific endpoints. However, due to the inability of other credible studies in several different laboratories to observe low dose effects of BPA, and the consistency of these negative studies, the Subpanel is not persuaded that a low dose effect of BPA has been conclusively established as a general or reproducible finding. (NTP, 2001)

In other words, because the majority of credible studies found no evidence of an effect, these studies outweighed the few studies that found positive evidence.

In 2007, NTP’s Center for the Evaluation of Risks to Human Reproduction (CERHR) released a report that detailed studies of reproductive and developmental effects of BPA and applied a ranking of the utility of each study for determining risks to humans using the “levels of concern” scheme (NTP, 2007). In April 2008, NTP issued a draft brief on BPA, in which it stated that it agreed with the CERHR expert panel that there was some concern for effects on neurobehavioral, prostate gland, mammary gland, and puberty endpoints in sensitive populations at current exposures levels, and that there was negligible concern for exposures in pregnant women impacting in fetal endpoints such as mortality, birth defects, or growth/weight.

The NTP concurs with the conclusion of the CERHR expert panel on BPA that there is negligible concern that exposure to BPA causes reproductive effects in nonoccupationally exposed adults and minimal concern for workers exposed to higher levels in occupational settings. (NTP, 2008)

The highest level of concern assigned by NTP was “some” concern for certain effects and “negligible” concern for others, which indicates that NTP concluded that the data did not indicate a high level of concern for any effect. This low level of concern also indicated that NTP could not determine whether any effects observed in animal studies were applicable to humans.

In 2008, FDA issued a draft assessment (i.e., not an official FDA statement) that considered the CERHR’s 2007 report on BPA. The draft assessment considered the NOAEL for systemic toxicity of 5 mg/kg-bw/day (derived from two multigenerational rodent studies) to be appropriate, and it estimated the BPA exposure from use in food contact

materials in infants and adults to be 0.00242 and 0.000185 mg/kg-bw/day, respectively. Consequently, FDA concluded that there were adequate margins of safety (of approximately 2000 and 27,000 for infants and adults, respectively) at current levels of BPA exposure from uses in food contact materials. The draft assessment also concluded that the data on endpoints such as prostate effects and developmental, neural, and behavioral toxicity were insufficient to alter the NOAEL, meaning that there is no indication of low-dose effects of BPA (FDA, 2008). After further review in 2012, FDA determined that BPA “is not harmful under the intended conditions of use” (Dorsey, 2012).

In 2008, Health Canada assessed BPA exposure to newborns and infants from polycarbonate baby bottles exposed to high temperatures and from the migration of BPA from cans into infant formula. Health Canada (2008) concluded that BPA exposures to newborns and infants are below levels that may pose a risk, but the gap between exposure and potential effects concentrations is not large enough. Consequently, in April 2008, the Canadian government began action to consider banning the importation, sale, and advertising of polycarbonate baby bottles containing BPA, to develop stringent migration targets for BPA in infant formula cans, and to possibly list BPA under Schedule 1 of the Canadian Environmental Protection Act of 1999 (CEPA) (Health Canada, 2008). This action set a timeline for finalizing implementation plans, compliance strategies, and other risk management proposals by April 16, 2012 (Canada Gazette, 2010).

In 2009, the Health Canada Food Directorate issued a statement that concluded that current BPA exposure through food packaging uses was not expected to pose a health risk to the general population, including newborns and infants. This conclusion was based on the overall weight of evidence, including reaffirmation by other international regulatory agencies (in the U.S., Europe, and Japan) and was consistent with the conclusions of Health Canada’s 2008 assessment. Because of the uncertainty raised by some animal studies relating to the potential effects of low levels of BPA, however, it was recommended that the general principle of *as low as reasonably achievable* (ALARA) be applied to limit BPA exposure to infants and newborns, specifically from prepackaged infant formula products as a sole source of food (INFOSAN, 2009). Consequently, on September 23, 2010, Canada listed BPA as a toxic substance under CEPA (Canada Gazette, 2010).

The use of BPA in products intended to come in contact with food was first evaluated in Europe in 1986 by the Scientific Committee for Food (SCF). SCF calculated a TDI of 0.05 mg/kg-day, based on a NOAEL of 25 mg/kg-bw/day for effects on body weight in a 90-day rat study and a composite uncertainty factor of 500 (SCF, 2002). In 2002, SCF conducted a comprehensive review of toxicity and exposure information focused on food contact applications

of BPA. SCF derived a temporary TDI of 0.01 mg/kg-bw/day, based on an overall NOAEL of 5 mg/kg-bw/day in a three-generation rat study (for which liver toxicity, not a hormonal effect, was the most sensitive response) and a composite 500-fold uncertainty factor (10 for interspecies differences, 10 for interindividual variability, and 5 for uncertainties in the database on reproductive and developmental toxicity); SCF concluded that worst-case human exposures to BPA are well below the temporary TDI (SCF, 2002).

A 2003 EU Risk Assessment Report (RAR) concluded that, based on a thorough review of the evidence, no risk management actions were necessary for polycarbonate plastic or epoxy resin products. It established an overall NOAEL of 50 mg/kg-bw/day, based on the multigeneration study of BPA in rats (ECB, 2003). The EU Scientific Committee on Toxicity, Ecotoxicity, and the Environment (CSTEE), an independent scientific committee, affirmed the key conclusions of the 2003 EU RAR in its detailed opinion (CSTEE, 2002). In 2008, the EU released an addendum to the 2003 RAR (ECB, 2008), in which it stated the following:

The worst case combined exposure would be for someone exposed via the environment near to a BPA production plant, and who is also exposed via food contact materials (oral exposure from canned food and canned beverages and from polycarbonate tableware and storage containers). Given the very large margins of safety, there are no concerns for repeated dose toxicity and reproductive toxicity . . . There is at present no need for further information and/or testing or for risk reduction measures beyond those which are being applied already.

In 2006, the European Food Safety Authority (EFSA) Scientific Panel on Food Additives, Flavorings, Processing Aids and Materials in Contact with Food (the CEF Panel) performed what is considered to be the most comprehensive risk assessment on BPA. The CEF Panel reported that the NOAEL of 5 mg/kg-bw/day was still valid and further supported by a two-generation BPA study in mice (EFSA, 2006). In addition, the panel reported that the database had been strengthened to the point that the database component of the uncertainty factor could be eliminated. EFSA established a final TDI of 0.05 mg/kg-bw/day, based on a composite 100-fold uncertainty factor. Ultimately, it stated the following:

The Panel considered that low-dose effects of BPA in rodents have not been demonstrated in a robust and reproducible way, such that they could be used as pivotal studies for risk assessment. Moreover, the species differences in toxicokinetics, whereby BPA as parent compound is less bioavailable in humans than in rodents, raise considerable doubts about the relevance of any low-dose observations in rodents for humans. The likely high sensitivity of the mouse to oestrogens raises further doubts about the value of that particular species as a model for risk assessment of BPA in humans. (EFSA, 2006)

EFSA has reconsidered low-dose effects of BPA several times since 2006 upon the European Commission's request, and it has repeatedly concluded that evidence on potential low-dose effects of BPA remain inconclusive:

- The CEF Panel's July 2008 opinion concluded that the differences in age-dependent toxicokinetics of BPA in animals and humans would have no implication for EFSA's 2006 BPA risk assessment (EFSA, 2008).
- In response to a request to assess conclusions by Lang et al. (2008) that suggested a link between elevated levels of urinary BPA to increased occurrence of serious medical conditions (e.g., heart disease and diabetes), EFSA's October 2009 opinion concluded that the Lang et al. (2008) study did not provide sufficient proof for a causal link between BPA exposure and the serious medical conditions evaluated in the study and, therefore, the 2006 TDI need not be revised (EFSA, 2008).
- The American Chemistry Council commissioned the Stump et al. (2010) study to address safety concerns raised by the Canadian government. At the European Commission's request, EFSA reanalyzed the data from Stump et al. (2010) and showed that, statistically, the possibility of an effect of BPA on the neurotoxicity variables could neither be confirmed nor ruled out and, therefore, deemed the study to be inconclusive (EFSA, 2010b).
- In September 2010, the CEF Panel performed a detailed and comprehensive review of recent scientific literature and studies on BPA toxicity at low doses and concluded that it "could not identify any new evidence which would lead [it] to revise the current TDI for BPA of 0.05 mg/kg body weight set by EFSA in its 2006 opinion and reconfirmed in its 2008 opinion" (EFSA, 2010a). [One CEF Panel member expressed a minority opinion regarding recent studies indicating significant uncertainties in adverse health effects below the level used to determine the current TDI, but agreed with the rest of the CEF Panel members' opinion that the relevance of these recent findings for human health cannot be assessed at present (EFSA, 2010a).]

The German Federal Institute of Risk Assessment (Bundesinstitut für Risikobewertung (BfR)) was involved in EFSA's reevaluation as a competent authority and confirmed the EFSA opinions on BPA. In its updated Q&A on BPA in consumer products (May 3, 2011), BfR stated that intakes of BPA pose no health risks for infants and young children during normal use (BFR, 2010).

EFSA and other agencies have repeatedly concluded that the evidence to date on low-dose effects of BPA does not indicate health risks. Nonetheless, BPA has been banned in baby bottles in France and in all materials in contact with

food for children aged 0–3 years old in Denmark. Interestingly, the Danish Minister of Food, Henrik Høegh, has said:

From DTU Food [the National Food Institute at the Technical University of Denmark], we have received an assessment based on new comprehensive studies of rats. Danish experts say there is no clear evidence that bisphenol A has harmful effects on the behaviour observed. However, the experts find that the new studies raise uncertainties about whether even small amounts of bisphenol A have an impact on the learning capacity of new-born rats. In my opinion these uncertainties must benefit the consumers, so we will utilize the precautionary principle to introduce a national ban on bisphenol A in materials in contact with food for children aged 0–3 years. (Danish Ministry of Food, 2010)

This opinion is based on the neurobehavioral study by Stump et al. (2010), which EFSA and other agencies have determined does not support low-dose BPA risks.

In Japan, the Ministry of Health and Welfare (MHW); the Ministry of Health, Labour and Welfare (MHLW); the Ministry of Economy, Trade and Industry (METI); the Ministry of the Environment (MOE); and others convened panels of experts in 1998, 2001, 2002, and 2004 to evaluate BPA's health risks (Nakanishi et al., 2007). None of these panels recommended prohibiting or restricting the use of BPA, but some recommended a comprehensive risk assessment (Nakanishi et al., 2007).

Based on a thorough review of safety information in 2005, the National Institute of Advanced Industrial Science and Technology (AIST), a public research organization affiliated with METI, concluded that it was unlikely that humans, including infants and children, were at unacceptable risks from possible exposures to BPA in air, food, consumer products, and water, and no adjustment to allowable exposures was deemed necessary for claimed low-dose effects (Miyamoto and Kotake, 2006). A comprehensive risk assessment conducted by this organization established a NOAEL of 50 mg/kg-bw/day for reproductive and developmental toxicity based on the results of a multigeneration study in rats (Nakanishi et al., 2007). The report further concluded, “an additional uncertainty due to the low dose effects was not incorporated because the findings in the low dose studies were not robust, while those in negative studies were consistent” (Nakanishi et al., 2007). MOE also concluded in 2005 that no clear endocrine disrupting effects of BPA were found at low doses and that no regulatory action was required to manage BPA risks (MOE, 2005). This was based on its own low-dose studies of BPA, including a comprehensive reproductive study in laboratory animals.

In 2007, AIST, together with the New Energy and Industrial Technology Development Organization (NEDO) and the Research Center for Chemical Risk Management (CRM), performed a risk assessment of BPA. This risk assessment reviewed and reanalyzed extensive data regarding BPA exposures and hazards; reduction in body weight gain, liver effects,

and reproductive toxicity were the key toxicological endpoints. Risk was characterized not only by conventional approaches (e.g., the hazard quotient or the margin of exposure method), but also by more sophisticated approaches, including Monte Carlo simulations that propagate uncertainties in exposure parameters. This 2007 risk assessment also reached the same conclusion as the 2005 AIST risk assessment—that the current BPA exposure levels “will not pose any unacceptable risk to human health” (Nakanishi et al., 2007). Regarding low-dose effects of BPA, the 2007 risk assessment mirrored the 2005 report, stating that “an additional uncertainty due to the low dose effects was not incorporated because the findings in the low dose studies were not robust while those in negative studies were consistent” (Nakanishi et al., 2007).

Food Standards Australia New Zealand (FSANZ) concluded that BPA intake levels are very low and do not pose a significant human health risk for any age group, based on a safety evaluation of BPA in food, including that consumed by infants. For example:

[A] nine month old baby weighing 9 kg would have to eat more than 1 kg of canned baby custard containing BPA every day to reach the TDI, assuming that the custard contained the highest level of BPA found (420 parts per billion). (FSANZ, 2014)

In Australia, there is currently no mandatory standard for or ban on consumer products containing BPA. According to the Australian Competition and Consumer Commission (ACCC):

The ACCC, in conjunction with the other relevant Australian government regulatory agencies namely; Food Standards Australia New Zealand (FSANZ), the National Industrial Chemicals Notification and Assessment Scheme (NICNAS), the Therapeutic Goods Administration (TGA) and the Australian Pesticides and Veterinary Medicines Authority (APVMA) have collectively considered the possible risks of BPA and they remain convinced that the weight of evidence, obtained from an extensive range of safety studies, indicates that BPA is safe for the whole population at the very low levels of current exposure. (ACCC, 2011).

The International Food Safety Authorities Network (INFOSAN) is a global network of 177 member states and a joint initiative between WHO and the United Nation's Food and Agriculture Organization (FAO). In a 2009 summary of the current state of knowledge on BPA, INFOSAN (2009) stated that hazard assessments by major regulatory and advisory bodies agree the overall NOAEL for BPA from robust data is 5 mg/kg-bw/day, which is minimally 500-fold above conservative estimates of human exposure, including in bottle-fed infants. The summary identified several areas of uncertainty in BPA risk assessment:

- The relevance of animal studies showing neurobehavioral effects following BPA exposure during the

- developmental period at doses below the overall NOAEL;
- The differences between primates, including humans, and rodents, and between exposure routes in kinetics of absorption, metabolism, and excretion of BPA and their implications for extrapolation of animal studies to humans; and
 - Absence of convincing evidence from animal studies on cancer risk from BPA exposure.

In November 2010, WHO and FAO, with the support of EFSA, Health Canada, US National Institute for Environmental Health Sciences (NIEHS), and FDA, convened a panel of over 30 international experts to review toxicological and health aspects of BPA (FAO and WHO, 2010). The panel concluded that exposures to BPA occurred primarily via ingestion of food and that exposures from soil, dental sealants, and cash register receipts were of “minor relevance.” It also stated:

Studies on developmental and reproductive toxicity in which conventional end-points were evaluated have shown effects only at high doses, if at all. However, some emerging new end-points (sex-specific neurodevelopment, anxiety, preneoplastic changes in mammary glands and prostate in rats, impaired sperm parameters) in a few studies show associations at lower levels . . . There is considerable uncertainty regarding the validity and relevance of these observations. While it would be premature to conclude that these evaluations provide a realistic estimate of the human health risk, given the uncertainties, these findings should drive the direction of future research with the objective of reducing this uncertainty. (FAO and WHO, 2010)

Since the completion of the various risk and safety assessments discussed in this section, FDA has continued to study the safety of BPA in consumer products (e.g., Delelos et al., 2014). The results of these studies continue to support that BPA does not have adverse effects below 5 mg/kg-bw/day, and that, “Based on FDA’s ongoing safety review of scientific evidence, the available information continues to support the safety of BPA for the currently approved uses in food containers and packaging” (FDA, 2014).

POLYSTYRENE/STYRENE

LESLIE A. BEYER AND JULIE E. GOODMAN

Polystyrene (CASRN 9003-53-6) is prepared by the polymerization of styrene under the influence of organic peroxides in solution. Addition of inhibitors such as hydroquinone or butylcatechol prevents the monomer from polymerizing in storage. The properties of the polymer vary depending on the additives involved and the fabrication method. It can be injection molded, blow molded, thermoformed, or extruded. Prepared as a resin in small spheres, polystyrene is a clear, rigid polymer that is relatively stable under most conditions.

Hazards associated with the manufacture of polystyrene are associated with the monomer, styrene, and not the actual polystyrene product. Primarily a packaging material, polystyrene is used mostly as a component of a variety of food containers, such as egg cartons and hot-cold vending cups. It is also used in small appliances, medical devices, and toys.

Exposure to polystyrene dusts may cause mechanical irritation of the eyes and respiratory tract. Degradation products resulting from fire release styrene at lower temperatures and mostly CO and carbon dioxide (CO_2) at higher temperatures, with an unusually dense smoke being produced.

STYRENE

Occupational exposure limits: 100 ppm (OSHA PEL); 50 ppm (NIOSH REL); 20 ppm (ACGIH TLV).

Reference values: 0.2 mg/kg-bw/day (IRIS RfD); 1 mg/m³ (IRIS RfC).

Hazard statements: H412—harmful to aquatic life with long lasting effects; H226—flammable liquid and vapor; H332—harmful if inhaled; H319—causes serious eye irritation; H335—may cause respiratory irritation;

H315—causes skin irritation; H372—causes damage to ear through prolonged or repeated inhalation exposure; H304—may be fatal if swallowed and enters airways.

Precautionary statements: P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking; P233—keep container tightly closed; P240—ground/bond container and receiving equipment; P241—use explosion-proof electrical/ventilating/lighting/ . . . /equipment; P242—use only non-sparking tools; P243—take precautionary measures against static discharge; P260—do not breathe dust/fume/gas/mist/vapors/spray; P261—avoid breathing dust/fume/gas/mist/vapors/spray; P264—wash . . . thoroughly after handling; additional text wash hands and open skin areas thoroughly after handling; P271—use only outdoors or in a well-ventilated area; P280—wear protective gloves/protective clothing/eye protection/face protection; P301 + P310: *If swallowed*—immediately call a poison center or doctor/physician; P302 + P352: *If on skin*—wash with plenty of soap and water; P303 + P361 + P353: *If on skin* (or hair)—remove/take off immediately all contaminated clothing. Rinse skin with water/shower.

P304 + P340: *If inhaled*—remove victim to fresh air and keep at rest in a position comfortable for breathing; P305 + P351 + P338: *If in eyes*—rinse cautiously with water for several minutes. Remove contact lenses, if present and easy to do. Continue rinsing; P312—call a poison center or doctor/physician if you feel unwell; P314—get medical advice/attention if you feel unwell; P321—specific treatment (see . . . on this label); P331—*do not* induce vomiting; P332 + P313: If skin irritation occurs—get medical advice/attention; P337 + P313: If eye irritation persists—get medical advice/attention;

P362—take off contaminated clothing and wash before reuse; P370 + P378: In case of fire—use . . . for extinction; additional text In case of fire: Use foam, dry chemical, carbon dioxide for extinction; P403 + P233: Store in a well-ventilated place. Keep container tightly closed; P403 + P235: Store in a well-ventilated place. Keep cool; P405—store locked up; P501—dispose of contents/container to . . . ; additional text dispose of contents/container in accordance with local/regional/national/international regulation.

Risk phrases: R10—flammable; R20—harmful by inhalation; R36/37/38—irritating to eyes, respiratory system, and skin; R48/20—harmful: danger of serious damage to health by prolonged exposure through inhalation.

Safety phrases: S23—do not breathe gas/fumes/vapor/spray (appropriate wording to be specified by the manufacturer) vapor; S62—if swallowed, do not induce vomiting: Seek medical advice immediately and show this container or label.

to be negligible from the point of view of absorption and subsequent risk of systemic effects, although dermal contact with styrene can cause irritation (ACGIH, 2001).

Air concentrations are highest in the reinforced plastic, styrene–butadiene, and styrene monomer and polymer industries, in which workers are potentially exposed to higher concentrations of styrene than the general public, who are exposed to styrene levels outdoor and indoor (including levels in most other occupational settings) that are generally below 1 part per billion (ppb) (0.001 part per million (ppm). Air levels in the reinforced plastics industry have been generally lower than 100 ppm since the 1980s, although much higher levels have frequently been measured, while levels in the styrene–butadiene industry and the styrene monomer and polymer industries have rarely been reported to exceed 20 ppm (NTP, 2008). Air concentrations of styrene in the workplace have decreased over time, but in some workplaces younger workers with little seniority are typically exposed to higher concentrations of styrene and styrene oxide than their coworkers (Serdar et al., 2006).

BACKGROUND AND USES

Styrene (monomer CASRN 100-42-5) is a viscous, highly flammable liquid that evaporates easily and polymerizes readily to polystyrene unless a stabilizer is added. Large amounts are produced in the United States with an estimated 11.4 billion pounds produced in 2006 (NTP, 2008). Estimated production capacity was 13.7 billion pounds in 2006 (NTP, 2008) and over 12 billion pounds in 2008 (ATSDR, 2010). Styrene is used in multiple industries, especially in reinforced plastics (e.g., fiberglass boats), and is widely used to make plastics and rubber, packaging materials (e.g., packing “peanuts”), insulation for buildings, plastic pipes, food containers (e.g., takeout containers), and carpet backing (ATSDR, 2010). The industry directly employs 128,000 workers (SIRC, 2012).

EXPOSURE

People are exposed to small amounts of styrene that occur naturally in a variety of foods, such as fruits, vegetables, nuts, and meats; styrene can also migrate into food from packaging (ATSDR, 2010). Small amounts of styrene are naturally present in legumes, beef, clams, eggs, nectarines, and spices (ATSDR, 2010). Smoking and occupational exposures are the largest sources of exposure in the U.S. The highest potential exposure occurs in the reinforced plastics industry, where workers may inhale styrene and also have dermal exposure to liquid styrene or resins (ATSDR, 2010). In occupational settings, inhalation exposure is the largest source of exposure. Studies have shown dermal exposure

HEALTH EFFECTS

Noncancer

In humans, the nervous system is the most sensitive target following chronic inhalation exposure and likely the most sensitive target following shorter-term exposure (ATSDR, 2010). Styrene is a neurotoxin with acute toxicity considered to be low or moderate (NTP, 2008). The primary effects of acute exposure in both animals and humans include irritation of the skin, eyes, and respiratory tract, and central nervous system (CNS) effects. Common signs of styrene intoxication include drowsiness, listlessness, muscular weakness, and unsteadiness. A no observed adverse effect level (NOAEL) of 49 ppm has been identified by the Agency for Toxic Substances and Disease Registry (ATSDR) for acute effects based on Ska et al. (2003), who identified a NOAEL of 49 ppm in people based on a lack of significant styrene-related alterations in color discrimination, olfactory threshold, and neurobehavioral tests (ATSDR, 2010). Effects on color vision, hearing threshold, reaction time, and postural stability have also been reported in workers following long-term occupational exposure to styrene at concentrations ranging from about 20 to 30 ppm (NTP, 2008). For chronic inhalation exposure, ATSDR identified a lowest-observed adverse effect level (LOAEL) of 20 ppm based on the Benignus et al. (2005) meta-analysis of color discrimination impairment in styrene workers; the alterations were reversible and the workers were not aware of the changes (ATSDR, 2010). A multicenter study of 1620 styrene workers in the United States found that occupational exposure to styrene (at 3.5–22 ppm styrene and above) is a risk factor for hearing loss

and that exposure to noise significantly increases the effect (Morata et al., 2011). A comprehensive evaluation by the National Toxicology Program (NTP) concluded that the total scientific evidence was sufficient to conclude that styrene exposures to workers (and the general population) in the U.S. were unlikely to “adversely affect human development or reproduction” (NTP, 2006).

Cancer

Excess tumors at one site—the lung—have been found following both inhalation and oral exposure in some strains of mice (NTP, 2008). In rats, however, no excess lung tumors have been observed nor has increased cancer incidence of any type has been found consistently. None of the gavage or intraperitoneal or subcutaneous injection studies in rats reported an increased incidence in any tumor type (NTP, 2008) and inhalation studies have shown no consistent increases. The differences in effects in mice and rats are thought to be due to differences in metabolism and mode of action (see below).

Numerous epidemiology studies have been conducted in the reinforced plastics industry, manufacture of styrene monomer and polystyrene, and production of styrene–butadiene rubber. The reinforced plastics workers have generally been exposed to higher concentrations of styrene with less potential for confounding exposures to other chemicals in the workplace; therefore, these studies are the most informative (Cohen et al., 2002; Boffetta et al., 2009). Although some epidemiology studies have reported an excess of certain lymphatic and hematopoietic cancers, the results cannot be interpreted as supporting a causal association because of the small number of observed and expected deaths from these cancers, the potential for confounding by other occupational exposures, the lack of consistent dose-response patterns, the fact that excess risks were not found in all cohorts, and the fact that the types of lymphohematopoietic cancer observed in excess varied across different cohort studies (NTP, 2011; ACGIH, 2001; Cohen et al., 2002; ATSDR, 2010).

Studies in groups with the highest exposure (e.g., workers in the reinforced plastics industry as studied by Wong et al., 1994; Kogevinas et al., 1994; Ruder et al., 2004) have not found a clear excess of hematopoietic cancers (Cohen et al., 2002; Rhomberg et al., 2013; Delzell et al., 2006). Collins et al. (2013) updated a series of epidemiology studies in which the original study examined 15,908 workers exposed between 1948 and 1977 in 30 U.S. reinforced plastic facilities in 16 states. No increased mortality was observed for all lymphatic and hematopoietic cancer combined, non-Hodgkin lymphoma, or leukemia; and there was no trend with either cumulative exposure to styrene or number of peaks (Collins et al., 2013). However, the limited size of the populations having both high exposure and a long period of time since first exposure limits the available data (Cohen et al., 2002; NTP, 2011).

A series of epidemiology studies on North American synthetic rubber industry workers evaluated mortality from 1944 to 1998 among 17,924 men. Although the studies found an association between working in the industry and leukemia, after controlling for the effects of butadiene, no consistent exposure-response relationship was found (Delzell et al., 2006). Several other types of cancer have been associated with styrene exposure, but the overall pattern of the results demonstrates no consistent hazard and does not suggest a causal association between styrene and any form of cancer in humans (Cohen et al., 2002; Boffetta et al., 2009; Rhomberg et al., 2013; Delzell et al., 2006; ATSDR, 2010).

The differences in effects in mice, rats, and humans are thought to be due to differences in metabolism and mode of action (see below).

Absorption, Distribution, Metabolism, and Excretion

The most important route of exposure for people in occupational settings is by inhalation, which results in rapid absorption and distribution of approximately 60–70% of inhaled styrene (NTP, 2008). Styrene can also be absorbed through ingestion or skin contact.

Inhaled styrene is initially metabolized in the lung by the Clara cells, and subsequently in the liver. The initial step in styrene metabolism is catalyzed by P450 cytochromes, predominantly CYP2E1 and CYP2F2, but a number of other CYPs are involved; the degree to which they are involved and whether they predominate in the lung or liver varies between mice, rats, and humans. CYP2F2 is the primary enzyme in the mouse lung and is thought to be largely responsible for the lung cancer observed in mice but not rats or humans (NTP, 2008; Cohen et al., 2002; ATSDR, 2010). A recent study using CYP2F2 knockout mice found that styrene toxicity in the mouse lung required CYP2F2 metabolism (Cruzan et al., 2011).

Metabolic activation of styrene results in the formation of styrene-7,8-oxide, a mutagen *in vitro*, which is detoxified by glutathione conjugation or conversion to styrene glycol (NTP). Concern about the potential carcinogenicity of styrene stems largely from the ability of styrene oxide to bind covalently to DNA and to its activity in a variety of genotoxicity test systems (Henderson and Speit, 2005; Rueff et al., 2009).

Almost all absorbed styrene is excreted as urinary metabolites, primarily mandelic acid, and phenylglyoxylic acid (NTP, 2008). Generally accepted biomarkers of exposure to styrene are mandelic acid and pheylglyoxylic acid in urine and styrene in blood (IARC, 2002; ACGIH, 2003). The Biological Exposure Indices (BEIs) recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) are mandelic acid plus phenylglyoxylic acid in urine (sampled at the end of the shift) of 400 mg/g creatinine and styrene in venous blood (sampled at the end of the shift) of 0.2 mg/l (ACGIH, 2012a). Up to about 150 ppm in air, extrapolation

between the degree of exposure and biological levels of the metabolites is linear (ACGIH, 2003). The production of metabolites is suppressed by the presence of ethanol and is also affected by exposure to other solvents, and work load (Truchon et al., 2009; ACGIH, 2003). (For sampling and analytical methods and more information, see ACGIH, 2003). Styrene-7,8-oxide-DNA adducts and styrene-7,8-oxide-hemoglobin adducts are also generally accepted biological indices of exposure to styrene (NTP, 2008).

MODE OF ACTION, GENOTOXICITY

Styrene itself is not DNA reactive, but styrene-7,8-oxide binds covalently to macromolecules, including proteins and nucleic acids, forming stable N2 and O6 adducts of guanine in cultured mammalian cells. These adducts have also been measured in the lymphocytes of workers exposed to styrene. Other studies have shown an association between occupational exposure to styrene and DNA strand breaks, but such breaks are quickly repaired (Bastlova et al., 1995, as cited in Cohen et al., 2002), so their significance is unclear. In some animal studies (but not others), styrene has been associated with an increase in the frequency of aberrations, sister chromatid exchanges, and micronucleated cells (Cohen et al., 2002; Henderson and Speit, 2005). Human studies have shown conflicting associations between styrene exposure and the frequency of chromosomal abnormalities; there is less evidence for an association between styrene exposure and the frequency of sister chromatid exchanges; and no compelling evidence for micronuclei formation in human studies (Cohen et al., 2002; Henderson and Speit, 2005). Although some studies have shown DNA adducts and strand breaks in styrene-exposed workers, these types of damage indicate exposure, but may not result in heritable changes (Henderson and Speit, 2005). Genetic polymorphisms in the population may affect both metabolism and DNA repair (Henderson and Speit, 2005; Rueff et al., 2009).

CANCER CLASSIFICATION

Agencies have characterized/classified styrene's carcinogenicity as follows: ATSDR—may be a weak human carcinogen, (ATSDR, 2010); ACGIH—A4, not classifiable as a human carcinogen (ACGIH, 2001); IARC—possibly carcinogenic in humans (Group 2B) based on limited evidence in animals and humans (IARC, 2002); and NTP—reasonably anticipated to be a human carcinogen (NTP, 2011).

OCCUPATIONAL STANDARDS

The current Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) is 100 ppm as a

time-weighted average (TWA) for an 8-h work day (US Office of the Federal Register, 2014, although in 1996 industries using styrene adopted a voluntary compliance program to reduce exposure to 50 ppm, the NIOSH-recommended exposure limit (NIOSH, 1983 and OSHA, 1996, both as cited in Ruder et al. 2004). ACGIH threshold limit value (TLV) is 20 ppm (ACGIH, 2012b). NIOSH (2011) and ACGIH (2012b) have recommended short-term (15-min TWA) exposure limits of 100 and 40 ppm, respectively. OSHA has a ceiling limit of 200 ppm that can be exceeded but only to an acceptable maximum peak concentration of 600 ppm for a maximum of 5 min in any 3 h (US Office of the Federal Register, 2014; OSHA 29 CFR Part 1910.1000). NIOSH has designated 700 ppm as the concentration that is Immediately Dangerous to Life or Health (IDLH) (NIOSH, 2011).

Standards are based on protection from neurological effects, including decrements in color vision and hearing.

PHTHALATES

ROBERT W. BENSON

Target organ(s): Developing male reproductive tract

Occupational exposure limits: None

Reference values: There are no occupational exposure limits for this chemical; SML of 30, 0.3, and 1.5 mg/kg food for BBP, DBP, and DEHP, respectively

BACKGROUND AND USES

The phthalate esters that are the subject of this chapter are derivatives of phthalic acid where the acid groups are in the ortho position. The two alcohol groups can be the same or different and straight or branched chain. Phthalates are manufactured by reacting phthalic anhydride with alcohols.

Phthalate esters are used to impart flexibility to plastic products. Many consumer products and food packing products contain phthalate esters. The major uses of selected phthalate esters are summarized in Table 80.1. The phthalate ester is not covalently bound in the products in which they are used and can leach into the surrounding environment.

PHYSICAL AND CHEMICAL PROPERTIES

Selected physical and chemical properties are summarized in Table 80.2.

MAMMALIAN TOXICOLOGY AND MECHANISM OF ACTION

Extensive data have been published since 2000 showing that phthalate esters with side chains of three to ten carbon units

are developmental toxicants for the male reproductive tract (Foster, 2006). Johnson et al. (2012) provide a recent review. For those phthalate esters that cause malformations of the male reproductive tract, the phthalate monoester metabolite is believed to be the toxic chemical. The phthalate diester is rapidly converted to the phthalate monoester in rats and in humans. This metabolism occurs in the digestive tract prior to the absorption and after absorption by nonspecific esterases.

Matsumoto et al. (2008) summarized the studies available in human populations. A number of studies show an association between the effects (sperm and semen parameters in adults; anogenital distance in newborn males; and serum hormone levels in newborn infants) and environmental exposure to phthalates. After a thorough review of these studies, Matsumoto et al. (2008) concluded: “*some of the findings in human populations are consistent with animal data suggesting that PAEs (phthalic acid esters) and their metabolites produce toxic effects in the reproductive system. However, it is not yet possible to conclude whether phthalate exposure is harmful for human populations.*”

Based on the extensive data available from laboratory animals, there is concern that an environmental exposure to phthalate esters could cause adverse effects on the developing human male reproductive system. Additional concern is raised by the demonstration that phthalate monoesters, known to cause developmental toxicity in rats, are detected in a large percentage of human amniotic fluid samples (Silva et al., 2004). The exposure window of concern for humans is the late first trimester of pregnancy, gestation weeks 8–14 (Welsh et al., 2008).

Benson (2009) conducted a literature review for the phthalate esters that have the potential to be developmental toxicants based on their structure–activity relationships. The

TABLE 80.1 Phthalate Diester, Its Corresponding Monoester Metabolite, and Uses

Phthalate Diester	Monoester Metabolite	Major Uses
Dibutyl phthalate (DBP) CAS # 84-74-2	Monobutyl phthalate (MBP)	Plastic products containing nitrocellulose, polyvinyl acetate, or polyvinyl chloride; pharmaceutical coatings; lubricant for aerosol valves; antifoaming agent; skin emollient; nail polishes; fingernail elongators; and hair spray
Diisobutyl phthalate (DiBP) CAS # 84-69-5	Monoisobutyl phthalate (MiBP)	Same as dibutyl phthalate but less commonly used
Butylbenzyl phthalate (BBP) CAS # 85-68-7	Monobutyl phthalate (MBP) and monobenzyl phthalate (MBzP)	Polyvinyl chloride products, including vinyl tile, food conveyer belts, carpet tile, artificial leather, tarps, automotive trim, weather strippers, traffic cones, and vinyl gloves
Diethylhexyl phthalate (DEHP) CAS # 117-81-7	Monoethylhexyl phthalate (MEHP)	Polyvinyl chloride products, including building products, car products, clothing, food packaging, children's products, and in medical devices (storage containers, bags, and flexible tubing)
Dipentyl phthalate (DPP) CAS # 131-18-0	Monopentyl phthalate (MPP)	Not found
Diisononyl phthalate (DiNP) CAS # 68515-48-0 and 28553-12-0	Monoisononyl phthalate (MiNP)	Flexible polyvinyl chloride products, including children's toys, flooring, gloves, food packaging material, drinking straws, and garden hoses

focus was on the phthalate esters with a side chain containing four to ten carbons in the ortho position. The shorter chain phthalate esters (dimethyl phthalate and diethyl phthalate) were not included because these chemicals are not developmental toxicants in laboratory animal studies. Relevant toxicological data following an *in utero* exposure were located for dibutyl phthalate (DBP), diisobutyl phthalate (DiBP), butylbenzyl phthalate (BBP), diethylhexyl phthalate (DEHP), dipentyl phthalate (DPP), and diisononyl phthalate (DiNP). Benson (2009) focused on the most sensitive effect in the most sensitive life stage, the reproductive tract of the developing male fetus, to develop the reference dose (RfD) for each of the phthalate esters.

The development of the male reproductive tract is dependent on the presence of testosterone and the androgen receptor (Sharpe, 2008; Sharpe and Skakkebaek, 2008). Any chemical that reduces the concentration of the androgen

receptor–testosterone complex during the critical developmental window has the potential of causing irreversible malformations of the male reproductive tract. The mechanism of action in laboratory rats for each of the phthalate esters that are the subject of this chapter is the decrease in the concentration of fetal testosterone in Leydig cells during the critical developmental window in rats, gestation days 15.5–19.5 (Welsh et al., 2008). The decrease in testosterone concentration is triggered by a decrease in gene expression for the proteins involved in the rate limiting steps of testosterone synthesis. These steps include transport of cholesterol into the mitochondria facilitated by steroidogenic acute regulatory protein (STAR) and the conversion of cholesterol to pregnenolone by the enzyme CYP11A1 (also known as P450-SCC, side-chain cleavage enzyme).

There is experimental evidence that the decrease in fetal testosterone caused by cumulative exposure to these six

phthalate esters in rats follows a dose additional model (Howdeshell et al., 2008). Therefore, it is appropriate to conduct a cumulative risk assessment for simultaneous exposure to these phthalate esters using a dose addition model. This chapter provides examples of a cumulative risk assessment using exposure information from a U.S. and a German population.

SOURCES OF EXPOSURE

Occupational

Occupational exposures can occur during manufacture of the individual chemicals and their incorporation into plastic products during their manufacture. There are no quantitative data on exposures in occupational settings.

Environmental

Because the phthalate esters are used in such a wide variety of consumer products and are not covalently bound in the products in which they are used, human exposure to the phthalate esters is widespread. Some common examples are listed below.

- Inhalation of emissions from manufacturing facilities
- Dermal uptake from use in vinyl gloves and cosmetics
- Ingestion of dust from emissions from floor tile, carpet tile, and products used in automotive interiors
- Ingestion from plastic coatings on pharmaceuticals
- Ingestion from uses in children's chew toys
- Ingestion from uses in food packaging
- Intravenous exposure from uses in medical storage bags and tubing

Phthalate esters have no direct use in food. Atmospheric deposition on agricultural products from nearby manufacturing facilities is possible. However, the occurrence of a phthalate ester in food is more likely to be the result of contamination by transfer of the phthalate ester from materials in contact with the food during processing, handling, or transportation. Examples of materials that can contain a phthalate ester capable of transfer to the food include plastic bottles and containers, flexible plastic tubing, food conveyer belts, and various food packaging materials. Migration is more extensive to fatty foods because the octanol–water partition coefficient ($\log K_{ow}$) exceeds 1. It is believed that ingestion from food is the primary route of exposure for the general population. Quantitative data on total exposure to the U.S. population are available from the National Health and Nutritional Examination Survey (NHANES) reports (CDC, n.d.).

INDUSTRIAL HYGIENE

There are no occupational exposure limits for the phthalate esters.

The United States and the European Union have limited the quantity of BBP, DBP, and DEHP in children's toys that can be taken into the mouth to 0.1% by mass of the product. The European Union has also restricted the use of BBP, DBP, and DEHP to food contact surfaces only for nonfatty foods up to 0.1, 0.05, and 0.1%, respectively, in the final product. These restrictions also established specific migration limits (SML) of 30, 0.3, and 1.5 mg/kg food for BBP, DBP, and DEHP, respectively. There are no comparable restrictions in the United States on the use of BBP, DBP, and DEHP in products with contact to food.

MEDICAL MANAGEMENT

There are no generally recognized medical management strategies for the malformations of the male reproductive tract caused by an *in utero* exposure to the phthalate esters. The preventive strategy is to limit the exposure in women of childbearing age to the phthalate esters showing developmental toxicity, especially during the critical window of exposure, gestation weeks 8–14 (Welsh et al., 2008).

RISK ASSESSMENTS

The standard U.S. Environmental Protection Agency (EPA) approach was used to derive the RfD for the selected phthalate esters. The uncertainty factors included a factor of 10 for intraspecies variability, a factor of 10 for inter-species variability, and, if needed, a factor for extrapolation from a lowest observed adverse effect level (LOAEL) to a no observed adverse effect level (NOAEL).

For these phthalate esters the most vulnerable target for adverse health effects is the reproductive tract of the developing male fetus. Therefore, the RfD is based on exposure-response data from studies following an *in utero* exposure. This RfD will protect humans from other adverse effects that may occur at a higher exposure during neonatal or adult life.

Benson (2009) derived RfDs for DBP, DiBP, BBP, DEHP, DPP, and DiNP using the NOAEL or LOAEL values for each phthalate ester from the published literature. If appropriate, a benchmark dose analysis was conducted using the EPA software. These values are summarized in Table 80.3.

These RfDs are based on the assumption that the adverse health effect observed at the lowest exposure in laboratory rats (decrease in testosterone concentration in fetal Leydig cells) is relevant to humans. Some recent toxicological studies provide fairly convincing evidence that the decrease in fetal testosterone concentration is a species-specific response. Gaido et al. (2007)

TABLE 80.3 Reference Dose for Selected Phthalate Esters

Chemical	Critical Effect and Reference	POD/UF	RfD
DBP	Decreased fetal testosterone NOAEL = 30 mg/kg-day LOAEL = 50 mg/kg-day (Lehmann et al., 2004)	NOAEL/100	0.3 mg/kg-day or 0.00108 mmol/kg-day
DiBP	Decreased fetal testosterone production BMDL _{1SD} = 80 mg/kg-day LOAEL = 300 mg/kg-day (Howdeshell et al., 2008)	BMDL _{1SD} /100	0.8 mg/kg-day or 0.00288 mmol/kg-day
BBP	Decreased fetal testosterone production BMDL _{1SD} = 102 mg/kg-day LOAEL = 300 mg/kg-day (Howdeshell et al., 2008)	BMDL _{1SD} /100	1 mg/kg-day or 0.00327 mmol/kg-day
DEHP	Small or absent male reproductive organs BMDL ₁₀ = 27 mg/kg-day LOAEL = 14–23 mg/kg-day (NTP-CERHR, 2006)	BMDL ₁₀ /100	0.3 mg/kg-day or 0.000692 mmol/kg-day
DPP	Decreased fetal testosterone production BMDL _{1SD} = 17 mg/kg-day LOAEL = 100 mg/kg-day (Howdeshell et al., 2008)	BMDL _{1SD} /100	0.2 mg/kg-day or 0.000548 mmol/kg-day
DiNP	Decreased fetal testosterone LOAEL = 750 mg/kg-day (lowest dose tested) (Borch et al., 2004)	LOAEL/1000	0.8 mg/kg-day or 0.00179 mmol/kg-day

POD is the point of departure and UF is the total uncertainty factor.

BMDL_{1SD}=lower 95% confidence limit of the exposure necessary to give a 1 standard deviation decrease in testosterone versus control.

BMDL₁₀=lower 95% confidence limit of the exposure necessary to give a 10% increase in adverse effect versus control.

The RfD in mg/kg-day is rounded to one significant digit.

RfD (mmol/kg-day) = RfD (mg/kg-day)/molecular weight (mg/mmol).

first demonstrated that adverse developmental effects occurred in mice in the absence of a decrease in testosterone concentration and an absence in a decrease in gene expression for the proteins involved in the rate limiting steps in cholesterol transport into the mitochondria and formation of pregnenolone. A 250 or 500 mg DBP/kg-day exposure to mice from gestational day 16 to 18 significantly increased seminiferous cord diameter, the number of multinucleated gonocytes per cord, and the number of nuclei per multinucleated gonocytes. An exposure of 250 mg/kg-day was the lowest exposure tested in this study.

Two research groups have further investigated the possibility of a species-dependent response using xenografts of testicular tissue from different species implanted into rodent hosts (Mitchell et al., 2012; Heger et al., 2012). Mitchell et al. (2012) compared the effect in human fetal tissue versus rat fetal tissue xenografts in host mice. Human fetal tissue xenografts in mice showed no significant decrease in testosterone concentration following an exposure to DBP or monobutyl phthalate. In contrast rat fetal tissue xenografts showed decreases in testosterone concentration and decreased expression of rat testis CYP11A1 and STAR mRNA as found in intact rats.

Heger et al. (2012) found comparable results. These researchers implanted fetal rat, fetal mouse, or fetal human testes tissue

into immunodeficient rat and mouse hosts. Host animals were treated by gavage with a range of doses of DBP. Consistent with the *in utero* response, phthalate exposure induced mononuclear gonocytes formation in rat and mouse xenografts, but only the rat xenograft exhibited suppressed expression of steroidogenesis genes. Across the range of doses tested, human fetal testis xenografts exhibited mononuclear gonocyte induction at all exposures (100, 250, and 500 mg/kg-day) but were resistant to suppression of steroidogenic genes at all exposures.

It is not known whether transport of the toxic metabolite into the testicular xenografts is the same as that in intact animals. In the studies of Heger et al. (2012), an exposure of 100 mg/kg-day of DBP in the host animal is an adverse effect level in the human testicular xenograft. In intact rats, Lehmann et al. (2004) found a no effect level for a decrease in testosterone concentration at 30 mg/kg-day and an effect level at 50 mg/kg-day. This comparison would suggest that a hazard quotient for DBP using a decrease in testosterone concentration or using induction of mononuclear gonocytes as the end point would be in the same range. However, there are no comparable data available for the other phthalate esters.

Data on human exposure to phthalate esters is available for the U.S. population from the NHANES surveys in

TABLE 80.4 Exposure to Selected Phthalate Esters for a US Population in mg/kg-day

Chemical	Median	95th Percentile	Maximum
DBP	0.0013	0.0061	0.094
DiBP	0.0002	0.0011	0.016
BBP	0.00088	0.0040	0.029
DEHP	0.00071	0.0036	0.046
DPP	Not available	Not available	Not available
DiNP	<LOD	0.0017	0.022

Exposure to BBP, DEHP, and DiNP is directly from Kohn et al. (2000), Table 2. The original data used reported the urinary excretion of DBP and DiBP as a single summed value. Subsequent data collected by NHANES shows that urinary excretion of DiBP (creatinine corrected) is approximately 15% of the excretion of DBP (creatinine corrected). Accordingly, the DBP values have been reduced by 15%, and the remainder is attributed to DiBP.

1999–2000, 2001–2002, 2003–2004, 2005–2006, and 2007–2008 (CDC, n.d.). These studies measured the concentration of the monoester metabolites in the urine of a cross section of the U.S. population aged 6 years and above. As the monoester metabolites and additional oxidation products are rapidly excreted in urine (that is, they do not bioaccumulate), measurements of metabolites in urine can be used to estimate the total exposure to phthalate esters in the individual.

Kohn et al. (2000) used an earlier data set from 289 individuals and a linear two-compartment model to estimate the exposures (mg/kg-day) in the general population. No study has used the same method as Kohn et al. (2000) to update these exposure estimates taking into account the additional data sets available from the NHANES surveys. However, these subsequent NHANES data sets show values that are comparable to or somewhat lower than those used in the original analysis of Kohn et al. (2000). Therefore, large differences in the exposure estimates are not anticipated.

Data on human exposure to phthalate esters are also available from a German population (Wittassek and Angerer, 2008). The authors calculated the oral exposure from the urinary levels of the metabolites and urinary excretion factors determined from human metabolism studies. These data for both the United States and German populations are summarized in Table 80.4 and Table 80.5, respectively.

DECABROMODIPHENYL ETHANE

MAREK BANASIK

First aid: Eyes: Irrigate immediately and seek medical advice; skin: flush with water promptly; inhalation: remove to fresh air; ingestion: give 500 ml of water to drink

Occupational exposure limit: Derived no effect level (DNEL) (systemic effects, long-term inhalation): 71 mg/m³ (ECHA, 2014)

Reference values: DNEL (systemic effects, long-term inhalation): 17.4 mg/m³; DNEL (systemic effects, long-term oral): 5 mg/kg body weight (bw)/day (ECHA, 2014)

Hazard statement(s): None

Precautionary statement(s): None

Risk phrase(s): None

Safety phrase(s): None

BACKGROUND AND USES

Decabromodiphenyl ethane [DBDPEthane; Chemical Abstracts Service Registry Number (CASRN): 84852-53-9] is a brominated flame retardant used as an additive in a variety of polymer and textile applications. In polymeric applications, such as high impact polystyrene, DBDPEthane is compounded or blended into the resin. The resulting DBDPEthane-containing plastics are then converted to finished products by, for example, injection molding. For textile applications, DBDPEthane is blended with various latices and applied as a back coating to the textile.

Decabromodiphenyl ethane is a high production volume chemical. In the United States (US), the national production volume in 2012 was between 50 and 100 million pounds (*ca.* 22,680–45,359 tonnes) (EPA, 2012). In the European Union,

the production volume is between *ca.* 2.2 and *ca.* 22 million pounds (1,000–10,000 tonnes) per annum (ECHA, 2014).

Decabromodiphenyl ethane has undergone extensive toxicological testing to evaluate potential hazards to aquatic- and terrestrial-dwelling organisms and to humans through subchronic experimental animal studies. Based on these data, the United Kingdom's Environment Agency (EA) conducted an environmental and human health risk assessment on DBDPEthane. The sections that follow provide an overview of this information and the EA's risk conclusions.

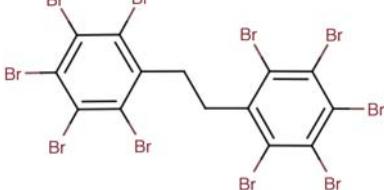

PHYSICAL AND CHEMICAL PROPERTIES

Decabromodiphenyl ethane is a powder with a high molecular weight, very low water solubility, and low lipophilicity (as indicated by log K_{ow}). The particles are <15 µm in diameter, and thus, this substance is expected to be respirable after inhalation exposure. A summary of DBDPEthane's physicochemical properties is provided in Table 81.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Decabromodiphenyl ethane's physicochemical properties suggest that it will partition predominantly in sediment and soil through binding to the organic fraction of particulate matter. In the EA environmental risk assessment, it concluded that DBDPEthane is unlikely to rapidly undergo photodegradation in the presence of hydroxyl radicals, it is not readily biodegradable in the aquatic environment

TABLE 81.1 Chemical and Physical Properties of Decabromodiphenyl Ethane

Characteristic	Information
Chemical structure	
Chemical name	1,1'-(Ethane-1,2-diyl)bis [pentabromobenzene]
Synonyms/trade names	DBDPE, DBDPE/RDT-3, DBDPEthane, decabromodiphenyl ethane, Ecoflame B-971, SAYTEX 8010, YCFR-03
Chemical formula	C ₁₄ H ₄ Br ₁₀
CASRN	84852-53-9
Molecular weight	971.22 g/mol
Physical state	Odorless white powder at room temperature
Melting point	350 °C
Vapor pressure	<1.0 × 10 ⁻⁴ Pa at 20 °C
Relative density	2.67 at 20 °C
Water solubility	ca. 0.72 µg/l at 25 °C
Octanol/water partition coefficient (log K _{ow})	3.55 at 25 °C
Particle size distribution	Mass median diameter: 5 µm

under aerobic conditions, and it is not hydrolysable (no hydrolysable groups) (Dungey and Akintoye, 2007). No data were available to assess the biodegradation under anaerobic conditions [e.g., wastewater treatment plants (WWTPs) or in sediments]; the EA noted the possibility of reductive debromination under these conditions.

The potential for DBDPEthane to bioconcentrate was evaluated in an 8-week fish bioconcentration study (Dungey and Akintoye, 2007). When fish were exposed to DBDPEthane at concentrations of 0.5 and 0.05 mg/l, the respective fish bioconcentration factors (BCFs) were <2.5 and <25 l/kg wet weight (ww), respectively. Since the water concentrations used exceeded DBDPEthane's water solubility, the dissolved concentration was unknown. The EA appropriately considered this study invalid. No additional BCF studies are available; however, based on the physicochemical properties, low toxicity in acute and repeated dose mammalian, aquatic, and terrestrial studies, it is unlikely that DBDPEthane will bioaccumulate.

ECOTOXICOLOGY

Decabromodiphenyl ethane has been evaluated in a series of aquatic, sediment, and terrestrial studies. No toxicity

was observed when fish (*Oncorhynchus mykiss*), algae (*Pseudokirchneriella subcapitata*), and daphnia (*Daphnia magna*) were acutely exposed to water-accommodated fractions of DBDPEthane at 110 mg/l (Hardy et al., 2012). In 28-day sediment toxicity studies, no treatment-related effects were observed on midge (*Chironomus riparius*) (development times, emergence, or development rates) or oligochaeta (*Lumbriculus variegatus*) [survival, reproduction, or dry weight (dw)] at 5,000 mg/kg dw, the highest concentration was tested. Hardy et al. (2012) calculated a predicted no effect concentration (PNEC) for sediment of 100 mg/kg dw. Using these same data, the EA converted the dw measures to wws and calculated PNECs for freshwater sediment and marine sediment of ≥21 mg/kg ww and ≥6 mg/kg ww (Dungey and Akintoye, 2007).

Terrestrial toxicity evaluations have been reported on sewage sludge respiration inhibition, soil bacteria nitrification, survival, and reproduction in earthworms, seedling emergence, and growth in six plants (Hardy et al., 2011).

Decabromodiphenyl ethane caused 5.3% inhibition in a 3-h sewage sludge respiration test at 10 mg/l. 3,5-Dichlorophenol, the positive control, caused 1.9, 40.6, and 80.8% inhibition at 3, 15, and 50 mg/l, respectively. In the soil nitrification study, a 28-day exposure to DBDPEthane at 2,500 mg/kg dry soil caused 5.6% inhibition of soil nitrate (mg NO₃⁻/kg dw) and 5.9% inhibition in soil nitrate formation (mg NO₃⁻/kg/day). 2-Chloro-6-(trichloromethyl)pyridine, the positive control, at 500 mg/kg dw caused 83.5% inhibition of soil nitrate and 95.0% inhibition of nitrate formation rate.

In the earthworm survival (28 days) and reproduction (56 days) studies, no treatment-related effects were observed on survival or bw up to the limit dose of 3,720 mg/kg dw. Reproduction was decreased by 60% at the limit dose. A no observed effect concentration (NOEC) of 1,907 mg/kg dw was reported. Reproduction median effect concentration (EC₅₀) and EC₁₀ (concentration that causes the measured effect in 10% of organisms) of 3,180 and 1,860 mg/kg dw, respectively, were calculated.

No treatment-related effects on survival or growth were observed with corn, ryegrass, or soybean up to the limit concentration of 6,250 mg/kg dw. Height and dw were decreased in onion and tomato plants at 3,125 mg/kg dw and 6,250 mg/kg dw, respectively. Survival was decreased in cucumber plants at the limit concentration. The following NOECs were reported: onion, height and dw (1,563 mg/kg dw); tomato, height and dw (3,125 mg/kg dw); and cucumber, survival (3,125 mg/kg dw).

Based on these findings, Hardy et al. (2011) calculated PNECs for sewage treatment plants and soil of 2,500 mg/kg dw and 156.3 mg/kg dw, respectively. The EA converted these dw measures to wws and calculated a PNEC for soil of 26 mg/kg ww (Dungey and Akintoye, 2007).

MAMMALIAN TOXICOLOGY

The toxicity of DBDPEthane has been evaluated by the oral and dermal routes of exposure in a number of experimental animal studies. Overall, DBDPEthane has low acute toxicity by all routes of exposure and is neither a skin/eye/respiratory irritant, nor a skin/respiratory sensitizer in animals and/or humans (ECHA, 2014). Most toxicity studies (e.g., repeated dose and developmental) conducted in rodents by the oral route of exposure indicate a low hazard concern; in the majority of these studies, no effects were found at the highest doses tested (typically $\geq 1,000$ mg/kg bw/day). A summary of acute and repeated dose toxicology studies is provided below.

Acute Studies

The acute toxicity of DBDPEthane has been evaluated by the oral and dermal routes using standard methods. No inhalation toxicity studies have been performed due to DBDPEthane's low vapor pressure (i.e., $<1.0 \times 10^{-4}$ Pa at 20 °C) and the absence of toxicity by the inhalation route on decabromodiphenyl ether, a structurally similar compound (Hardy et al., 2009). The oral and dermal toxicity studies performed on DBDPEthane are summarized below.

Mallory (1988a) evaluated the acute oral toxicity of DBDPEthane under good laboratory practice (GLP) standards (Dungey and Akintoye, 2007; citing Mallory, 1988a). A limit test with a dose level of 5,000 mg DBDPEthane/kg bw was conducted using young adult Sprague-Dawley rats ($n = 5/\text{sex}$). The animals were fasted 18 h prior to test substance administration. No changes in bw or clinical signs of toxicity were observed during the 14-day follow-up. No animals died during the study, and no visible lesions were observed at the terminal necropsy. The estimated acute oral median lethal dose (LD_{50}) was determined to be $>5,000$ mg/kg bw.

The acute dermal toxicity of DBDPEthane was evaluated under GLP using New Zealand white rabbits ($n = 5/\text{sex}$) as the test species (Dungey and Akintoye, 2007; citing Mallory, 1988b). A limit dose of 2,000 mg/kg bw was applied to unabraded, shaven skin over approximately 10% of the body surface. The test substance was occluded and remained in place for 24 h. Following the 24-h period, the wrappings were removed, along with any residual test substance. No changes in bw were observed during the 14-day period. Other than diarrhea observed in one animal, no other clinical signs of toxicity were observed. No animals died during the course of the study, and no visible lesions were observed at terminal necropsy. The estimated dermal LD_{50} was determined to be $>2,000$ mg/kg bw.

In summary, the dose levels tested in the acute oral and dermal toxicity studies exceeded or equaled the highest dose levels (i.e., 2,000 or 5,000 mg/kg bw) recommended under

current validated testing guidelines. Since no changes in bw, clinical signs, mortality, or tissues were observed at these dose levels, these studies support that DBDPEthane presents a low concern for acute exposures *via* the oral and dermal routes.

Repeated Dose Studies

Margitich (1991) performed a 28-day repeated dose toxicity study on male and female Sprague-Dawley rats ($n = 6/\text{sex/group}$), which included two 14-day recovery groups (control and high dose; $n = 6/\text{sex/group}$) (Dungey and Akintoye, 2007; citing Margitich, 1991). Decabromodiphenyl ethane was administered by gavage in a corn oil vehicle at dose levels of 0, 125, 400, and 1,250 mg/kg bw/day. At the end of 28 days, all animals were sacrificed, with the exception of the recovery groups. No treatment-related effects were reported with clinical signs of toxicity, bw, food consumption, ophthalmology, urinalysis, and histopathology of the same sex between the control and the low, middle, and high dose groups or between the recovery control and the recovery high dose groups at any point in the study. Differences were noted in some hematology and clinical chemistry measures, but were non-dose dependent and within historical control values. A dose-dependent increase in relative liver weight in female rats was reported (by 4% in the low and mid dose groups and by 10% in the high dose group). The EA concluded that there were no adverse effects up to the limit dose of 1,250 mg/kg bw/day.

Hardy et al. (2002) performed a guideline compliant 90-day repeated dose study in Sprague-Dawley rats, under GLP. Groups of male and female rats ($n = 10/\text{sex/group}$) included two 28-day recovery groups (control and high dose; $n = 10/\text{sex/group}$). Decabromodiphenyl ethane was administered daily by gavage using a corn oil vehicle at 0, 100, 320, and 1,000 mg/kg bw/day. At the end of the 90-day treatment period, all animals were sacrificed with the exception of the recovery groups. No treatment-related effects were reported with clinical signs of toxicity, body weight, food consumption, ophthalmology, or urinalysis between the controls and treated animals in the main study or the recovery groups. Differences in hematology and clinical chemistry were reported on days 30 and 90; however, they did not show a consistent pattern nor were they inconsistent with historical control ranges. In the high dose females, a statistically significant increase (by 13%) in the relative and absolute liver weight was reported at study termination. In high dose males, a statistically significant increase (by 8%) in the relative liver weight was reported at study termination. These changes were not present in recovery animals. Minimal to slight histopathological changes were observed at terminal sacrifice, which consisted of hepatocellular vacuolation (high dose males) and minimal to slight hepatocytomegaly (mid and high dose males). These changes were not observed in the recovery animals. Hardy et al. (2002) identified a no-observed-adverse-effect level (NOAEL) of

$\geq 1,000$ mg/kg bw/day. The EA concluded that the studied NOAEL was 1,000 mg/kg bw/day.

Decabromodiphenyl ethane has been evaluated in two separate, high quality prenatal developmental toxicity studies (Dungey and Akintoye, 2007; citing Mercieca, 1992a, 1992b; Hardy et al., 2010). In the first study, 25 mated female Sprague-Dawley were administered DBDPEthane by gavage with a corn oil vehicle at dose levels of 0, 125, 400, and 1,250 mg/kg bw/day from gestation day (GD) 6 through 15. The animals were sacrificed on GD 20 and subjected to cesarean section. In dams, no treatment-related effects were reported. In fetuses, no treatment-related effects were reported on weight, sex ratio, early/late resorption, or external/visceral abnormalities. Skeletal abnormalities (i.e., unossified hyoid and reduced ossification of skull) were statistically significantly increased in litters from the 400 mg/kg bw/day group. The EA considered this effect incidental to treatment because it was not seen in the high dose group, and concluded there was no evidence of developmental toxicity in rats up to 1,250 mg/kg bw/day.

In the second study, 20 artificially inseminated New Zealand white rabbits were administered DBDPEthane by gavage with a 0.5% methylcellulose vehicle at dose levels of 0, 125, 400, and 1,250 mg/kg bw/day from GD 6 through 18. The animals were sacrificed on GD 29 and subjected to cesarean section. In dams, no treatment-related effects were observed. In fetuses, no treatment-related effects were reported on weight, sex ratio, early/late resorption. Abortion occurred in one fetus from the 125 and 400 mg/kg bw/day groups and in two fetuses from the 1,250 mg/kg bw/day group. The EA considered this finding incidental given the low incidence observed in the study and the high spontaneous abortion rate in this species. A statistically significant increase in the number of litters with 27th presacral vertebra was observed in the high dose group (nine litters compared to four controls); however, the EA did not consider this effect adverse based on the historical control range (12.5–93.8%). The EA concluded that no adverse developmental effects occurred in rabbits up to the limit dose of 1,250 mg/kg bw/day.

Overall, the available database in animals supports that DBDPEthane presents a low concern for repeated subchronic exposures up to 1,000 mg/kg bw/day. The EA concurred with the foregoing study conclusions and utilized a NOAEL of 1,000 mg/kg bw/day for risk characterization. No studies have been performed to evaluate the potential reproductive or chronic/carcinogenic effects of DBDPEthane. However, DBDPEthane did not cause histological changes in the reproductive organs of male or female rats in a 90-day repeated dose study that suggests a low concern for reproductive toxicity. For chronic/carcinogenic effects, DBDPEthane was negative in standard *in vitro* mutagenicity and clastogenicity studies. The EA concluded that DBDPEthane is unlikely to be carcinogenic due to the negative genotoxicity data and the absence of proliferative lesions in the subchronic studies.

SOURCES OF EXPOSURE

Occupational

The greatest potential for worker exposure to DBDPEthane is through the inhalation of particulates in the workplace. The primary opportunities for exposure are activities that generate dust (e.g., compounding or blending of additives into the polymer) or through fumes from heated materials (e.g., conversion or injection molding). Decabromodiphenyl ethane is not combustible. It will, however, decompose at temperatures above 320 °C and generate corrosive fumes of hydrobromic acid, bromine, and oxides of carbon (ECHA, 2014).

Environmental

Environmental releases of DBDPEthane may occur during manufacture and packaging, compounding and converting, from finished articles, and from end-of-life disposal. Decabromodiphenyl ethane has been detected in virtually all environmental media, including house dust, sewage sludge, and sediment. In house dust, Stapelton et al. (2008) reported concentrations ranging from <10.0 ng/g up to 11,070 ng/g (median value = 201 ng/g). De la Torre et al. (2012) measured DBDPEthane at 47.0 ± 29.7 ng/g dw (mean \pm SD) in WWTPs in Spain. Ricklund et al. (2008) reported sludge levels of DBDPEthane as high as 216 ng/g dw in Germany. Wei et al. (2012) reported sediment levels of DBDPEthane as high as 2,400 ng/g dw in water bodies surrounding US manufacturing facilities. Though present in these media, the relatively low levels are of questionable toxicological concern given the effect levels identified from the available human health and environmental toxicity studies.

INDUSTRIAL HYGIENE

Decabromodiphenyl ethane is manufactured as an odorless white powder. The exposure controls and personal protection equipment recommended in the work place are designed to minimize eye, skin, and respiratory exposures (ECHA, 2014). Local exhaust is needed to minimize dust. Personal protection equipment includes a dust respirator fitted with high efficiency (dust, fumes, and mist) filter cartridges, protective gloves resistant to chemical penetration, and chemical goggles or safety gloves.

RISK ASSESSMENTS

The EA evaluated the potential human health and environmental risks from DBDPEthane's use as a polymer additive and its use in textiles. It concluded that DBDPEthane's use as a polymer additive "... does not appear to pose any direct environmental risks (including risks to humans exposed via

the environment) based on present knowledge." For the textile uses, the EA did not identify risks for "... surface water, WWTP, the atmosphere, predators or humans following environmental exposure." The EA noted the possibility of risks to sediment- and soil-dwelling organisms during the formulation and application of textile back coatings. It recommended several data needs that would aid with resolving this uncertainty, including textile site emission information, the number of user sites and geographical spread, and further sediment and soil toxicity studies to refine the PNECs, although the EA noted that "... [DBDPEthane] is not highly toxic."

TETRABROMOBISPHENOL A

DAVID Y. LAI

First aid: Eye: Irrigate immediately; skin: flush with water promptly; breathing: respiratory support; swallow: seek medical attention immediately

Target organ(s): Liver and uterus

Occupational exposure limits: DNEL (inhalation): 705 mg/m³; DNEL (dermal): 100 mg/kg-bw/day

Reference values: DNEL (inhalation): 174 mg/m³; DNEL (dermal): 50 mg/kg-bw/day; DNEL (oral): 5 mg/kg-bw/day

Hazard statement: H410: Very toxic to aquatic life with long-lasting effects

Precautionary statements: P273: Avoid release to the environment; P391: Collect spillage; P501: Dispose of contents/containers in accordance with appropriate local and national regulations

Risk phrases: 50/53

Very toxic to aquatic organisms, may cause long-term adverse effects in the environment

Safety phrases: 60-61

This material and its container must be disposed of as hazardous waste. Avoid release to the environment, refer to special instructions/safety data sheets.

BACKGROUND AND USES

Tetrabromobisphenol A (TBBPA; CASRN 79-94-7) is a brominated flame retardant used in a variety of reactive and additive applications. It is reacted (i.e., covalently bound) with epoxy, vinyl esters, and polycarbonate systems

(e.g., high impact polystyrene (HIPS), and is used as an additive in acrylonitrile-butadiene-styrene (ABS) thermoplastic resins (Albemarle, 1999). Its primary application is in printed wire boards (PWBs) as a reactive flame retardant (BSEF, 2012).

It is a high production volume chemical. In the United States (U.S.), the national production volume, including manufacturing and importing, in 2012 was >119 million pounds (EPA, 2012). In Europe, the national production volume in 2010 was between 2.2 and 22 million pounds (ECHA, 2013). Though not manufactured in Canada, an industry survey in 2000 indicated that imports of pure TBBPA or TBBPA contained in PWBs, ABS, and HIPS were between 0.2 and 2.2 million pounds (Canada, 2013).

It has undergone extensive toxicological testing and environmental monitoring. Based on these data, several regulatory agencies from around the world have conducted risk assessments on this compound. The sections that follow provide an overview of this information and the conclusions from these regulatory evaluations.

PHYSICAL AND CHEMICAL PROPERTIES

Tetrabromobisphenol A is a crystalline particle/powder with a moderately high molecular weight, low water solubility, and moderately high lipophilicity (as indicated by log K_{ow}). Only about 4% of the particles are <15 µm in diameter, and thus, little (<4%) is expected to be respirable (<10 µm in diameter) and absorbed from the lung after inhalation exposure. A summary of TBBPA's physicochemical properties is provided in Table 82.1.

TABLE 82.1 Chemical and Physical Properties of tert-Butyl Alcohol (ECHA, 2013)

Characteristic	Information
Chemical name	2,2',6,6'-Tetrabromo-4,4'-isopropylidenediphenol
Synonyms/trade names	2,2',6,6'-Tetrabromobisphenol A; tetrabromobisphenol A; TBBPA
Chemical formula	C ₁₅ H ₁₂ Br ₄ O ₂
CASRN	79-94-7
Molecular weight	543.8
Melting point	179–181 °C
Physical state	White solid crystalline powder
Particle size distribution	Mass median diameter: 52.2 µm, ca 4% with a particle size <15 µm
Vapor pressure	<1.19 × 10 ⁻⁵ Pa at 20 °C
Density/specific gravity	2.17
Water solubility at 25 °C	0.148 mg/l (pH 5); 1.26 mg/l (pH 7); 2.34 mg/l (pH 9)
Octanol/water partition coefficient (log K _{ow})	5.903 ± 0.0340 at 25 °C
Dissociation constant (pK _a)	9.40

ENVIRONMENTAL FATE AND BIOACCUMULATION

Its physicochemical properties suggest that it will partition to all compartments (i.e., water, sediment, and soil), predominantly to sediment and soil through binding to the organic fraction of a particulate matter. Available environmental fate studies indicated that TBBPA is persistent in water (half-life [$t_{1/2}$] ≥ 182 days), soil ($t_{1/2}$ ≥ 182 days), and sediment ($t_{1/2}$ ≥ 365 days) (Canada, 2013). It lacks functional groups that are expected to undergo hydrolysis (Canada, 2013). A number of laboratory studies (ECHA, 2013) showed that it can degrade to bisphenol A under aerobic conditions (Canada, 2013).

Tetrabromobisphenol A is identified as a persistent, bioaccumulative, and toxic (PBT) compound under the U.S. Environmental Protection Agency's Toxic Release Inventory (EPA, 2013). It was also placed on the State of Washington's Department of Ecology's PBT List (DOC, 2013). However, Environment Canada and Health Canada concluded that TBBPA did not meet their criteria for bioaccumulation (i.e., bioaccumulation factor >5000) (Canada, 2013). This conclusion was based on TBBPA's low bioaccumulation potential from its physicochemical properties (e.g., maximum diameter of 1.3–1.4 nm, ionization at environmentally relevant pH, and variable log K_{ow}), as well as from studies that showed TBBPA is rapidly metabolized and excreted in aquatic and terrestrial organisms (Canada, 2013).

ECOTOXICOLOGY

It has been shown to exert adverse effects on organisms in a variety of ecological toxicity test systems, with reported acute and chronic effect levels <1 mg/l in daphnia, mussels, and fish (Canada, 2013). Though the precise mode of action(s) is unknown, toxicity is expected to be higher for the non-ionized form of TBBPA than the ionized forms. In the non-ionized state, TBBPA is expected to act as a narcotic or baseline toxicant by altering membrane integrity or function, whereas the ionized forms are expected to be less bioavailable, and hence less toxic (Canada, 2013).

MAMMALIAN TOXICOLOGY

The toxicity of TBBPA has been evaluated by the oral, dermal, and inhalation routes of exposure in a number of experimental animal studies. Overall, TBBPA has low acute toxicity by all routes of exposure and is neither a skin/eye/respiratory irritant, nor a skin/respiratory sensitizer in animals and/or humans (ECHA, 2013). Most toxicity studies (e.g., repeated dose, developmental, reproductive, and neurobehavioral) conducted in rodents by all routes of exposure indicate a low hazard concern; in the majority of these studies, no effects were found at the highest doses tested. The European Union (EU) has reviewed many of the toxicological studies and has published a Risk Assessment Report (RAR) on TBBPA (EURAR, 2006), a summary of acute and repeated dose toxicology studies is provided below.

Acute Studies

Acute oral, dermal, and inhalation studies have been performed on TBBPA and submitted to regulatory agencies as part of regulatory dossiers. These studies support that TBBPA presents a low hazard concern by all routes of exposure (oral LD₅₀ > 5000 mg/kg-bw in male/female Sprague-Dawley rats; dermal LD₅₀ > 2000 mg/kg-bw in male/female New Zealand White rabbits; and inhalation is 8-h LC₅₀ > 500 mg/m³ in male/female Wistar rats, NDMI mice, and guinea pigs) (ECHA, 2013).

Repeated Dose Studies

In general, the repeated dose toxicity studies with TBBPA have shown low hazard concerns. This is expected based on the available toxicokinetic data. Metabolism and toxicokinetic studies in rats and humans have shown that TBBPA can be absorbed following oral exposures and rapidly excreted after Phase II metabolism/conjugation to more water-soluble metabolites. Over 95% of TBBPA or metabolites are excreted in the feces within 72 h after a single administration, and there is little tissue retention or bioaccumulation.

Tetrabromobisphenol A's estimated half-life in humans is about 2 days (Sjodin et al., 2003).

The chronic/subchronic toxicity of TBBPA has been investigated in three repeated dose studies. The findings from these studies are summarized below and in Table 82.2. In a 14-day inhalation study, the EU concluded that no adverse effects were reported up to the limit dose of 18 mg/l, with the exception of signs of mechanical irritation in all treatment groups due to the high dust levels. In a 90-day oral gavage study, rats were administered TBBPA at dose levels of 0, 100, 300, or 1000 mg/kg-bw/day. No neurobehavioral effects were observed during the weekly functional observational battery (FOB) evaluations. Slight changes in hematological evaluations and clinical chemistry were reported; however, the EU concluded that these effects were not toxicologically significant. Statistically significant decreases in serum T_4 were reported in males and females, but no accompanying change in serum T_3 , thyroid stimulating hormone (TSH), or histopathology of the liver, thyroid, parathyroid, and pituitary was reported. Therefore, the EU concluded that the decreases in serum T_4 were not considered to be adverse. Absolute spleen weight was decreased in males in the top two dose groups; no histopathological findings were noted. The EU concluded that these were chance findings of no toxicological significance. Finally, an increase in relative epididymis weight was reported in the middle dose group; however, no changes in relative epididymis weight or histopathology were identified in the high dose group. The EU concluded that these findings were of no toxicological significance. In a 21-day dermal study, TBBPA was administered to rabbits at dose levels up to 2500 mg/kg-bw/day for 6 h/day, 5 days/week. No toxicologically significant effects were identified.

The EU identified three principal studies and two supporting studies to assess reproductive/developmental toxicity. The principal studies are summarized below and in Table 82.3. TBBPA was evaluated in a two-generation reproductive performance and fertility study, which included a neurobehavioral and a neuropathological component. F_0 and F_1 rats were administered TBBPA by gavage at dose levels of 0, 10, 100, or 1000 mg/kg-bw/day. Animals were dosed during a 10-week premating period and during a 2-week mating period. Females were also dosed during gestation and lactation. The only treatment-related effect observed in the F_0 and F_1 generations was a statistically significant, 7% decrease in bodyweight gain during the 10-week premating period in the high dose group. Statistically significant decreases in serum T_4 were reported at various dose levels in males and females from the F_0 and F_1 generations. The EU concluded that these effects were not toxicologically significant because there were no other parameters associated with disruption of thyroid homeostasis. Detailed clinical examinations were performed on male and female F_2 pups on postnatal days (PNDs) 4, 11, 21, 35,

45, and 60; no treatment-related effects were identified. Motor activity, including horizontal and vertical activity counts and distance traveled, was assessed on male and female F_2 pups on PND 13, 17, 21, and 60. Subtle, non-dose-dependent changes were reported on PNDs 17, 21, and 60; however, the EU interpreted these as chance findings and unrelated to treatment. Learning and memory were assessed in male and female F_2 pups using a Step-through Passive Avoidance Test (SPAT) on PNDs 22 and 60. Some differences were reported for male pups on PNDs 22 and 60; no consistent pattern was observed. No differences were reported between treated and control female pups. The same animals evaluated in the SPAT testing were also evaluated in a Water M-maze beginning on PND 110 to assess short-term and long-term memory. No treatment-related differences were reported. A neuropathological evaluation on the central nervous system and peripheral nerves was performed on F_2 male and female pups on PND 60. No treatment-related differences were reported. Morphometric evaluations were also performed on F_2 males and females on PNDs 11 and 60. A statistically significant decrease in the thickness of the parietal cortex was observed in sexes on PND 11 but not on PND 60. No histologic changes were evident in the parietal cortex of F_2 male and female pups on PNDs 11 or 60. The EU interpreted the decreased thickness of the parietal cortex on PND 11 as a transient or chance finding that was unlikely to be toxicologically significant.

In a range-finder developmental study, mated female rats were administered TBBPA by gavage at 0, 30, 100, 300, 1000, 3000, or 10,000 mg/kg-bw/day from gestation days (GDs) 6 to 15. The animals were sacrificed on GD 20. No effects were reported on the number of viable and nonviable fetuses, early and late resorptions, total implantations, or corpora lutea. Three dams died at the top dose; no signs of toxicity were observed in animals receiving 3000 mg/kg-bw/day or less.

In a nonstandard developmental study, TBBPA was administered by gavage at dose levels of 0, 40, 200, or 600 mg/kg-bw/day to newborn rats from PND 4 to 21. A recovery group was maintained and sacrificed at 12 weeks of age. No changes in bodyweight, physical development, or reflex ontogeny were observed in any of the dose groups. Males and females in the 200 and 600 mg/kg-bw/day groups had sporadically occurring diarrhea. Changes were observed in hematology and clinical chemistry. Statistically significant decreases in hemoglobin and activated thromboplastin time were reported in males and females in the 600 mg/kg-bw/day groups, respectively. Total bilirubin was statistically significantly increased in both sexes in the top dose. Relative and absolute kidney weights were significantly increased in males (280%) and females (365%) compared to controls. Relative liver weight was increased by 11% in males in the 600 mg/kg-bw/day group. Histopathology of the kidney revealed moderate to severe polycystic lesions associated

TABLE 82.2 Summary of Repeated Dose Toxicity Studies on TBBPA Used by the EU

Study Type	Dose	Exposure Regimen	Species/Sex; Sample Size	Effect Levels	EURAR Conclusion
14-Day inhalation study (non-guideline/non-GLP)	2, 6, or 18 mg/l (particle size not documented)	4 h/day, 5 days/week for 2 weeks	Rat/♂ and ♀; 5 animals per sex per group	Some evidence of local irritation of eyes and upper respiratory tract at all dose levels as a consequence of mechanical irritation caused by high dust levels	No evidence of treatment-related systemic toxicity up to the highest dose of 18 mg/l
90-Day oral gavage study (guideline/GLP)	0, 100, 300, or 1000 mg/kg-bw/day (corn oil vehicle)	Daily	Rat/♂ and ♀; 10 animals per sex per group, 5 additional animals in the control and 1000 mg/kg-bw/groups for 6 week post-treatment evaluation (recovery)	<p><u>1000 mg/kg-bw/day:</u> 17% ↓ in platelet count, ♂; 2–3-fold ↑ in total bilirubin, ♂ and ♀; 18% ↓ in absolute spleen weight, ♂ (resolved at recovery); 1.7-fold ↑ in serum alkaline phosphatase, ♀ (resolved at recovery)</p> <p><u>300 mg/kg-bw/day:</u> 2–3-fold ↑ in total bilirubin, ♀; 15% ↓ in absolute spleen weight, ♂; 13% ↑ in relative epididymis weight, ♂</p> <p><u>All doses:</u> Non-dose-dependent ↓ in serum T₄ levels on day 33 and 90, ♂ and ♀ (resolved at recovery)</p>	No clear toxicologically significant adverse effects up to the highest dose tested, 1000 mg/kg-bw/day
21-Day dermal study (non-guideline/non-GLP)	0, 100, 500, or 2500 mg/kg-bw/day	6 h/day, 5 days/week	Rabbit/♂ and ♀; 5 animals per sex per group	No treatment-related effects reported at the highest dose tested	No toxicologically significant compound related effects were apparent

TABLE 82.3 Summary of Reproductive/Developmental Studies on TBBPA Used by the EU

Study Type	Dose	Exposure Regimen	Species/Sex; Sample Size	Effect Levels	EURAR Conclusion
2-Generation oral gavage study (guideline/GLP)	0, 10, 100, or 1000 mg/kg-bw/day (corn oil vehicle)	Daily, F ₀ generation treated during a 10-week premating period and a mating period of 2 weeks; Dams also treated during gestation and lactation F ₁ generation treated using same protocol	Rat/♂ and ♀; F ₀ and F ₁ , 30 animals per sex per group; F ₂ , 10 animals per sex per group for neurobehavioral investigations, and 10 animals per sex per group for neuropathological examination	<p><u>1000 mg/kg-bw/day:</u> F₀: 28% ↓ and 44% ↓ in mean serum T₄ in ♂ and ♀, respectively; F₀: 19% ↓ in mean serum T₃ in ♂; F₁: 47% ↓ and 32% ↓ in mean serum T₄ in ♂ and ♀, respectively; F₁: 7% ↓ bodyweight in parental ♂ during pre-mating period F₂: PND 60, 76% ↓ in horizontal activity in the 0–5 min segment in ♂; F₂: PND 60, 68% ↓ in horizontal activity in the 5–10 min segment in ♂; F₂: PND 60, ↓ in the thickness of the parietal cortex in ♀ and ♂</p> <p><u>100 mg/kg-bw/day:</u> F₀: 17% ↓ in mean serum T₄ in ♂; F₁: 38% ↓ and 32% ↓ in mean serum T₄ in ♂ and ♀, respectively; F₂: PND 17, ↓ horizontal activity in 20 min segment in ♀ F₂: PND 21, ↓ horizontal activity and distance traveled in the 5–10 min segment and over the 20 min test period in ♀ F₂: PND 60, 70% ↓ in horizontal activity in the 0–5 min segment in ♂;</p> <p><u>10 mg/kg-bw/day:</u> F₂: PND 17, ↓ horizontal activity in 15–20 min segment in ♀</p>	No effects on fertility or development, including neurodevelopment, or any other effects of toxicological significance were observed in this study up to a dose of 1000 mg/kg-bw/day

(continued)

TABLE 82.3 (Continued)

Study Type	Dose	Exposure Regimen	Species/Sex; Sample Size	Effect Levels	EURAR Conclusion
Developmental oral gavage study (range finder; non-guideline/non-GLP)	0, 15, 30, 100, 300, 1000, 3000, or 10,000 mg/kg/day	Daily, ♀, GDs 6 to 15	Rat/adult ♀ and fetuses ♂ and ♀; 5 dams assigned to each group	<u>10,000 mg/kg-bw/day:</u> 3 dams died; ↓ weight gain between GDs 6 and 15	There were no adverse effects on the developmental parameters assessed, up to very high dose levels, including a dose level producing severe maternal toxicity
Developmental study (non-guideline/non-GLP)	0, 40, 200, or 600 mg/kg-bw/day (0.5 w/v% carboxymethyl-cellulose vehicle)	Daily, ♂ and ♀, PNDs 4 to 21	Rat, ♂ and ♀; 6 animals per sex per group	<u>600 mg/kg-bw/day:</u> Sporadic diarrhea in ♂ and ♀; ↓ Hemoglobin in ♀; ↓ Activated prothrombin time in ♂; 280% and 365% ↑ in absolute/relative kidney weights in ♂ and ♀; Moderate to severe polycystic lesions associated with dilation of the tubules bilaterally from the cortico-medullary junction to the inner cortex in ♂ and ♀; 1.3 times ↑ absolute kidney weight in ♂ and ♀ after recovery; 11% ↑ in relative liver weight in ♂; <u>Centrilobular hypertrophy in 3/6 ♂.</u> <u>200 mg/kg-bw/day:</u> Slight polycystic lesions of the kidneys in 2/6 males; Slight, multiple kidney cysts in one ♂ and ♀	It is considered that the effects on the kidneys are likely the consequence of the unconventional direct gavage administration of very high doses of TBBPA to such young animals. Therefore, the relevance to human health of this isolated finding is considered questionable

with dilation of the tubules in all animals in the 600 mg/kg-bw/day groups and slight lesions in 2/6 males in the 200 mg/kg-bw/day group. Centrilobular hypertrophy was reported in 3/6 males in the 600 mg/kg-bw/day group. In the recovery animals, absolute kidney weights were 1.3 times higher than controls. Moderate to severe cysts of the kidneys were reported in all animals in the 600 mg/kg-bw/day groups. Slight cysts of the kidneys were reported in one animal per sex in the 200 mg/kg-bw/day group. Based on these findings, the EU concluded that directly dosed young animals are more susceptible to the nephrotoxic effects of TBBPA than older animals and utilized the no-observed-adverse-effect level (NOAEL) of 40 mg/kg-bw/day for characterizing risks to infants from environmental exposures.

The U.S. National Toxicology Program (NTP) (NTP, 2013) conducted 2-year carcinogenicity studies on TBBPA in male and female rats and mice at dose levels of 0, 250, 500, or 1000 mg/kg-bw/day. The test substance was administered by gavage using a corn oil vehicle. Animals were dosed 5 days per week for the duration of the studies. In rats, no treatment-related effects were observed with survival. At a 3-month interim sacrifice, no treatment-related effects were reported, with the exception of decreased thymus weights and increased liver weights in the 1000 mg/kg-bw/day groups. At terminal sacrifice, a slight increase in the incidence of interstitial cell adenomas was observed in the 500 and 1000 mg/kg-bw/day groups. No other treatment-related effects were observed. In female rats, endometrial atypical hyperplasia was observed in female rats in all dose groups. In the 500 and 1000 mg/kg-bw/day females, the incidence of uterine adenomas, adenocarcinomas, or malignant Müllerian tumors were significantly increased. In male rats, a slight increase in the incidence of interstitial cell adenomas of the testis was observed in the 500 and 1000 mg/kg-bw/day groups.

In mice, survival at terminal sacrifice was significantly less in males and females in the 1000 mg/kg-bw/day groups compared to controls. Significant increases in the incidences of ulcer, mononuclear cell cellular infiltration, inflammation, and epithelial hyperplasia were observed in females in the 250 and 500 mg/kg-bw/day groups and in males in the 500 mg/kg-bw/day group. No other treatment-related effects were reported in female mice. In male mice, nonneoplastic lesions occurred primarily in the kidney and liver. The incidences of renal tubule cytoplasmic alteration were significantly increased in the 250 and 500 mg/kg-bw/day groups. In the liver, eosinophilic focus and clear cell focus were significantly increased in the 250 and 500 mg/kg-bw/day groups and the 500 mg/kg-bw/day groups, respectively. Several non-dose-dependent neoplastic lesions were observed. The incidences of hepatoblastoma, hepatocellular carcinoma, or hepatoplasma and hepatocellular carcinoma (combined) were significantly increased in the 250 mg/kg-bw/day group. A significantly increased incidence of multiple hepatocellular adenoma was observed in the

500 mg/kg-bw/day group. Significant positive trends in the incidences of adenoma or carcinoma (combined) of the cecum or colon and of hemangiosarcoma in all organs were observed. Based on these findings, NTP concluded there was *clear evidence of carcinogenic activity* of TBBPA in female rats (uterine epithelial tumors), *some evidence of carcinogenic activity* in male mice (hepatoblastoma), *equivocal evidence of carcinogenic activity* in male rats (testicular adenoma), and *no evidence of carcinogenic activity* in female mice.

Modes of Action

The mechanisms/modes of action (MOA) of TBBPA toxicity/carcinogenicity are not clearly understood. Based on the toxicokinetics data, it seems likely that the thyroid hormone level changes and liver effects (i.e., enlargement of hepatocytes, increased liver weight, and slight focal necrosis of hepatocytes) observed in adult rats and/or mice after exposures to high doses of TBBPA for extended periods are due to saturated metabolic capability and diminished elimination/excretion of the compound.

Both *in vitro* and *in vivo* assays have shown that TBBPA is not genotoxic (EURAR, 2006; NTP, 2013), so a direct genotoxic MOA can be eliminated from consideration for tumorigenesis. Uterine tumors can arise in response to endogenous estrogen overstimulation in aged rats that can be exacerbated by administration of exogenous chemicals by direct and indirect pathways (Alison et al., 1994; Lax, 2004). After binding directly to estrogen receptors (ER) in a cell, estrogen/estrogen agonists can turn on hormone-responsive genes that promote DNA synthesis and cell proliferation. Therefore, estrogen/estrogen agonists can act as tumor promoters by inducing cell proliferation with preexisting mutations leading to tumor formation.

The ER-binding activity of TBBPA has been investigated in a number of *in vitro* screening assays. Review of the overall weight-of-evidence from *in vitro* assays has indicated that there is no significant estrogenic potential for TBBPA (EU, 2006; Canada, 2013). A recent study in mice has shown that TBBPA was negative for estrogenic responses by both subcutaneous injection and oral route of exposure up to 1000 mg/kg-bw/day (Ohta et al., 2012). Since *in vitro* and *in vivo* studies showed that TBBPA has no significant estrogenic potential (*reviewed in:* EU, 2006; Canada, 2013; Ohta et al., 2012), the direct ER pathway may also be eliminated from consideration as the MOA for the induction of uterine tumors by TBBPA.

Conjugations (glucuronidation and sulfation) are the major biotransformation pathways for excretion of TBBPA in rats, and these pathways are shared by estrogen, and its potentially genotoxic catechol metabolite (Raftogianis et al., 2000). Competition for glucuronosyltransferases and/or sulfotransferases by TBBPA could indirectly result in higher

serum levels of estrogen and increased formation of estrogen-derived reactive radicals following exposure to high concentrations of TBBPA (NTP, 2013). Reactive oxygen radicals produced after metabolism of estrogen can cause DNA damages and if unrepaired, these mutations may lead to tumor formation.

The *Tp53* tumor suppression gene is responsible for cell cycle checkpoint maintenance and genomic stability, and loss of cell cycle checkpoint control due to inactivation of *Tp53* by mutations can result in the development of various tumor types in rodents and humans (Blagosklonny, 2000; Muller and Vousden, 2013). In the NTP bioassays (NTP, 2013), a statistically significant increase in the incidence of mutations of the *Tp53* tumor suppression gene was noted in uterine adenocarcinomas from TBBPA-treated rats (60%) compared to spontaneous tumors from control rats (20%). It is possible that increased incidence of *Tp53* mutations may be caused by the reactive oxygen radicals or metabolites produced after metabolism of the high levels of circulating estrogens due to competitive inhibition of estrogen conjugations (glucuronidation and/or sulfation) and elimination/secretion by high doses of TBBPA. However, with the exception of multiple mutations in uterine tumors of two rats treated with TBBPA, there was no difference between the mutation spectra of spontaneous tumors and those from TBBPA-treated rats. Therefore, it is more likely that increased circulating estrogen levels due to competitive inhibition of estrogen conjugations by high doses of TBBPA may cause uterine tumors by inducing cell proliferation with preexisting *Tp53* mutations.

There are two types of uterine carcinoma with respect to histology, MOA, and molecular genetic pathways. Type I carcinoma (the most common type), is associated with expression of ER, estrogen overstimulation, endometrial hyperplasia, and *Tp53* mutations in only about 10–20% of the carcinoma. Type II carcinoma is unrelated to estrogen and frequent lack of estrogen receptor activities. It is associated with atrophic endometrium and *Tp53* mutations (90%) are the most frequent genetic alterations (Lax, 2004). In light of high incidence of *Tp53* mutations in the uterine adenocarcinomas, and lack of ER binding potential and increased levels of circulating estrogen in the TBBPA-treated rats, it is likely that TBBPA-induced type II carcinoma in the rats (rather than type I carcinoma). This notion is supported by the findings that there was no increase in endometrial hyperplasia (which is associated with type I carcinoma) in all dosed groups of female rats in the NTP bioassays when the original and residual tissues evaluations were combined; instead a new atypical hyperplasia was identified (NTP, 2013).

Uterine tumors can also be induced by dopamine receptor agonists in the rat through another indirect estrogen pathway. Dopamine serves as a key regulator of serum prolactin by activating dopamine receptors on the pituitary to inhibit the secretion of prolactin. Chronic administration of

dopamine receptor agonists to rats can result in decreased serum prolactin levels after competitively binding to the dopamine receptors on the pituitary, leading to estrogen dominance due to increase of estrogen synthesis after luteolysis of the persistent corpora lutea and the formation of new follicles. This estrogen dominance then leads to estrogen activity (i.e., expression of hormone-responsive genes that promote cell proliferation) and oxidative stress, which may induce hyperplasia and tumors of the uterine. This carcinogenic effect is unique to rodents and has not been demonstrated in other species, including humans since prolactin is the luteotrophic hormone in rodents but not in primates (Neumann, 1991; Alison et al., 1994). In an *in vitro* study investigating the effects of TBBPA on the uptake of neurotransmitters into isolated rat brain synaptosomes, a concentration-dependent inhibition of dopamine uptake showing a mixed competitive and non-competitive mode of inhibition has been reported (Mariussen and Fonnum, 2003). However, it is unknown if TBBPA can also compete with dopamine in receptor binding and be a dopamine receptor agonist. Further research is warranted to investigate this MOA for TBBPA-induced uterine tumors.

SOURCES OF EXPOSURE

Occupational

Workers may be exposed to TBBPA through inhalation and dermal contact in the workplace. However, absorption of TBBPA by inhalation and dermal route of exposure is low based on its physicochemical properties. The primary opportunities for exposure are activities that generate dust or through fumes from heated materials. TBBPA is not combustible. It will, however, decompose at temperatures above 284°C and generate corrosive fumes of hydrogen bromide.

Environmental

Tetrabromobisphenol A has been detected in virtually all environmental media. The relative contribution of TBBPA to environmental exposures depends on the end-use application. For example, when TBBPA is used as a reactive flame retardant, exposure is limited to residual quantities of the unreacted compound. Additive uses, such as those in ABS resins, represent the greatest opportunity for release due to migration or abrasion. A summary of reported levels of TBBPA in air, water, and sewage sludge is provided below.

Indoor air levels of TBBPA range from 1.6 to 8.0×10^{-7} mg/m³ in residences in the United Kingdom and Japan, respectively (Canada, 2013). Comparable levels were reported in commercial buildings. For example, Batterman et al. (2010) measured TBBPA levels in three out of 10 buildings in Michigan, USA. The levels in two university

buildings ranged from 1.2 to 2.3×10^{-8} mg/m³. The highest level of TBBPA was measured in one computer server room/office at 8.6×10^{-8} mg/m³.

Surface water levels of TBBPA have been measured in a variety of geographical locations, including Japan, Germany, France, and the United Kingdom (Canada, 2013). In Japan, TBBPA was detected in one sample at 5×10^{-2} µg/l out of 297 taken between 1977 and 2000. In 2000, TBBPA was detected in seven of thirty samples in German surface water downstream of a local industrial discharge at 2.04×10^{-2} µg/l. Finally, the levels of TBBPA in France and the United Kingdom ranged from <3.0 to 3.0×10^{-3} µg/l, respectively.

The levels of TBBPA in sewage sludge from 22 municipal treatment plants in Sweden ranged from non detects up to 220 ng/g wet weight(ww) (Oberg et al., 2002). The Swedish Environmental Protection Agency performed a similar study at 50 sewage treatment plants across Sweden and reported levels of TBBPA that ranged from <4 µg/kg⁻¹ dry weight up to 180 µg/kg⁻¹ dry weight (Law et al., 2006).

INDUSTRIAL HYGIENE

Tetrabromobisphenol A is manufactured as a white crystalline powder. Dermal absorption is a low concern for this chemical, as evidenced by its physicochemical properties and low toxicity in dermal studies. After inhalation, most of the inhaled particles will be deposited in the upper respiratory tract and some of which are expected to be swallowed into the gastrointestinal tract. The exposure controls and personal protection equipment (PPE) recommended in the work place are designed to minimize inhalation. Ventilation requirements include maintaining airborne levels below 3 mg/m³ for respirable particles and below 10 mg/m³ for inhalable particles. PPE include a dust respirator, protective gloves, chemical safety gloves, and body covering clothes and boots.

RISK ASSESSMENTS

The human health and environmental risks from TBBPA exposures have been evaluated by several agencies. Environment Canada and Health Canada concluded “there is currently low risk of harm to organisms or the broader integrity of the environment from TBBPA . . .” (Canada, 2013). Based on the adequacies of the margins of exposure between critical effect levels and upper bound estimates of exposure to TBBPA, Health Canada also concluded that “TBBPA is a substance that is not entering the environment in a quantity or concentration or under conditions that constitute or may constitute a danger in Canada to human life or health” (Canada, 2012).

A recent group of international experts has evaluated the mammary toxicology and potential risk of TBBPA (Colnot et al., 2014). Like the EU and Canada assessments, it was concluded that TBBPA has a low potential for systemic or reproductive/developmental toxicity. Review of the endocrine-mediated effects of TBBPA led to the conclusion that TBBPA should not be considered an “endocrine disruptor” in accordance with internationally accepted definitions. A health concern due to present levels of exposure of the general population with TBBPA is not supported by the available data.

In its draft environmental report, the European Union concluded “[t]here is a need for further information and/or testing” on TBBPA (EURAR, 2007). This conclusion was based on concerns over TBBPA’s degradation to bisphenol A in anaerobic sewage sludge treatment processes and land application of the sludge. Though no environmental risks were identified in the EURAR on bisphenol A, additional testing on bisphenol A with an aquatic snail species formed the basis for this conclusion (EURAR, 2007). Additional environmental concerns were expressed for additive uses of TBBPA in ABS resin compounding sites. In the final human health report, the European Union concluded that “[n]o health effects of concern have been identified for [TBBPA]” (EURAR, 2006). The European Food Safety Authority concluded that the following exposures do not present a human health concern: dietary exposures in adults, breast feeding exposures in infants, and house dust exposures in young children (EFSA, 2011).

TRIS[2-CHLORO-1-(CHLOROMETHYL)ETHYL] PHOSPHATE (TDCPP)

MAREK BANASIK

First aid: Eyes: flush with copious amounts of water for at least 20 min; get medical attention immediately; skin: remove contaminated clothing, wash skin thoroughly with mild soap and plenty of water for at least 15 min—get medical attention if irritation occurs; inhalation: remove to fresh air, keep person quiet and warm, apply artificial respiration if necessary and get medical attention immediately; ingestion: if swallowed, wash mouth thoroughly with plenty of water—get medical attention immediately.

Occupational exposure limits: Derived no effect level (DNEL) (systemic effects, long-term inhalation): 0.327 mg/m³; DNEL (systemic effects, long-term dermal): 0.047 mg/kg body weight (bw)/day (ECHA, 2013).

Reference values: DNEL (systemic effects, long-term inhalation): 0.058 mg/m³; DNEL (systemic effects, long-term dermal): 0.017 mg/kg bw/day; DNEL (systemic effects, long-term oral): 0.017 mg/kg bw/day (ECHA, 2013).

Hazard statements: H351: suspected of causing cancer; H411: toxic to aquatic life with long lasting effects.

Precautionary statements: P202: do not handle until all safety precautions have been read and understood; P273: avoid release to the environment; P308 + 313: if exposed or concerned, get medical advice/attention; P391: collect spillage; P405: store locked up; P501: dispose of contents/containers to . . . (*in accordance with local/regional/national/international regulation*).

Risk phrases: R40: limited evidence of carcinogenic effect; R51/53: toxic to aquatic organisms, may cause long-term adverse effects in the aquatic environment.

Safety phrases: S2: keep out of the reach of children; S20/21: when using do not eat, drink or smoke; S36/37: wear suitable protective clothing and gloves; S61: avoid release to the environment/refer to special instructions/safety data sheet.

BACKGROUND AND USES

Tris[2-chloro-1-(chloromethyl)ethyl] phosphate [TDCPP; Chemical Abstracts Service Registry Number (CASRN): 13674-87-8] is a halogenated phosphorus flame retardant used in a variety of sectors, including manufacturing of paints/coatings, furniture and related products, building/construction materials, fabrics/textiles/leather products, and foam seating and bedding products (EPA, 2012).

It is used extensively as an additive to flexible polyurethane foams (PUFs). Its end uses include molded automotive seating foam (e.g., seat cushions and headrests), slabstock foam in furniture, automotive fabric lining, and car roofing (ECHA, 2013). It is a high production volume chemical. In the United States (US), the 2012 national production volume, including manufacturing and importing, ranged from 10 to 50 million pounds (ca. 4,536–22,680 tonnes) (EPA, 2012). In the European Union (EU), the production volume is between ca. 2.2 and ca. 22 million pounds (1,000–10,000 tonnes) per annum (ECHA, 2013).

It has undergone extensive toxicological testing to evaluate potential hazards to aquatic- and terrestrial-dwelling organisms and to humans through subchronic and chronic experimental animal studies. The EU conducted a definitive environmental and human health risk assessment on TDCPP

TABLE 83.1 Chemical and Physical Properties of TDCPP

Characteristic	Information
Chemical structure	
Chemical name	Tris[2-chloro-1-(chloromethyl)ethyl] phosphate
Synonyms/trade names	Amgard TDCP, FR2, Fyrol FR-2, TDCP, TDCPP, Tolgard TDCP, Tolgard TDCP MK1
Chemical formula	C ₉ H ₁₅ Cl ₆ O ₄ P
CASRN	13674-87-8
Molecular weight	430.91 g/mol
Physical state	Colorless liquid
Melting point	<-20 °C
Vapor pressure	5.6 × 10 ⁻⁶ Pa at 25 °C
Relative density	1.51 at 20 °C
Water solubility	18.1 mg/l at 20 °C
Octanol/water partition coefficient (log K _{ow})	3.69 ± 0.36 at 20 °C
Henry's law constant	1.24 × 10 ⁻⁴ Pa m ³ /mol at 25 °C

Source: ECHA (2013); EURAR (2008).

in 2008 (EURAR, 2008). The sections that follow provide an overview of this information and the EU's risk conclusions.

PHYSICAL AND CHEMICAL PROPERTIES

Tris[2-chloro-1-(chloromethyl)ethyl] phosphate is a clear colorless viscous liquid with a relatively low molecular

weight, low water solubility, and low lipophilicity (as indicated by log K_{ow}). A summary of TDCPP's physicochemical properties is provided in Table 83.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

A series of studies have been performed to evaluate the environmental fate and bioaccumulation potential of TDCPP. Based on the data provided in Table 83.2, the EU concluded that TDCPP is expected to be persistent in water, sediment, sewage sludge, and soil. When emitted to the environment, the EU concluded that TDCPP will likely adsorb to particulate matter, based on its low volatility and relatively high adsorption coefficient. The Henry's law constant suggests that TDCPP will preferentially partition to water, rather than air. When assessing TDCPP's potential for persistence or bioaccumulation, the EU determined that TDCPP can potentially be persistent or very persistent and that it does not meet the criteria for bioaccumulative or very bioaccumulative compounds.

ECOTOXICOLOGY

The aquatic and terrestrial toxicity of TDCPP has been evaluated in a series of guideline studies. A summary of the studies selected by the EU as the most reliable for use in risk assessment is provided in Table 83.3. Based on these data, the EU calculated the following compartmental predicted no effect concentrations: freshwater (0.01 mg/l), freshwater sediment [0.18 mg/kg wet weight (ww)], wastewater

TABLE 83.2 Environmental Fate and Bioaccumulation Data on TDCPP

End Point	Protocol	Result
Hydrolysis	OECD ^a 111	<i>t</i> _{1/2} ^b at pH 9: >120 days at 20 °C
Photodegradation	Model estimate (AOPWIN TM program k) ^c	Reaction with hydroxyl radicals = 18.1 × 10 ⁻¹² cm ³ /molecule/s
Ready biodegradability	Modified Sturm test	Not readily biodegradable
Anaerobic biodegradation	None	<30 mg/l of chloride (limit of quantification) after 60 days

MAMMALIAN TOXICOLOGY

Acute and repeated dose toxicity studies on TDCPP have shown that it presents a low concern for acute adverse health effects from the inhalation, oral, and dermal routes. Repeated dose toxicity studies have only been performed by the oral route. These studies support that TDCPP presents a high concern for subchronic and chronic adverse health effects. A summary of the available acute and repeated dose toxicity studies utilized by the EU when assessing the potential risks from exposures to TDCPP is provided in the following sections.

Acute Studies

Tris[2-chloro-1-(chloromethyl)ethyl] phosphate shows low acute toxicity by the inhalation, oral, and dermal routes of exposure (Table 83.4). Skin and eye irritation studies produced minimal dermal and eye irritation, with no evidence of

corrosivity (EURAR, 2008). No respiratory irritation studies have been performed; however, in the 4-h acute inhalation study, no signs of irritation were observed at the limit concentration of 5.22 mg/l.

Repeated Dose Studies

No repeated dose studies on TDCPP are available by the inhalation or dermal routes of exposure. Several repeated dose studies have been performed using the oral route of exposure. The EU critically evaluated these studies and utilized two developmental toxicity studies and a 2-year carcinogenicity study to evaluate the potential risks of TDCPP. A summary of these three studies is provided below.

In the first developmental toxicity study, 20 female Sprague-Dawley rats were administered TDCPP in a corn oil vehicle at dose levels of 0, 25, 100, or 400 mg/kg bw/day from gestation days (GDs) 6 through 15. Dams were observed daily, and bodyweight was measured on GDs 0, 6, 11, 15, and 19. On GD 19, all dams were sacrificed, and gross examinations were performed on dams and fetuses. Pregnancy rates, mean number of corpora lutea, implantation

sites, and implantation efficiencies were unaffected by treatment. Several treatment-related effects were reported in the high dose group. The rate of resorptions was statistically significantly increased by 14.4% as compared to 6.7% in controls. Fetal viability index was statistically significantly decreased. Slightly lower mean fetal weight and crown-rump length was observed. Retarded skeletal development was considerable; however, it was unclear whether these effects were related to treatment or to maternal toxicity at the high dose. A no-observed-adverse-effect level (NOAEL) of 100 mg/kg bw/day was derived based on the increased number of resorptions and decreased fetal viability index in the high dose group.

In the second developmental toxicity study, 15–24 female Wistar rats were administered TDCPP in an olive oil vehicle at dose levels of 0, 25, 50, 100, 200, and 400 mg/kg bw/day from GDs 7 through 15. Postnatal functional tests were performed on surviving pups (date not stated). During gestation, 11 of 15 dams in the high dose group died and exhibited symptoms and signs of toxicity, including piloerection, salivation, and hematuria. Body weight gain and food consumption were significantly reduced in this group. A 17% reduction in body weight gain was observed in surviving dams. Maternal absolute kidney weights were increased by 8.7 and 35.5% in the 200 mg/kg bw/day and 400 mg/kg bw/day groups, respectively. Maternal relative kidney weights were increased by 12.2 and 65.3% in the 200 and 400 mg/kg bw/day groups, respectively. In the 400 mg/kg bw/day group, fetal death was significantly increased. Of the four surviving dams, one had total dead implants. Three had live fetuses. The number of live fetuses in all other treatment groups was comparable to controls. No treatment-related effects on skeletal formation were observed at any dose level. Postnatal functional tests were performed on surviving pups in the 0, 25, 50, 100, and 200 mg/kg bw/day groups. No changes were observed at any dose level in the following tests: open field, water maze, rota rod, inclined screen, pain reflex, and preyer's reflex examinations.

One long-term carcinogenicity study was completed on TDCPP in 1981; the complete details of the study are not available (Bio/dynamics, Inc., 1981). Freudenthal and Henrich (2000) subsequently published a summary of these data. Groups of 60 male and female Sprague-Dawley rats were fed TDCPP at dose levels of 0, 5, 20, or 80 mg/kg bw/day. An interim sacrifice was performed on 10 animals per sex per group.

A clear treatment-related effect on bodyweight was reported throughout the study. At study termination, the bodyweights of animals in the high dose group were decreased >20% of controls. At the interim and terminal sacrifice, absolute and relative liver weights in animals (both sexes) in the high dose group were increased. At terminal sacrifice, an increase in the number of foci of hepatocellular alterations and sinusoidal dilation was reported. No histological findings were reported in animals at interim sacrifice.

In the high dose groups (males and females), absolute and relative kidney weights were statistically significantly increased at the interim and terminal sacrifices. Histological findings at the interim sacrifice included discoloration and pitted surface irregularities in the mid and high dose males and in all treated females. At terminal sacrifice, an increased incidence of hyperplasia of the convoluted tubule epithelium was reported in males from all treatment groups and in females from the high dose group. Chronic nephropathy was increased in males in the mid and high dose groups and in females in the high dose group.

In high dose females, absolute thyroid weight was statistically significantly increased at terminal sacrifice. At the interim and terminal sacrifices, no changes in testes weights were observed in male rats at any dose level; however, gross findings in the mid and high dose groups at both sacrifice intervals included discoloration, masses/nodules, enlargement and flaccidity of the testes, and small seminal vesicles. Histological findings at the interim and terminal sacrifices included germinal epithelial atrophy with associated oligospermia in all dose groups. At the terminal sacrifice, the following findings were observed in all males: accumulation of amorphous eosinophilic material in the tubular lumens, sperm stasis, and periarteritis nodosa.

As shown in Table 83.5, the animals at terminal sacrifice had statistically significantly increased incidences of hepatocellular adenomas (high dose groups; male and female), hepatocellular carcinomas (high dose group; male only), hepatocellular adenomas/carcinomas (combined) (high dose groups; male and female), renal cortical adenomas (mid and high dose groups; male and female), adrenal cortical adenomas (high dose group; female only), and testicular interstitial cell tumors (mid and high dose groups; male only).

Based on the foregoing noncancer and cancer effects and the absence of positive results from *in vivo* mutagenicity studies, the EU concluded that TDCPP may be assumed to be a “threshold” carcinogen (EURAR, 2008).

The EU identified two separate NOAELs for performing its risk characterization. A NOAEL of 100 mg/kg bw/day was selected for developmental and maternal toxicity, based on the first developmental toxicity study. A lowest-observed-adverse-effect level (LOAEL) of 5 mg/kg bw/day was selected, based on preneoplastic effects observed in the kidney and testis.

SOURCES OF EXPOSURE

Occupational

The primary exposure concerns for workers include those that may occur by the inhalation and dermal routes. Tris[2-chloro-1-(chloromethyl)ethyl] phosphate is stable under normal working conditions; however, when heated to decomposition, it may release oxides of carbon and phosphorus and hydrogen

TABLE 83.5 Tumor Incidence in Sprague-Dawley Rats Fed TDCPP in a 2-Year Carcinogenicity Study

chloride. Measured data are available on typical exposures encountered in the workplace. The EU utilized the values in Table 83.6 when assessing risks to workers and included reasonable worse case (RWC) exposures in its assessment.

Environmental

Environmental releases of TDCPP may occur during manufacture and processing, from finished articles, and from end-of-life disposal. TDCPP has been detected in virtually all environmental media, including dust, sewage sludge, groundwater, drinking water, soil, and sediment. The end uses of TDCPP,

primarily as a flame retardant foam additive, are amendable to migration from the product; therefore, its ubiquitous presence in the environment is expected.

INDUSTRIAL HYGIENE

It is manufactured as a colorless liquid. The personal protection equipment recommended in the work place is designed to minimize eye, skin, and respiratory exposures (ECHA, 2013). Chemical goggles are recommended for eye protection. Suitable protective clothing (unspecified) is recommended to

Source: EURAR (2008).

avoid skin exposures. Neoprene rubber gloves are recommended for hand protection. A respirator fitted with high efficiency (dust, fumes, and mist) filter cartridges is recommended to reduce inhalation exposures.

RISK ASSESSMENTS

The US Consumer Product Safety Commission (CPSC) and the EU completed risk assessments on TDCPP. In its screening-level assessment, CPSC assessed cancer risks for adults and children from inhalation exposures to TDCPP released from furniture foam and covered fabrics (Babich, 2006). It identified lifetime population risks in adults of 300 excess cancers per million adults. In children during the first 2 years of life, CPSC identified 20 excess cancers per million children.

The EU assessed the potential risks from exposures to TDCPP in the environment and to workers, consumers, and from exposures to the general population from environmental sources (EURAR, 2008). For the environment, the EU concluded that no further testing/information or risk reduction measures were needed, beyond those currently being applied. For workers, the EU concluded that additional information and/or testing were warranted based on possible effects on female fertility. The same concerns about female fertility were expressed for consumers and for general population exposures from environmental sources. However, it was noted that the LOAEL of 5 mg/kg bw/day from the 2-year carcinogenicity study will likely be protective for

female reproductive effects for exposures occurring under these conditions.

TRIS(2-CHLORO-1-METHYLETHYL) PHOSPHATE (TCPP)

MAREK BANASIK

First aid: Eyes: Flush eyes with large amounts of water for at least 15 min, hold eyelids apart to ensure rinsing of the entire surface of the eye and lids with water—get medical attention immediately; skin: immediately remove and discard contaminated clothing and shoes/under a safety shower, wash all affected areas with plenty of soap and water for at least 15 min/do not attempt to neutralize with chemical agents; inhalation: remove victim to fresh air/if not breathing, give artificial respiration/if breathing is difficult, give oxygen—get medical attention; ingestion: get medical attention by calling a physician or poison control center immediately/do not induce vomiting unless directed to do so by the medical personnel/if vomiting occurs, keep head below hips to reduce the risk of aspiration

Occupational exposure limits: Derived no effect level (DNEL) (systemic effects, long-term inhalation): 5.82 mg/m³; DNEL (systemic effects, long-term dermal): 2.08 mg/kg body weight (bw)/day (ECHA, 2013)

Reference values: DNEL (systemic effects, long-term inhalation): 1.46 mg/m³; DNEL (systemic effects, long-term dermal): 1.04 mg/kg bw/day; DNEL (systemic effects, long-term oral): 0.52 mg/kg bw/day (ECHA, 2013)

Hazard statement: H302: harmful if swallowed

Precautionary statements: P264: wash . . . thoroughly after handling; P270: do not eat, drink or smoke when using this product; P301 + 312: if swallowed: call a poison center/doctor/. . ./ if you feel unwell; P330: rinse mouth; P501: dispose of contents/container to . . . (*in accordance with local/regional/national/international regulation*)

Risk phrase: R22: harmful if swallowed

Safety phrases: S46: if swallowed, seek medical advice immediately and show this container or label; S64: if swallowed, rinse mouth with water (only if the person is conscious); S29/35: do not empty into drains; dispose of this material and its container in a safe way

BACKGROUND AND USES

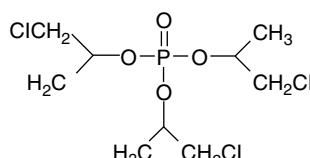

Tris(2-chloro-1-methylethyl) phosphate [TCPP, Chemical Abstracts Service Registry Number (CASRN): 13674-84-5] is a halogenated phosphorus flame retardant used in a variety of industrial sectors, including construction; plastics material and resin manufacturing; furniture and related product manufacturing; textiles, apparel, leather, paint, and coating manufacturing; and in the manufacture of other chemical products and preparations. Consumer uses of TCPP include foam seating and bedding products, building/construction materials not covered elsewhere, and adhesives and sealants (EPA, 2012).

It is commonly used as a flame retardant additive to rigid polyurethane foam (PUF) in panels and laminates for insulation applications. It is typically added to pentane-blown foam (15 parts by weight), which is used in applications such as roofing laminate. It is also used in polyurethane elastomers and in flexible PUFs when combined with melamine.

It is a high production volume chemical. In the United States (US), the 2012 national production volume, including manufacturing and importing, was 54,673,933 pounds (*ca.* 24,822 tonnes) (EPA, 2012). In the European Union (EU), the annual production volume is between *ca.* 2.2 and *ca.* 220.5 million pounds (1,000–100,000 tonnes) (ECHA, 2013).

It has undergone extensive toxicological testing to evaluate potential hazards to aquatic- and terrestrial-dwelling

organisms and to humans through subchronic and reproduction/developmental experimental animal studies. The EU conducted a definitive environmental and human health risk assessment on TCPP in 2008 (EURAR, 2008). The

sections that follow provide an overview of this information and the EU's risk conclusions.

PHYSICAL AND CHEMICAL PROPERTIES

Tris(2-chloro-1-methylethyl) phosphate is clear colorless liquid with high water solubility and low lipophilicity (as indicated by log K_{ow}). This substance is manufactured as a reaction mixture, which contains four isomers. It is the primary isomer in the mixture at 50–85% weight/weight (w/w), followed by bis(1-chloro-2-propyl)-2-chloropropyl phosphate [15–40% (w/w); CASRN: 76025-08-6], bis(2-chloropropyl)-1-chloro-2-propyl phosphate [<15% (w/w); CASRN: 76649-15-5], and tris(2-chloropropyl) phosphate [<1% (w/w); CASRN: 6145-73-9] (EURAR, 2008). A summary of TCPP's physicochemical properties is provided in Table 84.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

A series of studies have been performed to evaluate the environmental fate and bioaccumulation potential of TCPP. Based on the data provided in Table 84.2, the EU concluded that TCPP is expected to be persistent in water but inherently biodegradable in sewage sludge. The Henry's law constant suggests that TCPP will preferentially partition to water, rather than air. The EU determined that TCPP can potentially be

persistent or very persistent and that it does not meet the criteria for bioaccumulative or very bioaccumulative compounds.

ECOTOXICOLOGY

The toxicity of TCPP to aquatic and terrestrial organisms has been evaluated using standard test guideline methods.

Based on the data provided in Table 84.3, the EU derived the following predicted no effect concentrations: freshwater (0.64 mg/l), freshwater sediment [2.92 mg/kg wet weight (ww), equilibrium partitioning], wastewater treatment plant microorganisms (7.84 mg/l), seawater (0.064 mg/l, extrapolated from freshwater), marine sediment (0.292 mg/kg ww, extrapolated from freshwater), and soil (1.5 mg/kg ww) (EURAR, 2008).

MAMMALIAN TOXICOLOGY

Tris(2-chloro-1-methylethyl) phosphate is absorbed by all routes of exposure. The EU utilized the following absorption estimates when assessing the potential risks from TCPP: inhalation (100%), oral (80%), and dermal (40%). It has been evaluated in a series of guideline studies to assess its potential hazards from acute and subchronic

exposures, including reproduction and development. The studies utilized by the EU for risk characterization are summarized below.

Acute Studies

The acute toxicity of TCPP has been evaluated in rats administered the test substance by the inhalation, oral,

TABLE 84.4 Acute Toxicity Studies on TCPP

and dermal routes of exposure. An additional study investigating TCPP's potential to cause acute delayed neurotoxicity was conducted in hens, which the EU concluded as showing "... no concern for this end-point." Of the available studies, the EU relied upon those summarized in

Table 84.4 for determining TCPP's acute toxicity. The data support that TCPP presents a low hazard concern by the inhalation and dermal routes of exposure. The EU concluded that the oral gavage studies supported classification as "... R22, harmful if swallowed."

Repeated Dose Studies

In a 90-day study, male and female Sprague-Dawley rats were administered TCPP by diet at concentrations of 0, 800, 2,500, 7,500, or 20,000 parts per million. The intake concentration for males and females was 0, 52, 160, 481, or 1,349 mg/kg bw/day and 0, 62, 171, 570, or 1,745 mg/kg bw/day, respectively. At study termination, no treatment-related effects were reported on mortality, clinical observations, clinical chemistry, hematology, urinalysis, plasma, or erythrocyte or brain cholinesterase activity. Mean body-weight was statistically significantly ($p < 0.05$) reduced from day 22 or day 35 until study termination in the respective high dose males (decreased by 7.75% compared to controls) and females (decreased by 11.8% compared to controls). Absolute and relative liver weights were statistically significantly ($p < 0.05$) increased in all treated males and in females in the 570 and 1,750 mg/kg bw/day groups. Histological findings consisted of periportal hepatocyte swelling (hypertrophy) and were limited to the high dose animals (7/20 males and 8/20 females compared to controls [0/20 males and 5/20 females]). In male rats, mild thyroid follicular cell hyperplasia was observed in all treatment groups at 2/20, 2/20, 5/20, and 8/20 compared to 0/20 controls. This effect was limited to 5/20 high dose females compared to 0/20 controls. The EU noted that the effects on the liver and thyroid could be secondary to altered hepatic metabolic activity. A lowest-observed-adverse-effect level (LOAEL) of 52 mg/kg bw/day was reported for male rats, based on the liver and thyroid effects. In female rats, a no-observed-adverse-effect level (NOAEL) of 171 mg/kg bw/day was reported, based on increased liver weights. The EU utilized the LOAEL of 52 mg/kg bw/day for risk characterization.

In a two-generation study, groups of 28 male and female Wistar rats were fed diets containing TCPP during a 10-week premating period and throughout gestation and lactation. Litters were culled on postnatal day (PND) 4 to groups of 8 animals, consisting of 4 males and 4 females. On PND 21, the next generation of 28 males and females was weaned and selected at random. F_0 and F_1 dams were sacrificed after weaning, whereas F_0 and F_1 were treated for approximately 11 weeks, prior to sacrifice. The calculated overall intake for the respective control, low, middle, or high dose in females was 0, 99, 330, or 988 mg/kg bw/day and in males was 0, 85, 293, or 925 mg/kg bw/day.

No treatment-related effects were identified in either generation for the following end points: clinical signs, pre-coital time, mating index, female fecundity index, male and female fertility index, duration of gestation and postimplantation loss, epididymal sperm motility, sperm count, sperm morphology, mean testicular sperm count. Two mortalities occurred during the pre-mating period. A male was found dead on day 41, and a female was found moribund on day 50.

At necropsy, the cause of death or moribund condition could not be determined.

As shown in Table 84.5, statistically significant changes were reported in bodyweight and organ weights of F_0 or F_1 females and males primarily in the mid and/or high dose groups. The EU considered the kidney weight changes in male rats and the uterine weight changes in female rats as the main effects on organ weight changes. The EU noted that the uterine weight change was not accompanied by histological changes, that uterine weight may fluctuate during the estrus cycle, and that the reported changes may be reflective of normal variation in cycling females. As a precautionary approach, however, it considered the uterine weight changes as a treatment-related effect. In females in the F_0 and F_1 generations, the mean length of the longest estrus cycle was statistically significantly increased in all treated F_0 females and in high dose F_1 females. The EU considered this effect as toxicologically significant in high dose animals from the F_0 and F_1 generations because the effect on the low and mid dose animals may have been due to normal variation and not a specific fertility effect.

A summary of the pup and litter data for the F_0 and F_1 generations is provided in Table 84.6. A correlation was observed between decreased maternal bodyweight during gestation and the mean number of pups delivered and the mean number of live pups per litter. Both of these end points in the offspring were decreased in the F_1 mid dose group and in the high dose groups of both generations, which may have been due to maternal toxicity. One litter from a single F_1 dam was lost on PND 4; all other pups from all treatment groups survived. The mean number of runts in the F_0 generation was statistically significantly increased on PND 1 in all treatment groups. The number of runts persisted through PND 21 in the mid and high dose groups. In the F_1 generation, the number of runts was statistically significantly increased in the high dose group on PND 14 and in all dose groups on PND 21. In the F_2 generation, there was no effect on anogenital distance in male and female pups. In the high dose group, vaginal opening was delayed, although not statistically significantly, whereas preputial separation was statistically significantly delayed.

Based on the two-generation study, the EU used the following points of departure for risk characterization. The EU identified a LOAEL of 99 mg/kg bw/day in females for parental toxicity, based on decreased bodyweight and food consumption and effects on uterus weight. A NOAEL of 85 mg/kg bw/day was identified for males for parental toxicity, based on decreased bodyweight and food consumption and organ weight changes. For developmental toxicity, the EU identified a LOAEL of 99 mg/kg bw/day, based on the number of runts in the F_0 generation. The EU also noted that there was no concern for lactational effects.

No carcinogenicity data on TCPP are currently available; however, the US National Toxicology Program is in the

process of completing two-year dietary studies in rats and mice (NTP, 2014). At the time the EU evaluated TCPP, it concluded that TCPP is not genotoxic *in vivo* and that there is a potential concern for carcinogenicity by non-genotoxic

mechanisms, based on the 90-day repeated dose study, discussed herein, and read across from structurally similar chlorinated phosphate flame retardants (e.g., tris[2-chloro-1-(chloromethyl)ethyl] phosphate (TDCPP)).

^bNumbers in parentheses represent the number of litters with pups showing the observation.

SOURCES OF EXPOSURE

Occupational

The primary exposure concerns for workers include those that may occur by the inhalation and dermal routes from vapors or aerosols produced during the manufacture of TCPP and PUF. Dust exposures may also occur during the foam conversion and cutting of PUF. Tris(2-chloro-1-methylethyl) phosphate is stable under normal working conditions. The EU utilized measured data from 10 specific exposure scenarios encountered in the workplace when assessing potential

risks to workers and also derived reasonable worse case (RWC) exposure estimates (Table 84.7).

Environmental

Environmental releases of TCPP may occur during manufacture and processing, from finished articles, and from end-of-life disposal. The end uses of TCPP, primarily as a flame retardant foam additive, are amendable to migration from the product; therefore, its presence in the environment is expected. Stapleton et al. (2009) estimated the daily ingestion of flame retardants from house dust for a child and an adult at ca. 1.6 and

TABLE 84.7 Occupational Exposure Levels to TCPP

Exposure Scenario	Inhalation Exposure, µg/m ³		Dermal Exposure, mg/cm ² /day		Dermal Exposure Area, cm ²
	Typical	RWC	Typical	RWC	
1. Manufacture of TCPP	12.5	25	0.1	1	210

Source: EURAR (2008).

0.325 µg/day, respectively. The authors calculated these values based on the assumption that a child ingests 100 mg/day and an adult ingests 20 mg/day of dust. The EU evaluated environmental levels of TCPP and determined that the measured level in surface water from European countries, including the United Kingdom, generally ranged from 5 to 10 µg/l.

INDUSTRIAL HYGIENE

Tris(2-chloro-1-methylethyl) phosphate is manufactured as a colorless liquid. The personal protection equipment and mechanical controls recommended in the workplace are designed to minimize eye, skin, and respiratory exposures (ECHA, 2013). Chemical goggles or a face shield are recommended for eye protection against the liquid and aerosol. Suitable protective clothing (unspecified) is recommended to avoid skin exposures. Neoprene rubber gloves are recommended for hand protection. A respirator approved by the US National Institute of Occupational Safety and Health (NIOSH) for organic vapor/acid gas is recommended to reduce inhalation exposures under conditions that generate a vapor, mist, or aerosol. For conditions that warrant enhanced respiratory protection, a NIOSH-approved, positive pressure, pressure demand, air-supplied respirator is recommended. Mechanical controls are aimed at providing adequate ventilation.

RISK ASSESSMENTS

The EU assessed the potential risks from exposures to TCPP in the environment and to workers, consumers, and from exposures to the general population from environmental sources (EURAR, 2008). For the environment, the EU concluded that no further testing/information or risk reduction measures were needed, beyond those currently being applied. This conclusion applied to all environmental

compartments for all local life cycle stages and at the regional scale in all compartments. For workers, the EU concluded that there is a need for limiting risks from RWC dermal exposures during the manufacture of TCPP (Table 84.7, scenario 1) for potential effects on fertility and developmental toxicity. For typical dermal and inhalation exposures, both RWC and typical, during the manufacture of TCPP, the EU concluded that no information, testing, or risk reduction measures were recommended. No information, testing, or risk reduction measures were recommended for the remaining occupational exposure scenarios listed in Table 84.7. For consumers and humans exposed via the environment, the EU concluded that no information, testing, or risk reduction measures were needed beyond those currently being applied.

SECTION VI

PESTICIDES

SECTION EDITOR: RAYMOND D. HARBISON

85

INTRODUCTION

RAYMOND D. HARBISON

The well-accepted definition of a pest is any plant, animal, fungus, or other organism that adversely affects human health or welfare. A pesticide is a chemical used to kill a species that humans have designated as pests. Most pesticides fall in one of the four categories: insecticides, herbicides, fungicides, and rodenticides. Insecticides are the most widely recognized pesticides, but the greatest volumes of pesticides used are in the herbicide category.

Early in this century, pesticide use shifted from metallic pesticides to synthetic chemical formulations. More recently, pesticide use has shifted from broad-spectrum effects to formulations with greater specificity. The list of pesticides currently registered in the United States is continually changing because of the reregistration eligibility process. Triazine herbicides are a good example of the dynamic nature of pesticide regulation and use in the United States. They are some of the most commonly used pesticides in the United States today (Environmental Protection Agency [EPA], 1994). Triazine herbicides are characterized by a low oral toxicity but are relatively persistent in most environmental conditions. The EPA has requested voluntary cancellation of the triazine herbicide cyanazine because the agency considers cyanazine as a possible human carcinogen (EPA, 1996). Other triazine herbicides are also undergoing special review. In the span of 5 years, this group of pesticides probably will go from being the most widely used herbicides as a group to near disuse.

The changing status of triazine herbicides reflects regulatory concern for chronic toxicity. In the United States regulatory attention and public concern have shifted from acute toxicity to carcinogenicity, teratogenicity, and other

chronic effects. Another indication of this priority is the popularity of organophosphorus insecticides, which have largely replaced the organochlorine insecticides that was banned over two decades ago. Although the organophosphorus compounds may have severe acute effects, they are not biologically persistent and do not have a tendency to bioaccumulate.

Most modern pesticides are relatively safe when used properly; however, thousands of poisonings are attributed to pesticides each year. Many of these incidents involve intentional ingestion, but many more may be attributed to improper labeling, failure to follow label instructions, application by untrained individuals, or potent gray market pesticides, which often lack any label.

The estimated volume of pesticide used in the United States (by weight of active ingredient) has remained relatively stable for the past few years. The Environmental Protection Agency (EPA) attributes this plateau to the development of more potent pesticides, which require fewer applications, as well as to more efficient use of pesticides and lower farm commodity prices (EPA, 1994).

In spite of the long-time ban on the production and sales of organochlorine pesticides (e.g., dichlorodiphenyltrichloroethane) in the United States, they are still widely used in developing tropical and subtropical nations to control malaria through mosquito control.

Sadly, intentional and accidental ingestions remain the most common routes of overexposure to most pesticides. The most common form of occupational exposure is skin contact; for this reason, the importance of protective clothing in reducing exposure cannot be overstated.

The controversy over the chlorophenoxy herbicides (2,4,5-T and others) and over dioxin exposure and its health effects, particularly during the Vietnam conflict, continues to this day. Several large studies of veterans have shown no association between exposure and suspected health effects. But, a general mistrust of the U.S. government and a recent abundance of conspiracy theories have left the general public unconvinced and the scientific community somewhat divided.

INSECTICIDES

CAROL S. WOOD

ORGANOPHOSPHORUS AND CARBAMATE INSECTICIDES

First aid: Decontamination, symptoms

Target organ(s): Acetylcholinesterase inhibition

Occupational exposure limits: BEI[®] is 70% of baseline cholinesterase activity in RBC (ACGIH, 2010)

Reference values: Chemical specific, see below

Risk/safety phrases: Harmful if swallowed; avoid skin contact

BACKGROUND AND USES

Organophosphorus (OP) and carbamate insecticides have a wide variety of uses, including protection of crops, grains, gardens, and public health. Some also have application as therapeutic agents in certain disease conditions. Originally developed as chemical warfare agents, more than 30 OPs are registered for use as pesticides in the United States (Lowit, 2006). The volume of carbamates used exceeds that of the OPs because toxicity is generally less (Gupta, 2006) with 10 registered in the United States (Mortensen, 2006).

MAMMALIAN TOXICOLOGY

Acetylcholinesterase Inhibition

Acetylcholinesterase (AChE) is found primarily in the central nervous system (CNS), neuromuscular junctions, the hematopoietic system, and red blood cells (RBCs) and has a key

role in cholinergic neurotransmission. Acetylcholine (ACh) is involved in neurotransmission at motor, autonomic, and central synapses. For cholinergic neurotransmission to occur properly, ACh must be inactivated rapidly (in less than a millisecond) by the enzyme AChE. This removal prevents repeated stimulation of the receptor. ACh and AChE are present at the neuromuscular junction.

OP and carbamate insecticides inhibit cholinesterase by binding to, and phosphorylating, the active site of the enzyme, preventing the inactivation of ACh. The adverse effects of these insecticides are the result of accumulation of ACh at the neuromuscular junction, which causes muscular fasciculations and ultimately paralysis. Excessive ACh also causes excessive stimulation of the autonomic nervous system; this in turn causes excessive production of mucus, which accumulates in the lungs.

Particularly with certain OPs, the phosphorylated cholinesterase is irreversibly inactivated during an “aging” process of dealkylation of the phosphyl moiety. This aged enzyme is not reactivated by antidotes. Furthermore, an individual in whom the inactivated enzyme has not been replaced by synthesis of new enzyme will be hypersusceptible to additional exposure to OP insecticides. Regeneration of new enzyme usually requires several weeks.

When organisms are exposed chronically or subchronically to OP compounds, overt signs and symptoms of exposure may be absent. This phenomenon is called “tolerance.” Cholinergic muscarinic receptors (mAChR) in brain and peripheral tissues have been shown to decrease after repeated exposure to OP insecticides. This is thought to play a key role in the development of tolerance. Other mechanisms of tolerance development include the presence of

proteins that bind or inactivate the OP and more rapid metabolism to remove the OP (Fonnum and Sterri, 2006).

Individual variability in plasma cholinesterase activity is well documented (NRC, 2003). This variability includes age-related differences (neonates are more susceptible than are adults), gender differences (females tend to have lower plasma and RBC cholinesterase activity), and genetically determined variations in plasma cholinesterase activity. This genetic variability, which sometimes results in greatly reduced activity of plasma cholinesterase, may impart deficiencies in ability to detoxify organophosphates. Additionally, polymorphic variability in A-esterases, such as paraoxonase/arylesterase, may also contribute to individual variability in organophosphate ester detoxification processes (NRC, 2003).

Butyrylcholinesterase Inhibition

Butyrylcholinesterase (BuChE) is found in plasma, the liver, and the kidney. Its activity is also inhibited by OP and carbamate insecticides. BuChE is able to hydrolyze much larger substrates than AChE due to differences in their structure that allow BuChE to bind bulky ligands. The physiological role of BuChE is not completely understood, but it represents an important detoxification pathway for anticholinesterase compounds (Sultatos, 2006).

Acute Signs and Symptoms

Signs and symptoms of excessive exposure include headache, dizziness, and weakness. Anorexia, meiosis, impairment of vision, anxiety, and tremors of the tongue and eyelids may also be seen. Increasing exposure can result in increased salivation and lacrimation and uncontrolled urination and diarrhea. Increased sweating, abdominal cramps, nausea and vomiting, slow pulse, and muscle tremors also occur. Intoxication causes pulmonary edema, cyanosis, respiratory paralysis, coma, and heart block. With low level exposure, meiosis can be the only indication that exposure has occurred.

Occupational Monitoring

Both RBC AChE and plasma BuChE measurements are used to diagnose exposure and in occupational screening programs. Inhibition of RBC AChE to <50% of baseline, or preexposure levels, is considered diagnostic of exposure but not related to severity of poisoning. At levels of RBC AChE inhibition 30–50% of baseline, the worker should be removed from exposure while inhibition to >80% of baseline is associated with severe symptoms and mortality in the absence of treatment. Similar inhibition ranges are assigned to BuChE inhibition (Ballantyne and Salem, 2006).

Treatment

Removal from exposure and decontamination of the skin and clothing are the first treatment measures. Gastric lavage may be used in serious cases of ingestion, but induction of vomiting should be avoided especially if the victim may lose consciousness. Severe clinical intoxication requires rapid treatment with atropine and pralidoxime (2-PAM, Protopam); however, first excess airway secretions must be removed completely to maintain a patent airway. Atropine should be administered intravenously until signs of atropinization, especially reduced salivation and bronchial secretion, are observed. Atropine competitively blocks ACh and other muscarinic receptor agonists. Pralidoxime can be administered to reactivate cholinesterase. Treatment is effective when administered within 24 h of intoxication (Marrs and Vale, 2006).

While acute symptoms can be successfully treated if aggressively monitored, protection against intermediate syndrome (IMS) and organophosphate-induced delayed polyneuropathy (OPIDP) is less certain. Pralidoxime has been somewhat effective in preventing the development of IMS when given within 12 h of poisoning. No antidotal treatment for organophosphate-induced delayed neuropathy is recognized as effective (Marrs and Vale, 2006).

An individual recovering from overexposure has a hypersusceptibility to the effects of additional exposure to OP insecticides. This increased susceptibility usually lasts for several weeks, followed generally, by complete recovery.

Organophosphate-Induced Delayed Neuropathy

Organophosphate-induced delayed neurotoxicity (OPIDN) is a relatively rare toxicity of the nervous system caused by some OP compounds. It is characterized by sensory and motor axon degeneration in distal regions of the peripheral nerves and spinal cord tracts. The axonal degeneration is delayed for 1–3 weeks after exposure depending on dose. Organophosphate-induced delayed neurotoxicity is recognized as an effect independent of AChE or BuChE inhibition. Symptoms initially include cramping muscle pain in the lower limbs followed by distal numbness and paresthesia, and progressive wasting and flaccid weakness especially of the lower limbs (Moretto and Lotti, 2006). A high stepping gait associated with foot drop is the classic sign of OPIDN.

It occurs as a result of the inhibition of neuropathy target esterase (NTE). Phosphorylation and subsequent aging of at least 70% of NTE typically is sufficient to cause OPIDN (Johnson, 1990). Inhibition of NTE in the sciatic nerve and spinal cord is usually apparent within 24–48 h after exposure. This inhibition correlates with the clinical expression of OPIDN (Lotti, 1992). Neuropathy target esterase is widely distributed throughout the nervous system, except glial cells, and is also present in other tissues.

Despite evidence showing the involvement of NTE in OPIDN, the enzyme's role in axonal degeneration is unclear. Axonal degeneration has been shown to be associated with a deficit of retrograde axonal transport (Moretto et al., 1987). Other mechanistic studies have implicated protein kinase-mediated phosphorylation of cytoskeletal proteins; altered expression of neurofilament subunits; changes in protein kinases, glyceraldehyde-3-phosphate dehydrogenase, phosphorylated cAMP-response element binding protein, and α -tubulin expression; Ca^{2+} calmodulin-dependent auto-phosphorylation of proteins; and disruption of calcium homeostasis. These other mechanistic studies have been reviewed by Moretto and Lotti (2006).

The potency of individual OPs to inhibit AChE and NTE *in vitro* correlates with their toxicity *in vivo* and can be used as a measure of the potential of a specific compound to cause OPIDN. This fact is used in premarket testing such that commercial OPs in current use are much more acutely toxic with cholinergic effects rather than causing neuropathy (Moretto and Lotti, 2006).

Species vary greatly in their susceptibility to OPIDN with the hen being the experimental animal model because rodents are relatively resistant. In general, the young of any given species are less susceptible to OPIDN than adult animals. Case reports of OPs that cause OPIDN in humans have been reviewed by Lotti and Moretto (2005) and include poisoning by chlorpyrifos, dichlorvos, isofenphos, methamidophos, mipafox, trichlorfon, trichlornat, triaryl phosphates, and phosphamidon/mevinphos.

Intermediate Syndrome

The IMS following OP poisoning was first described in patients who developed facial, proximal limb, and respiratory muscle weakness (Senanayake and Karalliedde, 1987). The syndrome occurs after apparent recovery from the acute cholinergic crisis and before a possible OPIDN. IMS occurs in approximately 20% of patients following oral exposure to OP pesticides, with no clear association between the particular OP pesticide involved and the development of the syndrome (Karalliedde et al., 2006). It usually becomes established 1–4 days after exposure when the symptoms and signs of the acute cholinergic syndrome are no longer obvious. The characteristic features of the IMS are persistent inhibition of RBC AChE; weakness of the extraocular, bulbar, facial, respiratory, neck, and proximal limb muscles; and absent or depressed deep tendon reflexes (De Bleeker, 2006). These patients may not require ventilation but supportive care and monitoring is mandatory.

Gulf War Syndrome

After Operation Desert Storm ended in 1991, a large number of veterans who had served experienced chronic health

problems, including memory loss, fatigue, cognitive problems, somatic pain, skin abnormalities, and gastrointestinal difficulties. These veterans were potentially exposed to the OP chlorpyrifos, non-OP insect repellents, pyridostigmine bromide (a nerve agent antidote enhancer) and atropine, as well as an OP nerve gas from a detonated munitions bunker in Iraq. Individual chemical and mixture exposures cannot be quantified and despite years of research, a link to OP exposures and Gulf War Syndrome has not been definitively established. An historical perspective and summary of ongoing research can be found by McCauley (2006). A more recent study found association between symptoms and use of pyridostigmine bromine while being within one mile of an exploding SCUD missile for veterans near the front line; for those who remained in support areas, symptoms were significantly associated only with personal pesticide use (although specific pesticide(s) was not specified) (Steele et al., 2012).

EXAMPLES OF ORGANOPHOSPHATE AND CARBAMATE INSECTICIDES

CARBOFURAN

First aid: Decontamination, symptoms

Target organ(s): Acetylcholinesterase inhibition

Occupational exposure limits: BEI® is 70% of baseline cholinesterase activity in RBC (ACGIH, 2010)

Reference	1-Day and 10-Day Health Advisory values: (child) = 0.05 mg/l (U.S. EPA, 2012a) DWEL Health Advisory = 0.18 mg/l (U.S. EPA, 2012a) Life-time Health Advisory = 0.036 mg/l (U.S. EPA, 2012a) RfD = 0.005 mg/kg/day (U.S. EPA, 1987) REL-TWA = 0.1 mg/m ³ [skin] (NIOSH, 2013) TLV-TWA = 0.1 mg/m ³ [skin] (ACGIH, 2010)
-----------	---

Risk/safety phrases: Harmful if swallowed; avoid skin contact

BACKGROUND AND USES

Carbofuran is a broad-spectrum N-methyl carbamate sold under the trade name Furadan. First registered in 1969, it is

used to control a variety of insect pests on field, fruit, and vegetable crops. Carbofuran is not used in residential settings or food-handling establishments. The chemical is a restricted use pesticide with nearly 1 million pounds of active ingredient almost exclusively used on corn, alfalfa, and potatoes (U.S. EPA, 2006a).

PHYSICAL AND CHEMICAL PROPERTIES

Carbofuran (2,3-dihydro-2,3-dimethyl-7-benzofuranyl-N-methylcarbamate) is a white crystal-like solid. It is slightly soluble in water, is stable under neutral and acidic conditions, but decomposes under alkaline conditions (U.S. EPA, 2006a).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Carbofuran is highly mobile in soils and can leach into groundwater and enters surface water as runoff. The chemical breaks down through hydrolysis, photodegradation, and moderate bacterial degradation at rates that depend on environmental conditions. Hydrolysis is faster in water with a pH ≥ 7, with a half-life ranging from a few hours to 28 days. Carbofuran is stable to hydrolysis in acidic water. Photodegradation is fast in a thin water layer, with a half-life of 6 days. In the top few millimeters of a sandy loam soil, carbofuran degrades in 78 days. Bioconcentration is not expected to occur (U.S. EPA, 2006a).

ECOTOXICOLOGY

Carbofuran toxicity to nontarget species has been summarized by the U.S. EPA (2006a). The chemical is characterized as highly toxic to birds, fish, and honey bees. Ducks showed an LD₅₀ of 0.238 mg/kg and a high mortality rate when given carbofuran in the feed for several weeks. Chronic toxicity testing of freshwater fish showed larval survival as the most sensitive end point at water concentrations in the part-per-billion (ppb) range. Marine fish were more sensitive than freshwater fish.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute toxicity of carbofuran is typical of other carbamates with symptoms a result of AChE inhibition. Typical of this class of pesticides inhibition is followed by rapid recovery. Young animals are more susceptible to carbofuran toxicity than older animals (U.S. EPA, 2006a).

Chronic Effects

Chronic toxicity is also due to cholinesterase inhibition. Due to the rapid recovery (within 24 h) of AChE inhibition, longer-term exposures are considered a series of acute exposures (U.S. EPA, 2006a).

SOURCES OF EXPOSURE

Occupational

Workers can be exposed to a carbofuran through mixing, loading, and/or applying the pesticide, or reentering treated sites.

Environmental

Carbofuran is released to the atmosphere and water during foliage or soil application by ground or air broadcast equipment. On soils, the chemical is highly mobile and can enter streams and surface waters.

INDUSTRIAL HYGIENE

The occupational exposure limits shown in the table above, come with a skin notation indicating dermal absorption can occur and should be avoided.

RISK ASSESSMENTS

The Reference dose(RfD) is based on RBC AChE inhibition and testicular and uterine effects in beagle dogs given carbofuran in the diet for 1 year (U.S. EPA, 1987). The U.S. Environment Protection Agency (EPA) has not evaluated the chemical for carcinogenicity.

CHLORPYRIFOS

First aid: Decontamination, symptoms

Target organ(s): Acetylcholinesterase inhibition

Occupational exposure limits: BEI® is 70% of baseline cholinesterase activity in RBC (ACGIH, 2010)

Reference values:	1-Day and 10-Day Health Advisory (child)= 0.03 mg/l (U.S. EPA, 2012a) DWEL Health Advisory = 0.01 mg/l (U.S. EPA, 2012a) Life-time Health Advisory = 0.002 mg/l (U.S. EPA, 2012a)
-------------------	--

MRL (acute and intermediate) = 0.003 mg/kg/day (ATSDR, 1997)
 MRL (chronic) = 0.001 mg/kg/day (ATSDR, 1997)
 $\text{REL-TWA} = 0.2 \text{ mg/m}^3$ [skin] (NIOSH, 2013)
 $\text{REL-STEL} = 0.6 \text{ mg/m}^3$ [skin] (NIOSH, 2013)
 $\text{TLV-TWA} = 0.1 \text{ mg/m}^3$ [skin] (ACGIH, 2010)

Risk/safety phrases: Harmful if swallowed; avoid skin contact

BACKGROUND AND USES

Chlorpyrifos is a broad-spectrum organophosphate insecticide sold under the trade names of Dursban, Empire 20, Equity, and Whitmire PT 270. First registered in 1965 to control foliage- and soil-borne insect pests on a variety of food and feed crops, it is one of the most widely used and one of the major insecticides used residentially (U.S. EPA, 2000). Chlorpyrifos is the active ingredient in more than 800 registered products on the market, resulting in 21–24 million pounds used annually in the United States.

PHYSICAL AND CHEMICAL PROPERTIES

Chlorpyrifos (diethyl 3,5,6-trichloro-2-pyridyl phosphorothionate) is a white crystal-like solid with a strong odor. It does not mix well with water, so it is usually mixed with oily liquids before it is applied to crops or animals (ATSDR, 1997).

ENVIRONMENTAL FATE AND BIOACCUMULATION

In the atmosphere, the chemical exists as a vapor but will partition to airborne particulates (ATSDR, 1997). In water, chlorpyrifos may slowly volatilize but the amount available for volatilization from surface water is reduced by adsorption to sediments. Volatilization does not appear to be a major route of dissipation from soil for chlorpyrifos (ATSDR, 1997; U.S. EPA, 1999). Because of its low water solubility and high soil binding capacity, there is potential for chlorpyrifos sorbed to soil to run off into surface water via erosion (U.S. EPA, 1999).

Abiotic hydrolysis and photodegradation do not contribute significantly in the removal of chlorpyrifos from the environment. Based on available data, chlorpyrifos appears to degrade slowly in soil under both the aerobic and anaerobic conditions. Under aerobic conditions, the half-life of chlorpyrifos ranged from 11 to 141 days in seven soils

ranging in texture from loamy sand to clay, with the major degradate being CO_2 , comprising 27–88% of the applied total after 360 days aerobic incubation (U.S. EPA, 1999).

ECOTOXICOLOGY

Birds, fish, and amphibians are susceptible to AChE inhibition similar to mammals. Studies have shown ducks exposed to chlorpyrifos in the diet lost weight and hatched significantly fewer ducklings. Similarly, bobwhite quail had decreased food consumption and weight loss (HSDB, 2008). Alterations in swimming ability and cholinesterase inhibition have been measured in tadpoles (HSDB, 2008).

Coho salmon exposed to chlorpyrifos-treated water for 96 h showed concentration-related inhibition of brain AChE activity whereas changes in swimming performance were measured when AChE inhibition reached a threshold (Tierney et al., 2007). Reductions in spontaneous swimming and feeding behaviors were also shown to correlate with AChE inhibition in juvenile coho salmon exposed to concentrations <5 $\mu\text{g/l}$ (Sandahl et al., 2005).

Using the Nile tilapia, body size was shown to affect susceptibility to AChE inhibition. Following a 48-h exposure to chlorpyrifos, the concentrations resulting in 50% inhibition for fry, fingerlings, and subadults stages were 0.53, 0.75, and 3.86 $\mu\text{g/l}$, respectively (Chandrasekara and Pathiratne, 2007).

MAMMALIAN TOXICOLOGY

Acute Effects

Acute toxicity of chlorpyrifos is typical of other organophosphates with symptoms a result of AChE inhibition. Delayed neuropathy has been described in a number of human case reports following acute cholinergic symptoms from accidental or intentional poisoning (Aiuto et al., 1993; Kaplan et al., 1993; Lotti et al., 1986). Similarly, studies have demonstrated OPIDN in the hen, but only when the animals were atropinized to prevent lethality (Gaines, 1969; Capodicasa et al., 1991).

Chronic Effects

Epidemiology studies and case reports have implicated chlorpyrifos in causing birth defects in humans after the mother had been exposed to high levels during pregnancy (Whyatt et al., 2004; Perera et al., 2003). With repeat dosing to rats, generally doses of $\geq 1 \text{ mg/kg/day}$ resulted in mild clinical signs such as urine staining on females; doses of $\geq 3 \text{ mg/kg/day}$ caused miosis and brain cholinesterase activity inhibition; and at $\geq 5 \text{ mg/kg/day}$ rats developed adrenal lesions and offspring body weight and survival were decreased (Maurissen et al., 2000a, 2000b; Yano et al., 2000).

SOURCES OF EXPOSURE

Occupational

Exposure to chlorpyrifos can occur during foliage or soil application by ground or air broadcast equipment and by reentry into treated fields. Exposure can also occur during production of the chemical and mixing prior to application.

Environmental

Chlorpyrifos is released to the atmosphere and water during foliage or soil application by ground or air broadcast equipment. Leaching and runoff from treated fields, pesticide disposal pits, or hazardous waste sites may inadvertently contaminate both groundwater and surface water with chlorpyrifos. Entry into water can also occur from accidental spills, redeposition of atmospheric chlorpyrifos, and discharge of waste water from chlorpyrifos manufacturing, formulation, and packaging facilities (ATSDR, 1997).

INDUSTRIAL HYGIENE

The occupational exposure limits shown in the table above, come with a skin notation indicating dermal absorption can occur and should be avoided.

RISK ASSESSMENTS

The acute and intermediate minimal risk levels (MRLs) were based on the dose that did not cause symptoms in human volunteers given chlorpyrifos for 21–28 days. The chronic MRL is based on a no-observed-adverse-effect level (NOAEL) for RBC AChE inhibition in rats fed diets containing chlorpyrifos for 2 years (ATSDR, 1997). The U.S. EPA has not evaluated the chemical for long-term health effects or carcinogenicity.

METHYL PARATHION

First aid: Decontamination, symptoms

Target organ(s): Acetylcholinesterase inhibition

Occupational exposure limits: BEI® is 70% of baseline cholinesterase activity in RBC (ACGIH, 2010)

Reference values: 1-Day and 10-Day Health Advisory (child) = 0.3 mg/l (U.S. EPA, 2012a)
DWEL Health Advisory = 0.007 mg/l (U.S. EPA, 2012a)

Life-time Health Advisory = 0.001 mg/l
(U.S. EPA, 2012a)

RfD = 0.00025 mg/kg/day (U.S. EPA, 1991)
TWA = 0.2 mg/m³ [skin] (NIOSH, 2013)
TLV-TWA = 0.02 mg/m³ [skin] (ACGIH, 2010)

Risk/safety phrases: Harmful if swallowed; avoid skin contact

BACKGROUND AND USES

Methyl parathion is a restricted use organophosphate sold under a number of trade names and formulations. First registered in 1954, it is used to control a variety of insect pests on food and feed crops. Methyl parathion is not used in residential settings due to its toxicity to humans, birds, and honey bees. The chemical is a restricted use pesticide with nearly 4 million pounds of active ingredient mainly used on cotton, corn, wheat, soybeans, and rice (U.S. EPA, 2006b).

PHYSICAL AND CHEMICAL PROPERTIES

Methyl parathion (O,O-dimethyl)-*p*-nitrophenyl phosphorothioate) is a white crystalline solid. It is slightly soluble in water and has a low vapor pressure (U.S. EPA, 2006b).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Methyl parathion is mobile in soils and can leach into groundwater and enter surface water as runoff. The chemical breaks down through microbial degradation, aqueous photolysis, hydrolysis, and incorporation into soil organic matter; thus, it degrades rapidly in soil and water with a half-life <5 days. Photodegradation is rapid in aquatic environments with a half-life of 49 h. Bioconcentration is not expected to occur (U.S. EPA, 2006b).

ECOTOXICOLOGY

Methyl parathion toxicity to nontarget species has been summarized by U.S. EPA (2006b). The chemical is characterized as highly toxic to birds, fish, and honey bees. Ducks showed an LD₅₀ of 6.6 mg/kg and reproductive toxicity occurred in bobwhite quail when given in the feed for several weeks. Chronic toxicity testing of freshwater fish showed reduced growth.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute toxicity of methyl parathion is typical of other organophosphates with symptoms a result of AChE inhibition. Neuropathology may also occur (U.S. EPA, 2006b).

Chronic Effects

Chronic toxicity is also due to cholinesterase inhibition. Retinal degeneration, peripheral neuropathy of the proximal and distal sciatic nerve, and reduced RBC parameters have been seen in rats given methyl parathion for 2 years (U.S. EPA, 2006b).

SOURCES OF EXPOSURE

Occupational

Workers can be exposed to methyl parathion through mixing, loading, and/or applying the pesticide, or reentering treated sites. The use of human flaggers for aerial application is prohibited.

Environmental

Residues of methyl parathion can occur in food and drinking water.

INDUSTRIAL HYGIENE

The occupational exposure limits shown in the table above come with a skin notation indicating dermal absorption can occur and should be avoided.

RISK ASSESSMENTS

The RfD is based on RBC AChE inhibition, neuropathology, and changes in hematology parameters in rats given methyl parathion in the diet for 2 years (U.S. EPA, 1991). The U.S. EPA has not evaluated the chemical for carcinogenicity.

ORGANOCHLORINE INSECTICIDES

ALDRIN

First aid: Decontamination, symptoms

Target organ(s): Nervous system, liver

Occupational exposure limits:

REL-TWA = 0.25 mg/m³ [skin] (NIOSH, 2013)

TLV-TWA = 0.05 mg/m³ [skin] (ACGIH, 2010)

Reference values: 1-Day and 10-Day Health Advisory (child) = 0.0003 mg/l (U.S. EPA, 2012a)
DWEL Health Advisory = 0.001 mg/l (U.S. EPA, 2012a)
Acute MRL = 0.002 mg/kg/day (ATSDR, 2002a)
Chronic MRL = 0.00003 mg/kg/day (ATSDR, 2002a)
RfD = 0.00003 mg/kg/day (U.S. EPA, 1988a)

Risk/safety phrases: Harmful if swallowed; avoid skin contact

DIELDRIN

First aid: Decontamination, symptoms

Target organ(s): Nervous system, liver

Occupational exposure limits:

REL-TWA = 0.25 mg/m³ [skin] (NIOSH, 2013)

TLV-TWA = 0.1 mg/m³ [skin] (ACGIH, 2010)

Reference values: 1-Day and 10-Day Health Advisory (child) = 0.0005 mg/l (U.S. EPA, 2012a)
DWEL Health Advisory = 0.002 mg/l (U.S. EPA, 2012a)
Intermediate MRL = 0.0001 mg/kg/day (ATSDR, 2002a)
Chronic MRL = 0.00005 mg/kg/day (ATSDR, 2002a)
RfD = 0.00005 mg/kg/day (U.S. EPA, 1990)

Risk/safety phrases: Harmful if swallowed; avoid skin contact

DDT

First aid: Decontamination, symptoms

Target organ(s): Nervous system, liver, reproductive system

Occupational exposure limits:

REL-TWA = 0.5 mg/m³ (NIOSH, 2013)

TLV-TWA = 1 mg/m³ (ACGIH, 2010)

Reference values: Acute MRL = 0.0005 mg/kg/day (ATSDR, 2002b)
 Intermediate MRL = 0.0005 mg/kg/day (ATSDR, 2002b)
 RfD = 0.0005 mg/kg/day (U.S. EPA, 1996)

Risk/safety phrases: Harmful if swallowed; avoid skin contact

MIREX AND CHLORDECONE

First aid: Decontamination, symptoms

Target organ(s): Nervous system, liver

Occupational exposure limits:

REL-TWA = 0.25 mg/m³ [skin] (NIOSH, 2013)

TLV-TWA = 0.1 mg/m³ [skin] (ACGIH, 2010)

Reference values: Acute MRL = 0.01 mg chloredcone/kg/day (ATSDR, 1995)
 Chronic MRL = 0.0005 mg chlordecone/kg/day (ATSDR, 1995)
 Chronic MRL = 0.0008 mg mirex/kg/day (ATSDR, 1995)
 RfD = 0.0002 mg mirex/kg/day (U.S. EPA, 1992a)
 RfD = 0.0003 mg chlordecone/kg/day (U.S. EPA, 2009)

Risk/safety phrases: Harmful if swallowed; avoid skin contact

BACKGROUND AND USES

Organochlorine compounds were widely used in agriculture and malaria control programs for decades, beginning in the mid-1940s. They declined in use in the 1960s and now have been nearly completely banned in the United States. This action was taken in response to evidence that these insecticides have a high potential for persistence and bio-magnification in food chains. Organochlorine insecticides are still used in many other countries for malaria control because of their low cost and high efficacy (IPCS, 1995). Aldrin, dieldrin, and chlordane were used extensively to control termites around buildings until the early 1970s when their use was canceled (ATSDR, 2002a). dichlorodiphenyltrichloroethane (DDT) was widely used during World War II to protect troops and civilians from malaria and other insect-borne diseases; it was also found to be useful against agriculture and forest pests. In some malaria endemic regions of the world, DDT is still used for mosquito control (ATSDR, 2002b; IPCS, 1995).

PHYSICAL AND CHEMICAL PROPERTIES

The organochlorine insecticides are persistent organic pollutants that are highly resistant to biological, photolytic, or chemical degradation due to the stable carbon–chlorine bond. These compounds are characterized by low water solubility, high lipid solubility, and semi-volatility. Large molecular weight compounds with cyclic, aromatic, and cyclodiene-type structures include the organochlorine insecticides such as DDT, chlordane, lindane, heptachlor, dieldrin, aldrin, toxaphene, mirex, and chlordcone (IPCS, 1995).

ENVIRONMENTAL FATE AND BIOACCUMULATION

The organochlorines strongly adsorb to soils and do not readily leach into groundwater due to low water solubility. However, the presence of organic solvents at hazardous waste sites may promote leaching. Limited biodegradation by microorganisms may occur in soils and water. Photodegradation and hydrolysis are not important pathways for degradation of these compounds. Volatilization and adsorption to atmospheric particulates results in global transport and deposition. Bioconcentration has been measured throughout the food chain from plants to domestic livestock and fish (IPCS, 1995).

Chemical properties resulting in limited environmental degradation mean these compounds are persistent pollutants. While aldrin is rapidly converted to dieldrin, the half-life of dieldrin on temperate soils is about 5 years. As much as 50% of applied DDT and related compounds can remain on soils for >10 years (IPCS, 1995; ATSDR, 2002a,b).

ECOTOXICOLOGY

In general the organochlorine insecticides have low acute toxicity to birds. For example, LD₅₀ values to selected avian species range from 6.6 to 520 mg/kg for aldrin, 26.6 to 381 mg/kg for dieldrin, 386 to >2200 mg/kg for DDT and its derivatives, and 1400–10,000 mg/kg for mirex. Despite low toxicity to adult birds, adverse effects on reproduction are well known, especially for DDT and dichlorodiphenyl-dichloroethylene (DDE). These compounds are associated with egg shell thinning, which adversely impacts reproductive success, most notably in birds of prey (IPCS, 1995). In addition, DDT has been linked to feminization and altered sex ratios in several gull populations.

The acute toxicity of organochlorines to aquatic invertebrates is highly variable, with aquatic insects the most sensitive aquatic organisms. The organochlorines are highly toxic to most species of fish with 96-h LC₅₀ values

0.53–42 µg/l for DDT, 1.1–41 µg/l for dieldrin, and 2.2–53 µg/l for aldrin. Developmental behavior of hatched fry has been shown to be altered following exposure of salmon eggs to DDT (IPCS, 1995).

MAMMALIAN TOXICOLOGY

Acute Effects

Acute toxicity from high doses of organochlorine insecticides involves CNS stimulation leading to convulsions. Other signs and symptoms may include headache, dizziness, nausea, general malaise, and vomiting. The mechanisms of nervous system stimulation differ and are not entirely understood; aldrin and dieldrin may block inhibitory activity within the brain while DDT interferes with ion movement through the nerve membrane (ATSDR, 2002a,b).

Oral LD₅₀ values in laboratory animals range from 33 to 330 mg/kg for aldrin and dieldrin, and 113–1770 mg/kg for DDT, mirex, and chlordane (ATSDR, 2002a,b; ATSDR, 1995; IPCS, 1995).

Chronic Effects

Numerous epidemiology studies have been conducted to determine the health effects in humans from long-term exposure to organochlorine insecticides. Target organs include the nervous system and the liver for aldrin and dieldrin and the reproductive system for DDT. Long-term exposure of workers to aldrin or dieldrin resulted in headache, dizziness, hyperirritability, malaise, nausea, vomiting, and muscle twitching (ATSDR, 2002a). However, liver toxicity has not been conclusively observed in workers exposed to aldrin and dieldrin or in volunteers given up to 0.003 mg dieldrin/kg/day for up to 18 months. Dichlorodiphenyltrichloroethane is an endocrine disrupting compound that has estrogen-like properties. Studies in humans have shown associations between high body burdens of DDT and effects on lactation, maintenance of pregnancy, and fertility, as well as preterm births, small-for-gestational-age infants (ATSDR, 2002b), and decreased male reproductive parameters (ATSDR, 2008). A recent study found an increased risk of hypertension for adult daughters from mothers who had higher levels of DDT during pregnancy (La Merrill et al., 2013).

Chronic oral studies in laboratory animals confirm the effects observed in humans. In the 2-year oral studies in rats, liver lesions were observed at 0.025 mg/kg/day of aldrin or dieldrin (ATSDR, 2002a), 7 mg DDT/kg/day (ATSDR, 2002b), and 0.7 mg mirex/kg/day (ATSDR, 1995). Higher doses of these compounds resulted in decreased offspring survival, reduced fertility, decreased growth of offspring, and

developmental neurotoxicity. While most of the organochlorines cause cancer in laboratory animals, epidemiology studies in humans are inconclusive.

SOURCES OF EXPOSURE

Past uses of the organochlorine insecticides have resulted in soil residues and uptake in a wide range of foods such that exposures are mainly through the diet. Exposure to aldrin and dieldrin can occur through ingestion of contaminated crops and also through inhalation of contaminated air around homes that have been treated in the past with either chemical for termite control (ATSDR, 2002a). Although DDT residues are declining, exposure is still possible in meat, fish, poultry, and dairy products. Consumption of fish from the Great Lakes and traditional foods such as seals and caribou result in a higher intake of DDT (ATSDR, 2002b). Organochlorines have been detected in hundreds of hazardous waste sites across the United States indicating potential for continued release to the environment.

INDUSTRIAL HYGIENE

The occupational exposure limits for several individual organochlorine insecticides are shown in the tables above. Aldrin and dieldrin come with a skin notation indicating dermal absorption can occur and should be avoided. Both particulate and vapor fractions are of concern for inhalation exposures.

RISK ASSESSMENTS

The RfD for aldrin, dieldrin, DDT, and mirex is based on liver lesions in rats given the chemical in the diet for 2 years. The RfD for chlordeneone was based on kidney lesions in rats.

BOTANICALLY DERIVED INSECTICIDES

PYRETHRIN AND PYRETHROIDS

PERMETHRIN

First aid: Decontamination, symptoms

Target organ(s): Liver, skin, thyroid, nervous system

Occupational exposure limits:

TLV-TWA = 5 mg/m³ (pyrethrum) (ACGIH, 2010)

REL-TWA = 5 mg/m³ (pyrethrum) (NIOSH, 2013)

Reference values: MRL (acute) = 0.3 mg/kg/day (ATSDR, 2003)
 MRL (intermediate) = 0.2 mg/kg/day (ATSDR, 2003)
 RfD = 0.05 mg/kg/day (U.S. EPA, 1992b)

Risk/safety phrases: Avoid skin and eye contact

CYHALOTHrin

First aid: Decontamination, symptoms

Target organ(s): Liver, skin, thyroid, nervous system

Occupational exposure limits: None found

Reference values: MRL (acute) = 0.01 mg/kg/day (ATSDR, 2003)
 MRL (intermediate) = 0.01 mg/kg/day (ATSDR, 2003)
 RfD = 0.005 mg/kg/day (U.S. EPA, 1988b)

Risk/safety phrases: Avoid skin and eye contact

BACKGROUND AND USES

Pyrethrins are used to kill a number of different flying and crawling insects and arthropods. First registered in the 1950s, currently over 1350 end-use products containing pyrethrins are available for agricultural, commercial, residential, and public health areas. They are used as household insecticides, as grain protectants, and to control pests on edible products just prior to harvest in a variety of locations, including residential, public, and commercial buildings, animal houses, warehouses, fields, and green houses. Pyrethrins are also extensively used in the field of veterinary medicine (U.S. EPA, 2006c; ATSDR, 2003).

Commercially available pyrethroids include allethrin, bifenthrin, bioresmethrin, cyfluthrin, cyhalothrin, cypermethrin, deltamethrin, esfenvalerate (fenvalerate), flucythrinate, flumethrin, fluvalinate, fenpropathrin, permethrin, phenothrin, resmethrin, tefluthrin, tetramethrin, and tralomethrin.

PHYSICAL AND CHEMICAL PROPERTIES

Pyrethrum (CAS #8003-34-7), derived from extracts of the *Chrysanthemum cinerariaefolinum* plant, is a combination

of six pyrethrin isomers, namely, pyrethrin 1, pyrethrin 2, cinerin 1, cinerin 2, jasmolin 1, and jasmolin 2. Pyrethroids are synthetically derived commercial compounds similar to pyrethrum. Pyrethrins and pyrethrioids are insoluble in water and have a low vapor pressure. Pyrethrum is subject to photodegradation and is oxidized rapidly in the presence of air (U.S. EPA, 2006c; ATSDR, 2003).

ENVIRONMENTAL FATE AND BIOACCUMULATION

If released to air, the relatively low vapor pressure indicates that the pyrethrins and pyrethroids will exist in both the vapor and particulate phases in the atmosphere. Vapor-phase compounds are rapidly degraded by direct photolysis and by reaction with photochemically produced hydroxyl radicals and ozone; the half-lives for these reactions in air are estimated to be 1.3 h and 17 min, respectively. Particulates may travel long distances and are removed from the atmosphere by wet or dry deposition (HSDB, 2013; ATSDR, 2003).

Pyrethrins and pyrethroids are strongly adsorbed to the soil surfaces so they are not expected to be mobile. The compounds also strongly adsorb to suspended solids and sediment in the water column. Thus, partitioning to solids attenuates volatilization from soil and water surfaces. Pyrethrins and pyrethroids are often used indoors in sprays or aerosol bombs, and the volatilization rates from glass or floor surfaces may be significantly faster than from soils since these compounds are not likely to adsorb as strongly to these surfaces (ATSDR, 2003). These insecticides are readily biodegraded by microorganisms.

Pyrethrins and pyrethroids bioconcentrate in aquatic organisms, including fish, oysters, and insects. The bioconcentration factor for several commercial products in three species of fish ranged from 180 to 1200 depending on the amount of dissolved organic matter in the water column (ATSDR, 2003).

ECOTOXICOLOGY

Pyrethrins and pyrethroids are extremely toxic to fish with acute LC₅₀ values of 5.1 µg/l to freshwater fish and 16 µg/l to estuarine/marine fish. Chronic exposure to very low levels has caused impaired growth of freshwater fish and reproduction of freshwater invertebrates (U.S. EPA, 2006c).

These compounds are practically nontoxic to birds and have low toxicity to small mammals. However, the pyrethrins are highly toxic to honey bees and other nontarget beneficial insects (U.S. EPA, 2006c).

MAMMALIAN TOXICOLOGY

Acute Effects

The pyrethrins and pyrethroids have low acute toxicity to mammals and overexposure is uncommon. In rats, LD₅₀ is 1.4 g/kg and the LC₅₀ is 3400 mg/m³ (U.S. EPA, 2006c). However, exposure may be irritating to the eyes and nasal passages (HSDB, 2013) and dermal exposure may cause paresthesia as a result of the direct action of pyrethroids on sensory nerve endings (ATSDR, 2003).

Ingestion of large amounts may result in neurobehavioral effects, such as dizziness, headache, nausea, muscle twitching or tremors, reduced energy, and changes in awareness. The effects are due to the mechanism of action in which the compounds bind to sodium channels slowing the closing of channel gates following an initial influx of sodium during the depolarizing phase of an action potential, which results in a prolonged sodium tail current (ATSDR, 2003).

Chronic Effects

Allergic contact dermatitis is the most common health effect associated with pyrethrin and pyrethroid exposure (HSDB, 2013; ATSDR, 2003).

Chronic exposure to pyrethrins and pyrethroids may cause effects on the nervous system, thyroid, and liver. Some laboratory animal studies have shown increased liver weight and microscopic lesion in the liver at doses that also resulted in signs of neurotoxicity. Similarly, animals given a variety of commercial products by oral route had changes in thyroid hormones, including decreased T₃ and T₄ and increased thyroid stimulating hormone (TSH) (ATSDR, 2003; U.S. EPA, 2006c).

SOURCES OF EXPOSURE

Occupational

Exposure to pyrethrins and pyrethroids can occur during mixing and application for agriculture and residential use. Inhalation and dermal contact are of concern during use.

Environmental

Environmental exposure to pyrethrins and pyrethroids can occur following their application as indoor surface treatments or home gardens; exposures may be to the person applying the insecticide or others who enter the areas after application. Residues on fruits and vegetables are the main source of ingestion exposure (U.S. EPA, 2006c; ATSDR, 2003).

INDUSTRIAL HYGIENE

The occupational exposure limits for two individual pyrethrin and pyrethroid insecticides are shown in the tables above. Dermal contact should be avoided.

RISK ASSESSMENTS

The acute and intermediate MRLs for permethrin and cyhalothrin were based on neurotoxicity in rats and gastrointestinal effects in dogs, respectively, and are considered protective of chronic effects. The RfD for permethrin was based on increased liver weight in rats. For cyhalothrin, the RfD was based on decreased body weight gain observed in adult rats and their offspring when given the compound in the diet for three generations. The U.S. EPA has not evaluated the chemical for long-term health effects or carcinogenicity.

ROtenone

First aid: Decontamination, symptoms

Target organ(s): Upper respiratory tract, eye, skin, nervous system

Occupational exposure limits: TLV-TWA = 5 mg/m³ (ACGIH, 2010)
TWA = 5 mg/m³ (NIOSH, 2013)

Reference values: RfD = 0.004 mg/kg/day (U.S. EPA, 1988c)

Risk/safety phrases: Harmful if swallowed, irritating

BACKGROUND AND USES

Rotenone was first registered in 1947 and is currently used exclusively to kill fish (U.S. EPA, 2007). In 2006, registrants voluntarily canceled all livestock, residential and home owner uses, domestic pet uses, and all other uses except for piscicide uses. Currently the main uses include fish management strategies to remove nonnative fish species from lakes, ponds, or streams and in catfish aquaculture prior to stocking ponds with fry to remove undesirable fish species (U.S. EPA, 2006d).

Rotenone has been historically used by native people to paralyze fish for capture and consumption. Outside the United States, the compound is still used to control insects in fruit and vegetable cultivation and for control of fire ants and mosquito larvae in pond water (HSDB, 2012a).

PHYSICAL AND CHEMICAL PROPERTIES

Rotenone (CAS #83-79-4) is related to isoflavanoid compounds derived from the roots of *Derris* spp., *Lonchocarpus* spp., and *Tephrosia* spp., found primarily in Southeast Asia, South America, and East Africa. The isolated compound is an odorless, colorless to red crystalline solid. It is insoluble in water and has a very low vapor pressure (U.S. EPA, 2007; HSDB, 2012a).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Rotenone released to the atmosphere will exist as particulates due to the extremely low vapor pressure. Particulate-phase rotenone will be removed from the atmosphere by wet and dry deposition and may be degraded by direct photolysis. It is mobile to moderately mobile in soil and sediment and volatilization from soil surfaces is not expected to occur to any extent. If released to water, rotenone generally degrades quickly through abiotic (hydrolytic and photolytic) mechanisms, with half-lives of a few days to several weeks or longer depending on water temperature (U.S. EPA, 2007; HSDB, 2012a).

Rotenone has a relatively low potential for bioconcentration in aquatic organisms (Bioconcentration Factor (BCF) < 30X) (U.S. EPA, 2007).

ECOTOXICOLOGY

Rotenone is extremely toxic to fish with an acute LC₅₀ value of 1.94 ppb to freshwater fish. Chronic exposure to very low levels has caused impaired growth of freshwater fish and reproduction of freshwater invertebrates (U.S. EPA, 2007).

Rotenone has an extremely small margin between no lethality (5.0 µg/l) and 100% mortality (6.6 µg/l) for static-renewal 96-h toxicity tests with juvenile rainbow trout. Increasing the amount of dissolved organic carbon significantly increased the rotenone 96-h LC₅₀ probably as a result of rotenone adsorption, which decreased its bioavailability. The threshold concentration of rotenone for impairment of critical swimming performance was 3.0 µg/l (Cheng and Farrell, 2007).

Rotenone has very low toxicity to birds, and it is unlikely that piscivorous birds could consume enough killed fish to result in a toxic dose. Similarly, it is unlikely that a mammal foraging on dead or dying fish could consume toxic levels of rotenone (U.S. EPA, 2007).

MAMMALIAN TOXICOLOGY

Acute Effects

Rotenone has relatively high toxicity by the oral and inhalation routes, but relatively nontoxic by dermal exposure. The acute oral LD₅₀ in male and female rats is 102 and 39.5 mg/kg, respectively; the LC₅₀ is 0.0212 mg/l (U.S. EPA, 2007). The mechanism of action is uncoupling oxidative phosphorylation within cell mitochondria by blocking electron transport at complex I.

Ingestion of large amounts may result in vomiting, respiratory depression and hypoglycemia. The dust of rotenone is irritation to the eyes (HSDB, 2012a). In case reports of human exposures, the most common symptom was eye irritation; other symptoms reported included dermal irritation, throat irritation, nausea, and cough/choke (U.S. EPA, 2007).

Chronic Effects

Numerous studies indicate that the mechanism of rotenone toxicity at the mitochondria can cause symptoms of Parkinson's disease (U.S. EPA, 2006d). A study of agricultural workers showed strong evidence of an association between rotenone use and Parkinson's disease. The disease developed 2.5 times as often in those who reported use of rotenone compared with nonusers (Tanner et al., 2011).

Decreased body weight was found in adult rats and their offspring were given rotenone orally at doses ≥1.5 mg/kg/day. Rotenone has not been shown to cause cancer in animals or humans (U.S. EPA, 1981, 2006d).

SOURCES OF EXPOSURE

Occupational

Workers can be exposed to rotenone during mixing, loading, and application activities.

Environmental

Environmental exposure to rotenone may occur from recreational use of treated ponds or lakes. However, due to the rapid degradation, it is unlikely that exposures would be excessive (U.S. EPA, 2006d, 2007).

INDUSTRIAL HYGIENE

The occupational exposure limits shown in the table above are generally based on contact irritation to mucus membranes.

RISK ASSESSMENTS

The RfD was based on decreased offspring body weight when rats were given the compound in the diet for two generations. The U.S. EPA has not evaluated the chemical for long-term health effects or carcinogenicity.

NEONICOTINOIDS

THIAMETHOXAM

First aid: Decontamination, flush eyes and skin with water, symptoms

Target organ(s): Liver, kidney, testes

Occupational exposure limits: None found

Reference values: Acute RfD = 0.35 mg/kg (U.S. EPA, 2010)
Chronic RfD = 0.012 mg/kg/day (U.S. EPA, 2010)

Risk/safety phrases: Harmful if swallowed; avoid skin contact

IMIDACLOPRID

First aid: Decontamination, flush eyes and skin with water, symptoms

Target organ(s): Liver, thyroid

Occupational exposure limits: None found

Reference values: ADI = 0–0.6 mg/kg (WHO, 2001)
Acute RfD = 0.4 mg/kg (WHO, 2001)

Risk/safety phrases: Harmful if swallowed; avoid skin contact

CLOTHIANIDRIN

First aid: Decontamination, flush eyes and skin with water, symptoms

Target organ(s): Liver, kidney

Occupational exposure limits: None found

Reference values: Acute RfD = 0.025 mg/kg (U.S. EPA, 2003)
Chronic RfD = 0.0098 mg/kg/day (U.S. EPA, 2003)

Risk/safety phrases: Harmful if swallowed; avoid skin contact

BACKGROUND AND USES

The neonicotinoids are broad-spectrum nitroguanidine insecticides with activity against sucking and chewing insects. They are used in foliar, soil, and seed applications on a wide variety of crops, including fruiting and root vegetables, berries, pome and stone fruits, grains, cotton, turf and sod, and ornamentals (U.S. EPA, 2010; HSDB, 2006, 2012b). When used as a seed dressing, the insecticides become systemic in the plant, migrating in the sap to all parts of the plant and providing protection against pests. Imidacloprid is the active ingredient in AdvantageTM used to control fleas in dogs and cats (HSDB, 2006). Clothianidin is the major metabolite of thiamethoxam and both compounds are registered for use as insecticides.

Widespread use increased greatly in the 1990s as alternatives to organophosphorus and carbamate insecticides because of their much lower mammalian toxicity and resistance developed to other pesticides. Imidacloprid has become the most widespread insecticide used in the world.

PHYSICAL AND CHEMICAL PROPERTIES

Thiamethoxam (153719-23-4), imidacloprid (138261-41-3), and clothianidin (210880-92-5) are solid crystals or powder under ambient conditions and have a low volatility (U.S. EPA, 2010; HSDB, 2006, 2012b).

The compounds have relatively high water solubility and have been measured in runoff and surface waters (ABC, 2013).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Neonicotinoids are expected to be persistent, resistant to hydrolysis, and mobile in terrestrial and aquatic environments. These fate properties indicate that the compounds have a potential to move into surface water and shallow groundwater (U.S. EPA, 2003, 2010). In general, surface water surveys suggest that concentrations of several neonicotinoids are high enough to cause impacts on aquatic food chains by affecting invertebrates (ABC, 2013).

Imidacloprid is rapidly and almost completely absorbed (>92%) from the gastrointestinal tract of rats, and is eliminated from the organism rapidly and completely, with no indication of bioaccumulation of the parent compound or its metabolites (WHO, 2001). Similarly, thiamethoxam has relatively low solubility in nonpolar organic solvents and its octanol/water partition coefficient suggests that accumulation in fatty tissues is unlikely to occur (U.S. EPA, 2010).

ECOTOXICOLOGY

Neonicotinoids are extremely toxic to pollinators such as honey bees. Because these insecticides are systemic, pollinators are potentially exposed in the nectar and pollen during the flowering period of some crops. At nonlethal levels (1.34 ng/bee), thiamethoxam has been shown to increase mortality of bee foragers due to reduced homing success, an effect that can affect the survival of the entire colony (Henry et al., 2012). Similarly, bumble bee colonies exposed to imidacloprid at levels occurring in treated crops and allowed to develop naturally in the field showed reductions in both colony growth rate and in the production of new queens (Whitehorn et al., 2012).

Seeds treated with neonicotinoids can be toxic to bees and birds. Thiamethoxam and imidacloprid are toxic to fish and aquatic invertebrates (U.S. EPA, 2012b, 2012c).

Oral LD₅₀ values in various species of birds range from 15 to 152 mg imidacloprid/kg, 576 to 1552 mg thiamethoxam/kg, and 430 to >2000 mg clothianidin/kg (ABC, 2013). Exposure to treated seeds may cause adverse chronic effects in birds, such as eggshell thinning (U.S. EPA, 2003; ABC, 2013).

MAMMALIAN TOXICOLOGY

Acute Effects

Neonicotinoids bind selectively to insect nicotinic ACh receptors, although the specific binding site(s)/receptor(s) are unknown. Some evidence suggests that clothianidin operates by direct competitive inhibition, while thiamethoxam is a noncompetitive inhibitor. Structural variations between the insect and mammalian nicotinic ACh receptors produce quantitative differences in the binding affinity of the neonicotinoids towards these receptors, which confers the notably greater selective toxicity of this class towards insects, compared to mammals. These insecticides do not inhibit cholinesterase or interfere with sodium channels and, therefore, have a different mode of action than organophosphate, carbamate, and pyrethroid insecticides (U.S. EPA, 2010).

Imidacloprid was moderately toxic to rats and mice with LD₅₀ values of 380–650 mg/kg and 130–170 mg/kg, respectively. Transient clinical signs of toxicity included behavioral and respiratory signs, disturbances of motility, narrowed palpebral fissures, transient trembling, and spasms in rats and mice at doses ≥200 mg/kg and ≥71 mg/kg, respectively (WHO, 2001). Clothianidin is relatively nontoxic to rats with an oral LD₅₀ >500 mg/kg and no evidence of eye or dermal irritation (U.S. EPA, 2003).

Chronic Effects

Potential chronic effects of neonicotinoids to humans are unknown. A number of laboratory animal studies suggest different target organs for the individual compounds. For example, while the insecticidal action of the neonicotinoids is neurotoxic, the most sensitive toxicological effect in mammals was testicular lesions with thiamethoxam and thyroid gland lesions with imidacloprid. Thus, there is currently no evidence to indicate that neonicotinoids share common mechanisms of toxicity (U.S. EPA, 2010).

In laboratory animal studies with imidacloprid, reduced body weight gain, often accompanied by decreased food consumption, was the most sensitive toxicological end point in mice at doses >86 mg/kg bw/day, in rats at doses >30 mg/kg/day, in rabbits at doses >24 mg/kg/day, and in dogs at doses >22 mg/kg/day. Similarly, decreased body weight gain was the main effect during lactation in rat pups of dams given doses >6.6 mg/kg/day (WHO, 2001). The commercially available flea treatment given either dermally (intended use) or orally did not cause adverse effects in dogs or cats (Cal EPA, 2012).

The liver was the other main target organ after repeated administration of imidacloprid to mice, rats, and dogs at doses >410 mg/kg/day, >17 mg/kg/day, and >31 mg/kg/day, respectively. Effects in the liver included adaptive changes such as induction of hepatic microsomal enzymes as well as disturbances of hepatic function and microscopic lesions. Changes in blood cholesterol, triglyceride, protein, and albumin concentrations as well as increased activities of alanine aminotransferase, alkaline phosphatase, and galacto-dehydrogenase in plasma were also observed. An increased incidence of mineralization was seen in the colloid of thyroid gland follicles in a long-term study in rats given a dietary concentration equal to 17 mg/kg/day, although the plasma concentrations of thyroid hormones remained unchanged. No evidence of a carcinogenic effect of imidacloprid was found in either mice or rats in the long-term studies of dietary administration (WHO, 2001).

Male rats given diets containing up to 1500 parts per million (ppm) thiamethoxam for 2 years had kidney lesions which are specific to rats and not likely relevant to other mammals. Higher doses to rats for two generations resulted in decreased body weight of both adults and pups and testicular lesions in adult males, but no adverse effects on reproductive parameters. Male dogs given 750 ppm in the feed for 1 year had testicular atrophy. Pregnant rats given thiamethoxam had decreased body weight gain with 200 mg/kg/day and fetuses had decreased ossification at higher doses. Developmental neurological effects on brain morphometry measurements were seen in offspring when their dams were given about 300 mg/kg/day during gestation and lactation (Cal EPA, 2008).

Liver tumors have been observed in male and female mice given ≥ 500 ppm thiamethoxam in the diet for 18 months. Liver tumors are not seen in rats fed diets containing up to 3000 ppm thiamethoxam. The key metabolites responsible for the events leading to liver tumors in the mouse are not formed in sufficient quantities in the rat and explain the lack of a carcinogenic response in this species. Limited data suggest that humans are more similar to the rat than the mouse in producing the active metabolites. Thus, the mouse appears to be uniquely sensitive to this mode of action and humans are unlikely to be at risk for developing tumors following exposures to thiamethoxam (U.S. EPA, 2010).

With clothianidin, decreased body weight and food consumption occurred in rats and mice given up to 98 and 200 mg/kg/day, respectively, with females of both species slightly more sensitive. At these same doses, liver and kidney lesions were observed in rats and liver hypertrophy occurred in mice. Doses of ≥ 180 mg/kg/day to rats for two generation resulted in decreased parental and offspring body weight but no effects on reproductive end points (Cal EPA, 2003).

SOURCES OF EXPOSURE

Occupational

The neonicotinoids are to be applied by commercial applicators only, with the exception of flea treatments for pets. Farmers handling treated seeds should wear gloves, long sleeved shirts, and long pants to avoid contact.

Environmental

Exposures in the environment may occur through spray drift from aerial application and dermal contact from reentry to treated fields. Contaminated surface waters are another source of environmental exposures. Use of neonicotinoids on turf or sod, in crack and crevice applications, and flea treatments on pets are potential routes of exposure for the homeowner/family and general public.

INDUSTRIAL HYGIENE

Occupational exposure limits for several individual neonicotinoid insecticides have not been set by National Institute for Occupational Safety and Health (NIOSH) or American Conference of Governmental Industrial Hygienists (ACGIH).

RISK ASSESSMENTS

The risk assessments shown in the tables above were developed by the U.S. EPA as part of the pesticide registration process.

HERBICIDES

GIFFE T. JOHNSON

INTRODUCTION

In 2007, over 15 million dollars of herbicides were sold globally, constituting 39% of total pesticide sales. More than a third of those sales were in the United States where herbicides make up to 47% of total pesticide use. The agriculture industry uses 83% of the herbicides produced, which amounted to 442 million pounds in 2007. Herbicides are among the most widely used pesticides and since 2001 in the United States glyphosate and atrazine have had the highest estimated use for pesticides in terms of total pounds applied (EPA, 2011). Exposure to these agents can occur in agricultural, commercial, and residential settings.

The purpose of this chapter is to provide a broad overview of various classes of commonly used herbicides. The most up to date label information should always be consulted before transporting, mixing, or applying pesticides.

TRIAZINES

ATRAZINE

BACKGROUND AND USES

Atrazine is used as a selective herbicide to control broadleaf and grassy weeds for agriculture and other land not used for crops. In agriculture, atrazine is used on corn, sugarcane, and pineapple and for orchards, sod, tree plantations, and rangeland. Atrazine is moderately persistent in the environment because of its low solubility. It can be detected in the water table and in the upper layers of the soil profile in many areas (Huang and Frink, 1989). The Environmental Protection Agency (EPA) reported that atrazine was one of the two most commonly used agricultural herbicides in 2007 (EPA, 2011). It is an active ingredient in many brands, including Actinite PK, Atranex, Atrasine, Atrataf, Atrazin, Chromozin, Cyazin, Primatol A, Primase, AAatre, Griffex, and Weedex.

PHYSICAL AND CHEMICAL PROPERTIES

Atrazine (CAS #1912-24-9) is generally found as a dibromide salt. It has a solubility of 0.003% by weight in water and a vapor pressure of <0.0000003 mmHg at 20 °C (68 °F).

MAMMALIAN TOXICOLOGY

Acute Effects

Atrazine has a low oral acute toxicity in mammals with a minimum risk level of 0.01 mg/kg/day for oral exposure. There is little clinical experience with atrazine, and adverse effects in humans have been limited to cases of intentional ingestion (Pommery et al., 1993). High doses in cattle and sheep have caused anorexia, ataxia, salivation, dyspnea, and muscle spasms. Atrazine does not pose an acute inhalation hazard and has not been reported to cause skin irritation. Exposure to concentrated amounts may result in short-term eye and skin irritation.

Chronic Effects

Most chronic effects associated with long-term atrazine exposure are related to the potential for endocrine effects, developmental toxicity, or reproductive toxicity. Outcomes related to endocrine toxicity include increases in pituitary weight and alterations in levels of reproductive hormones. However, these effects occur only after substantial exposure and differ by receptor species. Pituitary prolactin levels increased and serum prolactin and luteinizing hormone levels decreased in ovariectomized, estrogen supplemented female Long-Evans rats receiving gavage doses of 50 mg/kg/day and higher for 1–3 days (Cooper et al., 2000). Similarly treated Sprague-Dawley rats exhibited similar outcomes after receiving 300 mg/kg/day via gavage for 1–3 days (Cooper et al., 2000). Serum estradiol levels were increased in Sprague-Dawley rats after receiving gavage doses of 200 mg/kg/day on gestational days 1–8 (Cummings et al., 2000). As well, juvenile male rats exposed to 50 mg/kg/day for 3 days experienced decreases in serum and intratesticular testosterone (Friedmann, 2002). At 120 mg/kg/day and higher, in rats, reproductive outcomes such as decreased fertility and altered estrus cycle have been observed (Cooper et al., 2000; Simic et al., 1994).

Mechanism of Action(s)

Several animal experiments have been conducted to determine whether atrazine has teratogenic potential. Infurna et al. (1988) conducted an *in vivo* study of atrazine's teratogenic effects in rats and rabbits. Statistically significant teratogenic effects were observed only at a dose sufficient to cause maternal toxicity (70 mg/kg). These researchers reported that rabbits were much more sensitive to atrazine exposure than rats. In another study, rats given dietary doses up to 500 ppm did not show any adverse reproductive effects (Giknis et al., 1988). A third study showed that rats injected with atrazine at dosages of 800, 1000, and 2000 mg/kg on the third, sixth, and ninth day of gestation, respectively, did have

reduced litter size and increased resorptions (Peters and Cook, 1973).

Reproductive effects do not appear to be the result of intrinsic estrogenic activity of atrazine. In the uterus of Sprague-Dawley, Long-Evans, or Donryu rats following 28 days of oral exposure up to 50 mg/kg/day atrazine there were no observed increases in BrdU-positive cells (Aso et al., 2000). A 300 mg/kg/day oral dose for 3 days in Sprague-Dawley rats demonstrated no increases in uterine weight, cytosolic progesterone receptor binding, or peroxidase activity compared to positive controls that received estradiol and demonstrated increases in all three outcomes (Connor et al., 1996).

Weisenberger et al. (1988) reported that atrazine alone was not mutagenic in the Ames assay. However, the authors did find that *N*-nitrosoatrazine, formed readily at an acidic pH when nitriles are present, was mildly mutagenic. This finding is relevant because nitrogen fertilizers are commonly found in farmlands where atrazine is also used.

Gojmerac and Kniewald (1989) examined the fate of metabolized atrazine in rats *in vivo*. The most common residues found were deethylatrazine, atrazine, and deisopropylatrazine, located in the liver, kidneys, and brain. These metabolites indicate that atrazine undergoes partial *N*-dealkylation. Total *N*-dealkylation follows with the formation of diaminoatrazine.

Atrazine apparently is not bioactivated by mammalian microsomal preparations (Dunkelberg et al., 1994).

SOURCES OF EXPOSURE

Occupational

The principal occupational exposure is for agricultural workers who may be directly applying formulations containing atrazine or workers harvesting crops in areas treated with atrazine. Atrazine is considered as a restricted use pesticide and is not available for private use. However, exposure can also occur during manufacture and transport. Other than direct exposure from manufacture, transport, mixing, and application, some exposure can occur from working in soils contaminated with atrazine after treatment. The half-life of atrazine in soils may be 2 to 14 weeks depending on environmental conditions. Workers exposed indirectly may be more susceptible to exposure due to a lack of personal protective equipment normally worn by applicators.

Environmental

In analyses conducted by the FDA and USDA atrazine residue concentrations on food products with common atrazine use was very low (0.001–0.028 µg/g) where it was detected. Occasionally, atrazine is detected in water supplies such as rural well water at low concentrations. While most

people have little to no potential for exposure to atrazine, people who live near agricultural areas that regularly use atrazine have increased potential to be exposed. Airborne exposure potential results from atrazine-containing dusts or precipitation that has absorbed atrazine-containing dusts. However, these concentrations are also small; one study in Paris, France measured rainfall concentrations of atrazine as <5–400 ng/l with a median of 50 ng/l (Chevreuil et al., 1996).

INDUSTRIAL HYGIENE

The National Institute for Occupational Safety and Health (NIOSH) and the American Conference of Governmental Industrial Hygienists (ACGIH) have set the recommended exposure limit (REL) and the threshold limit value (TLV), respectively, for atrazine at 5 mg/m³ (NIOSH, 2013; ACGIH, 2013). The allowable tolerances for atrazine in foodstuffs range from 0.02 ppm to 0.25 ppm. Allowances for fodder are significantly higher (EPA, 1988). Immunoassays may be helpful in monitoring atrazine residues (Goh et al., 1993); however, some reagents have been shown to interfere with this method of atrazine quantitation (Stearman and Wells, 1993). Exposure to atrazine correlates with urinary diaminoatrazine and other urinary metabolites (Ikonen et al., 1988; Catenacci et al., 1990; Meli et al., 1992). Appropriate work clothing and eye protection should be used to limit exposure when mixing, transporting, and applying atrazine.

MEDICAL MANAGEMENT

Flushing skin and eyes with water to remove minor exposures is appropriate. In cases of extreme acute atrazine exposure, basic life-support measures should be taken. Emesis should not be induced, but gastric lavage may be helpful if performed shortly after ingestion. Administration of oral charcoal may enhance total body clearance of atrazine. If atrazine has been inhaled, the patient should be moved to fresh air. If the patient develops difficulty breathing, humidified oxygen should be administered.

SIMAZINE

BACKGROUND AND USES

Simazine acts by inhibiting photosynthesis. The EPA estimates that more than 5–7 million pounds of simazine were applied in 2007 (EPA, 2011). It is an active ingredient in Aquazine, Cekusan, Gesatop, Primatol/S, Princep, Simades, and Simanex. This herbicide is used primarily on fruit and maize and at industrial and aquatic sites, including near swimming pools and cooling towers. It typically is found as an 80% wettable powder or a 90% granule.

PHYSICAL AND CHEMICAL PROPERTIES

Simazine (2-chloro-4,6-bis(ethylamino)-*s*-triazine; CAS #122-34-9) is a selective, herbicide that inhibits photosynthesis. It occurs as a white crystalline solid, soluble at 5 ppm (at 20–22 °C) in water and 400 ppm in methanol. The vapor pressure of simazine is 0.000000061 mmHg (at 20 °C [68 °F]).

MAMMALIAN TOXICOLOGY

Acute Effects

Simazine is slightly toxic. Mild to severe contact dermatitis has been reported occasionally from large dermal exposures to simazine. No systemic poisonings from simazine have been reported. Treatment of excessive exposure is the same as for atrazine. There are no published chronic effects of simazine exposure in humans.

Chronic Effects

Some 90-day feeding studies at 67–100 mg/kg/day and 150 mg/kg/day resulted in reduced body weight and kidney toxicity. A 2-year chronic oral feeding study with 5 mg/kg/day of simazine resulted in no signs of toxicity. Simazine has an oral RfD of 0.005 mg/kg/day (EPA, 1988, 2013).

Mechanism of Action(s)

An assay of *in vitro* sister chromatid exchanges in human lymphocytes did not indicate that simazine has genotoxic potential (Dunkelberg et al., 1994). Simazine did not test positive in mutagenicity assays (IARC, 1991; Trochimowicz et al., 1994). IARC has concluded that there is insufficient evidence to classify simazine as a carcinogen. There is limited evidence that simazine may be a teratogen in animals (Trochimowicz et al., 1994).

SOURCES OF EXPOSURE

Occupational

Inhalation and dermal exposure may occur during application. Exposure may occur during manufacture, transport, mixing, and application of simazine-containing pesticide formulations.

Environmental

Simazine may be encountered as a residue on crop plants or in drinking water that has been contaminated by nearby agricultural use of this herbicide. Simazine can leach rapidly through some soil profiles and penetrate the water table (Reddy et al., 1992). Acrysol adjuvants may be used to slow this leaching (Reddy and Singh, 1993). The half-life in bodies of water is approximately 30 days (EPA, 1988).

INDUSTRIAL HYGIENE

Industrial hygiene is the same for the principal triazine pesticide, atrazine. Appropriate work clothing and eye protection should be used to limit exposure when mixing, transporting, and applying atrazine. No specific TLVs or exposure limits have been established by the ACGIH, OSHA, or NIOSH.

MEDICAL MANAGEMENT

Medical management of simazine is similar to all atrazine pesticides. Flushing skin and eyes with water to remove

minor exposures is appropriate. In cases of extreme acute simazine exposure, removal from exposure and basic life support measures should be taken.

QUATERNARY NITROGEN COMPOUNDS

PARAQUAT

BACKGROUND AND USES

Paraquat is a quick-acting contact herbicide, which becomes tightly bound to soil. It is largely used in the agricultural industry as an herbicide and may also be used as a desiccant for cotton. It is the active ingredient in Crisquat, Dextrone, Dexuron, Esgram, Goldquat 276, Gramoxone, Herbaxon, Osaquat Super, Dexuron, and Sweep. The EPA estimates about 2–4 million pounds of paraquat were used in 2007 (EPA, 2011).

PHYSICAL AND CHEMICAL PROPERTIES

Paraquat (paraquat dichloride; methyl viologen; CAS #1910-42-5) is a yellow solid with a faint ammonia-like odor. It has a vapor pressure of <0.0000001 mmHg and is extremely soluble in water. Preparations are a brown liquid that resemble a cola beverage.

MAMMALIAN TOXICOLOGY

Acute Effects

One of the most striking aspects of paraquat toxicity is the delayed onset of acute effects. Depending on the amount consumed, patients may survive a few hours to several weeks (Cravey, 1979). A second remarkable aspect of paraquat toxicity is its pulmonary toxicity. Pulmonary fibrosis is the most common effect of acute exposure and follows exposure by any route. Dermal exposure may cause pulmonary fibrosis in addition to severe burns (Papiris et al., 1995; Ronnen et al., 1995).

Ingestion is a common route of accidental or intentional acute exposure. Consumption of as little as 10–15 ml of a 20% solution has proved fatal (Pond, 1990). Paraquat is most often ingested with suicidal intent or sometimes mistaken for a beverage (Cravey, 1979). Once consumed, it directly attacks the gastrointestinal tract. This injury may include buccal mucosa erosion, ulceration hemorrhage, and pseudomembranous formation in the esophagus and stomach. Gastric erosion in paraquat intoxication indicates a grim prognosis (Mui, 1993). Severe acute exposure to paraquat may also lead to renal failure. Patients who reach this level of toxicity have a poor prognosis (Pond, 1990).

In one study a community exposed to paraquat drift from aerial spraying reported a higher rate of coughing, diarrhea, eye irritation, headache, nausea, rhinitis, throat irritation, trouble breathing, tiredness, and wheezing compared with other nearby communities (Ames et al., 1993).

The number of paraquat poisonings worldwide is difficult to estimate. The countries where paraquat is most readily available do not keep a registry of pesticide-related deaths (Tinoco et al., 1993). Also, many deaths may occur in rural agricultural areas, where the cause of death may not be determined and record keeping may be less reliable.

Chronic Effects

When used properly, paraquat does not appear to produce significant chronic effects. One study of Sri Lankan tea workers with long-term use of paraquat found no reduced lung, liver, or kidney function compared with controls

(Senanayake et al., 1993). The same study did find an increased incidence of nosebleeds and skin and nail damage.

Some studies suggest that chronic exposure to paraquat may result in hyperpigmented macules or hyperkeratosis, whereas others have found no such association (Wang et al., 1987; Cooper et al., 1994).

Mechanism of Action(s)

The lungs are the primary target of paraquat-induced toxicity. The lungs provide an abundant supply of electrons and oxygen for paraquat redox activity and this toxicity is further enhanced by the fact that paraquat is similar in size and chemistry to putrescine, a similarity that facilitates its uptake through alveolar receptors. Paraquat has been demonstrated to competitively inhibit uptake of putrescine in human lung tissue (Hoet et al., 1994). The lungs and muscles provide a reservoir for paraquat, which slowly redistributes to the bloodstream (Pond, 1990). Upon pathological examination, the lungs of paraquat-intoxicated patients show consolidation and bronchiectasis (Lee et al., 1995). Magnifications of lung samples reveal interstitial areas containing collagen, fibrin, platelets, mature fibroblasts, plasma cells, and numerous leukocytes (Dearden et al., 1978). Alveolar septa may be absent.

There is also evidence that paraquat is a neurotoxin. Some animal studies suggest that paraquat may have a neuromuscular blocking action, which could contribute to respiratory failure (Yn et al., 1994).

The potential teratogenicity of paraquat has also been investigated. Neonatal mice dosed with paraquat at a critical growth stage (10 days) did not exhibit weight gain or pulmonary symptoms (Fredriksson et al., 1993). However, at 60 and 120 days of age, they exhibited behavioral deficits that increased with dose and age. The authors also reported that paraquat-dosed mice had significantly lower brain levels of dopamine. There are indications that this effect may be reversible, depending on the dose (Fredriksson et al., 1993).

In vitro studies of rat gastrointestinal epithelial cells show that absorption of paraquat is gradual but linear (Grabie et al., 1993). Absorption of paraquat through porcine skin, which closely resembles human skin, is also described as gradual (Srikrishna et al., 1992). These experiments revealed increasing levels of intercellular edema with increasing dermal paraquat exposure.

In vivo studies show that lipid peroxidation by paraquat is dose dependent (Peter et al., 1992). Cell death was also dose dependent, although not necessarily as a direct result of lipid peroxidation. Exposure to paraquat induces production of metallothionein, a radical scavenger that also aids in homeostasis of trace metals (Sato, 1991; Bauman et al., 1992).

SOURCES OF EXPOSURE

Occupational

Paraquat is used in a wide variety of agricultural crops and occupational exposure may occur for those who manufacture, mix, or apply this herbicide. Secondary exposure may occur in workers who maintain or harvest crops post application.

Environmental

As paraquat is a contact herbicide, very little residue exposure is expected to occur on crops. Environmental exposures are rare as paraquat is degraded by ultraviolet light and soil bacteria. Residual paraquat in the environment may interfere with the function of various species. Experiments with amphibians show that dilute concentrations of paraquat may interfere with offspring viability (Dial and Dial, 1995). Other studies show that paraquat may significantly reduce the ability of shrimp to feed (Chu and Lau, 1994).

INDUSTRIAL HYGIENE

Individuals employed in the manufacture of paraquat may be exposed to dust, vapor, or aerosol, or to all three (Kuo et al., 1993). NIOSH has set the REL for paraquat at 0.1 mg/m^3 (NIOSH, 2013). The permissible exposure limit (PEL) set by OSHA is much higher at 0.5 mg/m^3 . The ACGIH has set a TLV of 0.5 mg/m^3 for total particles and 0.1 mg/m^3 for respirable particles (ACGIH, 2013). Paraquat is considered IDLH at 1 mg/m^3 .

Paraquat levels may be quantified directly from serum or urine. However, estimation of urinary levels should be undertaken with the knowledge that paraquat intoxication can interfere with creatinine measurement. If creatinine measurement is to be done accurately, it should be performed by an Ektachem dry chemistry slide creatinine amidohydrolase method or some other method not affected by paraquat's influence on the Jaffé reaction (Price et al., 1995).

MEDICAL MANAGEMENT

There are no specific antidotes for paraquat intoxication. Fuller's earth or other adsorbent materials may be given. For adults, 11 of a 15% aqueous solution of adsorbent is suggested (Pond, 1990). Gastric lavage may be performed if <1 h has passed since ingestion.

Plasma concentrations of paraquat should be analyzed to spare minimally exposed patients from the rigors of over-treatment (Proudfoot et al., 1979). However, emergency treatment should not be withheld while tests are performed.

Oxygen therapy must be avoided unless absolutely necessary because it increases paraquat toxicity (Rhodes et al., 1976).

Hemoperfusion, dialysis, and diuresis are not usually effective in paraquat intoxications (Mascie-Taylor et al., 1983; Pond et al., 1993). Hemoperfusion has been shown to be helpful only if performed shortly after ingestion in the case of mild intoxication. Radiotherapy is not promising as a method of controlling paraquat-induced lung damage (Saenghirunvattana et al., 1992).
