ABBREVIATIONS	xvii
THE HERITAGE OF ALICE HAMILTON MD AND HARRIET HARDY MD	xix
IN MEMORY	xxi
PREFACE	xxiii
SECTION I INTRODUCTION	1
<i>Section Editor: Raymond D. Harbison</i>	
1 The Modern Approach to the Diagnosis of Occupational Disease	3
<i>Raymond D. Harbison and Jeffrey H. Mandel</i>	
2 Controls of Occupational Diseases	13
<i>Daniel A. Newfang, Giffe T. Johnson, and Raymond D. Harbison</i>	
SECTION II METALS AND METALLOIDS	19
<i>Section Editor: Richard V. Lee</i>	
3 Introduction	21
<i>Richard V. Lee</i>	
4 Alkali Compounds	25
<i>Steve Morris and Ann Lurati</i>	
5 Aluminum	33
<i>Giffe T. Johnson</i>	
6 Antimony	39
<i>Marie M. Bourgeois</i>	

7	Arsenic	45
	<i>Janice S. Lee and Santhini Ramasamy</i>	
8	Barium	57
	<i>Marie M. Bourgeois</i>	
9	Beryllium	63
	<i>Alison J. Abritis and Raymond D. Harbison</i>	
10	Bismuth and Related Compounds	73
	<i>Paul Jonmaire</i>	
11	Boron	79
	<i>Giffe T. Johnson</i>	
12	Cadmium	85
	<i>Frank D. Stephen</i>	
13	Chromium	95
	<i>Kathleen Macmahon</i>	
14	Cobalt	101
	<i>Davinderjit Singh and Raymond D. Harbison</i>	
15	Copper	109
	<i>Marie M. Bourgeois</i>	
16	Gallium and Indium	115
	<i>Jayme P. Coyle and Raymond D. Harbison</i>	
17	Germanium	119
	<i>Marek Banasik</i>	
18	Gold	123
	<i>Marek Banasik</i>	
19	Iron	127
	<i>Steve Morris and Jayme P. Coyle</i>	
20	Lead	131
	<i>Frank D. Stephen</i>	
21	Lithium	141
	<i>Ushang Desai</i>	
22	Manganese	149
	<i>Alex Lebeau</i>	
23	Mercury	157
	<i>Frank D. Stephen</i>	
24	Molybdenum	167
	<i>Paul Jonmaire</i>	
25	Nickel	173
	<i>Robyn L. Prueitt and Julie E. Goodman</i>	
26	Tantalum and Niobium	183
	<i>Jayme P. Coyle and Raymond D. Harbison</i>	
27	Platinum Group Elements: Palladium, Iridium, Osmium, Rhodium, and Ruthenium	187
	<i>Alex Lebeau</i>	

28	Platinum	193
	<i>Alex Lebeau</i>	
29	Rare Earth Metals	199
	<i>Raymond D. Harbison and David R. Johnson</i>	
30	Selenium and its Compounds	205
	<i>Anna M. Fan and Marco Vinceti</i>	
31	Silver	229
	<i>Giffe T. Johnson</i>	
32	Tellurium	233
	<i>Marek Banasik</i>	
33	Thallium	239
	<i>Nikolay M. Filipov</i>	
34	Tin	247
	<i>Raymond D. Harbison and David R. Johnson</i>	
35	Titanium	253
	<i>Ushang Desai and Raymond D. Harbison</i>	
36	Tungsten	257
	<i>Kambria K. Haire and Raymond D. Harbison</i>	
37	Vanadium	261
	<i>James C. Ball and Maureen R. Gwinn</i>	
38	Zinc	277
	<i>Giffe T. Johnson</i>	
39	Hafnium and Zirconium	283
	<i>Kambria K. Haire, Jayme P. Coyle, and Raymond D. Harbison</i>	
40	Metal Fume Fever and Metal-Related Lung Disease	289
	<i>Thomas Truncale</i>	
SECTION III CHEMICAL COMPOUNDS I		301
	<i>Section Editor: Raymond D. Harbison</i>	
41	Introduction	303
	<i>Raymond D. Harbison</i>	
42	Carbon Dioxide	305
	<i>Debra J. Price</i>	
43	Carbon Monoxide	309
	<i>Erin L. Pulster and James V. Hillman</i>	
44	Carbon Disulfide	317
	<i>Debra J. Price</i>	
45	Hydrogen Sulfide	325
	<i>Stephen C. Harbison and Jacob R. Bourgeois</i>	
46	Cyanide	331
	<i>Erin L. Pulster and James V. Hillman</i>	

47	Halogens	341
	<i>Joseph A. Puccio</i>	
48	Phosgene	357
	<i>Benjamin Wong, Michael W. Perkins, and Alfred M. Sciuto</i>	
49	Nitrogen Compounds	363
	<i>Kathleen T. Jenkins</i>	
50	Oxygen and Ozone	371
	<i>Robert A. Klocke</i>	
51	Phosphorus Compounds	383
	<i>M. Rony Francois and Frank Stephen</i>	
52	Sulfur Compounds	391
	<i>Frank Stephen and M. Rony Francois</i>	
SECTION IV ORGANIC COMPOUNDS		401
	<i>Section Editor: Raymond D. Harbison</i>	
53	Aliphatic Hydrocarbons	403
	<i>Mayowa Amosu, Nicole Nation, and Mary Alice Smith</i>	
54	Alcohols and Glycols	419
	<i>Kelly W. Hall</i>	
55	Aldehydes and Ketones	445
	<i>Jason S. Garcia and Raymond D. Harbison</i>	
56	Ethers and Epoxides	491
	<i>Erin L. Pulster, Jacob R. Bourgeois, and Raymond D. Harbison</i>	
57	Esters	505
	<i>Raymond D. Harbison and C. Clifford Conaway</i>	
58	Chlorinated Hydrocarbons	541
	<i>Michael H. Lumpkin</i>	
59	Other Halogenated Hydrocarbons	567
	<i>Michael H. Lumpkin</i>	
60	Aromatic Hydrocarbons	581
	<i>Raymond D. Harbison, Amora Mayo-Perez, David R. Johnson, and Marie M. Bourgeois</i>	
61	Amino and Nitro Compounds	615
	<i>David Y. Lai and Yin-Tak Woo</i>	
62	Methyl Tert-Butyl Ether (MTBE)	643
	<i>Janice S. Lee and Robyn Blain</i>	
63	Ethyl Tertiary Butyl Ether (ETBE)	651
	<i>Keith D. Salazar</i>	
64	tert-Butyl Alcohol	657
	<i>Janice S. Lee</i>	
65	Naphthalene	663
	<i>Lisa A. Bailey, Laura E. Kerper, and Lorenz R. Rhomberg</i>	

66	Gasoline (Petrol, Motor Spirits, Motor Fuel, Natural Gasoline, Benzin, Mogas)	669
	<i>Raymond D. Harbison and Daniel A. Newfang</i>	
67	1-Bromopropane	677
	<i>Marek Banasik</i>	
68	Diacetyl	683
	<i>David J. Hewitt</i>	
69	Perfluoroalkyl Compounds	689
	<i>Jason S. Garcia and Raymond D. Harbison</i>	
70	Tetrahydrofuran	719
	<i>Ghazi A. Dannan</i>	
71	Perchloroethylene (Tetrachloroethylene)	727
	<i>David G. Dodge and Julie E. Goodman</i>	
72	Trichloroethylene	733
	<i>David G. Dodge and Julie E. Goodman</i>	
73	Acrylonitrile	741
	<i>Jason M. Fritz and April M. Luke</i>	

**SECTION V ORGANIC HIGH POLYMERS, MONOMERS,
AND POLYMER ADDITIVES** **755**

Section Editor: Raymond D. Harbison

74	Introduction	757
	<i>Raymond D. Harbison</i>	
75	Plastics	759
	<i>Marek Banasik</i>	
76	Elastomers	785
	<i>Marek Banasik</i>	
77	Synthetic Fibers	791
	<i>Marek Banasik</i>	
78	Bisphenol A (4,4'-Isopropylidenediphenol)	795
	<i>Julie E. Goodman, Lorenz R. Rhomberg, and Michael K. Peterson</i>	
79	Polystyrene/Styrene	809
	<i>Leslie A. Beyer and Julie E. Goodman</i>	
80	Phthalates	815
	<i>Robert W. Benson</i>	
81	Decabromodiphenyl Ethane	821
	<i>Marek Banasik</i>	
82	Tetrabromobisphenol A	827
	<i>David Y. Lai</i>	
83	Tris[2-Chloro-1-(Chloromethyl)Ethyl] Phosphate (TDCPP)	837
	<i>Marek Banasik</i>	

84 Tris(2-Chloro-1-Methylethyl) Phosphate (TCPP)	845
<i>Marek Banasik</i>	
SECTION VI PESTICIDES	855
<i>Section Editor: Raymond D. Harbison</i>	
85 Introduction	857
<i>Raymond D. Harbison</i>	
86 Insecticides	859
<i>Carol S. Wood</i>	
87 Herbicides	877
<i>Giffe T. Johnson</i>	
88 Fungicides	901
<i>Amora Mayo-Perez and Raymond D. Harbison</i>	
89 Rodenticides	917
<i>Daniel L. Sudakin</i>	
SECTION VII DUSTS AND FIBERS	927
<i>Section Editor: Raymond D. Harbison</i>	
90 Introduction	929
<i>David R. Johnson</i>	
91 Benign Dusts (Nuisance Dusts)	931
<i>Humairat H. Rahman and Raymond D. Harbison</i>	
92 Fibrogenic Dusts	935
<i>Charles Barton</i>	
93 Mixed Dusts	949
<i>Charles Barton</i>	
94 Synthetic Vitreous Fibers	959
<i>Thomas Truncale and Yehia Y. Hammad</i>	
95 Organic Dusts	969
<i>David R. Johnson</i>	
96 Naturally Occurring Mineral Fibers	997
<i>Ali K. Hamade, Christopher M. Long, and Peter A. Valberg</i>	
97 Nanoparticles	1025
<i>Daniel A. Newfang, Giffe T. Johnson, and Raymond D. Harbison</i>	
SECTION VIII PHYSICAL AGENTS	1029
<i>Section Editor: Marie Bourgeois</i>	
98 Radio-Frequency Radiation	1031
<i>R. Timothy Hitchcock</i>	
99 Optical Radiation: Ultraviolet, Visible Light, Infrared, and Lasers	1045
<i>Joseph M. Greco</i>	

100	Ionizing Radiation	1055
	<i>Thomas A. Lewandowski, Juhi K. Chandalia, and Peter A. Valberg</i>	
101	Electromagnetic Waves (EMF and RF) and Health Effects	1069
	<i>Peter A. Valberg</i>	
102	Traumatogens Associated with Carpal Tunnel Syndrome	1087
	<i>Joan M. Watkins</i>	
103	Vibration	1099
	<i>Donald E. Wasserman</i>	
104	Occupational Noise	1115
	<i>David L. Dahlstrom</i>	
105	Heat Stress Illness	1123
	<i>Marie M. Bourgeois and David R. Johnson</i>	
 SECTION IX SPECIAL TOPICS		1129
<i>Section Editor: Raymond D. Harbison</i>		
106	Mode of Action/Human Relevance Framework	1131
	<i>M.E. (Bette) Meek</i>	
107	Carcinogenesis	1135
	<i>Carlos A. Muro-Cacho</i>	
108	Genotoxicity Testing Strategies, Guidelines, and Methods	1173
	<i>Ching-hung Hsu and Qingli Wang</i>	
109	Human Relevance of Rodent Leydig Cell Tumors	1189
	<i>Thomas J. Steinbach, Robert. R. Maronpot, and Jerry F. Hardisty</i>	
110	Reproductive Toxicology	1197
	<i>Judith W. Henck</i>	
111	Developmental Toxicology	1229
	<i>Thomas A. Lewandowski</i>	
112	Ototoxicity	1241
	<i>Matthew Mifsud and K. Paul Boyev</i>	
113	Dermal and Ocular Toxicity	1247
	<i>Jayme P. Coyle, Alison J. Abritis, Amora Mayo-Perez, Marie M. Bourgeois, and Raymond D. Harbison</i>	
114	Reactive Airways Dysfunction Syndrome (RADS)	1259
	<i>David J. Hewitt</i>	
115	Pulmonary Sensitization	1263
	<i>David J. Hewitt</i>	
116	“Street” and Prescription Drug Abuse	1267
	<i>Sharon S. Kelley, James Godin, and John Christie</i>	
117	Mycotoxins	1283
	<i>Clara Y. Chan and Bruce J. Kelman</i>	

118 Phosphine	1295
<i>Michael W. Perkins, Benjamin Wong, Dorian Olivera, and Alfred Sciuto</i>	
119 Diesel Exhaust	1301
<i>J. Michael Berg, Phillip T. Goad, and Thomas W. Hesterberg</i>	
120 Spaceflight Operations	1311
<i>Michael A. Cardinale, Philip J. Scarpa, James R. Taffer, and Daniel Woodard</i>	
121 Regulatory Toxicology	1321
<i>David M. Polanic and Marek Banasik</i>	
INDEX	1331

CONTRIBUTORS

Alison J. Abritis, MPH, Department of Environmental and Occupational Health, College of Public Health, University of South Florida, Tampa, FL, USA

Mayowa Amosu, Laboratory Manager, Smith Lab Environmental Health Sciences, University of Georgia, Athens, GA, USA

Lisa A. Bailey, PhD, Gradient Corporation, Cambridge, MA, USA

James C. Ball, PhD, Research Scientist, Integrated Risk Information System (IRIS), U.S. Environmental Protection Agency, Washington, DC, USA

Marek Banasik, MD, PhD, Institute of Public Health and Environmental Protection, Warsaw, Poland

Charles Barton, PhD, DABT, Senior Toxicologist & Toxicology Program Manager, Oak Ridge Institute for Science and Education (ORISE), Oak Ridge Associated Universities (ORAU), Oak Ridge, TN, USA

Robert W. Benson, PhD, Toxicologist, Office of Partnerships and Regulatory Assistance, U.S. Environmental Protection Agency, Denver, CO, USA

J. Michael Berg, PhD, Toxicologist, Center for Toxicology and Environmental Health, LLC, Houston, TX, USA

THE HERITAGE OF ALICE HAMILTON, M.D. AND HARRIET HARDY, M.D.

It has been over a century since Alice Hamilton graduated medical school, and almost a century since Harvard appointed her as the first female associate professor. It has only been just under three-quarters of a century since the first female full professor at Harvard, Harriet Hardy, was appointed. Few working people entering the fields of occupational and environmental health and hygiene are old enough to appreciate the incredible strides made in these fields to protect workers, families, flora, and fauna. Even fewer still are old enough to understand the personal and professional battles fought by Dr. Hamilton and Dr. Hardy in just trying to attend college, gain employment in their field, and establish the credibility automatically and generously granted to men with lesser education and experience.

Both women had to limit their choices of educational institutions to those designed or willing to accept women. Both had to withstand accusations of emotionalism and “hysteria” as naysayers sought to discredit them. Dr. Hamilton achieved a notable landmark in being appointed the first woman faculty at Harvard, but her position was without several of the privileges enjoyed by the male faculty, and she retired from Harvard still an associate professor. Dr. Hardy was similarly notable in her appointment as full professor at Harvard, but she suffered from several physical ailments that took a severe toll on her. However, it would be truly short-sighted to view their difficulties and successes only in terms of gender issues. They were scientists, first and foremost, and most of the dissension encountered during their professional

lives was primarily due to their challenging the deep-seated socially dismissive attitude toward worker health, the associations between chemicals and illness, and the industries’ unwillingness to incur expenses in attending to employee needs.

Certainly, the dimming of memories signifies positive strides in occupational and environmental health goals and gender equality. However, the historical advances in occupational and environmental health are now so much a part of our way of life that we risk losing the appreciation of the sacrifices, and the successes of the people behind these changes. Neither Dr. Hamilton nor Dr. Hardy proffered theories that were gracefully met with acceptance, regardless of the supporting evidence or the number of potential lives at risk. Their strength of character drove them, which in turn propelled the changes they sought.

Industrial Toxicology was first drafted by Dr. Hamilton in 1934. Fifteen years later, she teamed with her colleague Dr. Hardy for the second edition. The subsequent editions maintain their names in the title, not just as courtesy but as a genuine homage to their impressive contributions to the health and welfare of global populations, at times at great expense to their own personal life and health. Perhaps, ultimately, this is the legacy carried forth with these volumes, the reason we need to remember exactly who these women were and what they accomplished—so that we may honor them by our dedication and sacrifice in striving for greater knowledge and safer lives.

IN MEMORY

During the lengthy process of creating this sixth edition, we lost one of our most integral people when, on May 7, 2013, Dr. Richard Vaile Lee passed away. A brilliant physician and educator, Dick Lee was also a valued friend and colleague.

Dr. Lee began his collegiate experience at Yale, where he received both his B.S. and M.D. and gained membership in the Alpha Omega Alpha Honor Medical Society. His internship and residency concentration was internal medicine. Between his residency years, he also squeezed in 2 years of service at the Fort Peck Indian Reservation in Montana for the U.S. Public Health Service, remaining an additional year to assist a colleague in general practice. Upon his return to Yale, he completed his residency and was awarded a fellowship in infectious diseases. While a fellow, he also acted as Director for the medical clinics and emergency room for the Department of Medicine.

In 1976, Dr. Lee left Yale to assume the positions of Professor and Vice Chairman of the Department of Medicine at the State University of New York at Buffalo (UB), and Chief of Medical Services for the Buffalo Veterans

Administration Medical Center. In 1979, he took over as Head of the Department of Medicine at Buffalo's Children's Hospital. In 1997, he left Children's Hospital to establish a private practice in obstetrics medicine.

Dr. Lee's practice was not confined to a simple driving radius. He practiced "geographic medicine," bringing much-needed medical care and attention to remote locations. He treated tribal cultures in Northern Kenya and Brazil, and he traveled to Thailand, treating refugees from Laos and Cambodia. He developed an acquaintance with the Dalai Lama through his work with Tibetan refugees and was part of the UB board responsible for Dalai Lama's trip to Buffalo in 2006. He developed the UB's Medical Trek Program, sending students to perform medical care in field expeditions across the world.

The range of scholarship was almost as broad as the countries traveled. In addition to his experience in general practice, infectious diseases, and obstetrics, Dr. Lee also served as Medical Director for Ecology and Environment, Inc., in Lancaster. He taught classes at UB in pediatrics, gynecology, and obstetrics in the School of Medicine and Biomedical Sciences as well as various classes in the Department of Social and Preventive Medicine in the School of Public Health and Health Professions, and in the Department of Anthropology in the College of Arts and Sciences. He also served as a consulting physician to both the Buffalo Zoo and the Bronx Zoo.

His marriage in 1961 to Susan Bradley ultimately produced two sons, Benjamin and Matthew. It also unearthed a family secret. When he announced his impending marriage to his family, Dr. Lee learned that his paternal grandfather was Li Yan Phou, one of a select group of Chinese students to attend school in the United States. Because of strong anti-Asian prejudice (at the time there were laws preventing

Chinese and non-Chinese intermarriages in some states), Dr. Lee's parents had opted to hide the Asian heritage. However, Dr. Lee embraced his Chinese heritage, serving as a trustee for the Yale–China Association and participating in a UB delegation to China to renew an academic affiliation with a Beijing university. He also edited and wrote the foreword for the 2004 edition of his grandfather's book, *When I was a Boy in China*, published under the Anglicized name of Yan Phou Lee.

Dr. Lee produced over 70 publications and garnered several awards. In 2002, he was the Laureate Award winner

of the American College of Physicians–American Society of Internal Medicine, and in 2007, he was the winner of the C.G. Barnes Award from International Society of Obstetric Medicine. In the same year, the North American Society of Obstetric Medicine established a lecture in his name for their annual meetings.

So we dedicate this edition to Richard V. Lee, M.D., FACP, FPGS: a scholar, a humanitarian, an educator, a leader, a traveler, a guide, a speaker, a listener, and ultimately an inspiration. By his own words: "a professor." By our words, a great man.

PREFACE

The sixth edition of *Hamilton & Hardy's Industrial Toxicology* has been updated and expanded with new chapters on aspects of regulatory toxicology, toxicity testing, physical hazards, high production volume (HPV) chemicals, and workplace drug use. The format has been modified and now includes information on occupational and environmental sources of exposure, mammalian toxicology, industrial hygiene, medical management, and ecotoxicology where appropriate. The book is organized by substance and includes the latest research on industrial toxicants. The goal was to provide a broad range of professionals with an accessible text. We are extremely grateful to our contributors as they provided integral industry, regulatory, and academic perspectives.

The landscape of industrial toxicology has changed considerably since Dr. Alice Hamilton and Dr. Harriet Hardy published the first edition of the text in 1929. It is estimated that there are now more than 70,000 industrial chemicals in common use. In contrast, regulatory agencies have established fewer than 1000 exposure limits. Determination of an appropriate exposure limit is an exhaustive process; as an illustration, the U.S. Occupational Safety and Health Administration (OSHA) has promulgated fewer than 30 standards (new permissible exposure limits (PELs) for 16 agents, and standards without PELs for 13 carcinogens) since 1970. The European Union's REACH (Regulation on Registration, Evaluation, Authorization and Restriction of Chemicals) framework will require several decades to determine the exposure limits for common chemicals.

The assessment backlog is so critical that OSHA recommends that the employers consider using alternative occupational exposure limits established by the National Institute for Occupational Safety and Health (NIOSH) and American

Conference of Industrial Hygienists (ACGIH). Traditional toxicological testing is costly, time consuming, reliant on animal models, and fraught with uncertainty stemming from interspecies extrapolation. Tox21, an interagency project between the National Toxicology Program, the U.S. Environmental Protection Agency, the National Institutes of Health, and the Food and Drug Administration, is a high-throughput testing prototype robot created to address both the knowledge gap and problems of traditional toxicity testing. Tox21 will screen thousands of chemicals using advanced *in vitro* and cell-based assays and non-rodent models such as zebrafish in far less time than previously possible.

The evaluation of risk subsequent to exposure is an essential component of industrial toxicology. It is critical that readers remember that exposure only represents the *opportunity* for contact with a chemical. An exposure does not guarantee that an adverse effect will result. A dose is the amount of the chemical entering the body following an exposure. There are both harmful and safe doses of all chemicals. As Paracelsus said, "All things are poisons, for there is nothing without poisonous qualities . . . it is only the dose which makes a thing poison." Exposure and dose both need to be evaluated for an adequate hazard assessment. This edition of the text includes an assessment of risk where possible.

Hamilton & Hardy's Industrial Toxicology was prepared as a concise reference for academics and professionals alike. There is a wealth of information available on industrial exposures and toxicants. Distillation of these resources into something relevant can be daunting. It is our hope that this text will be that something relevant for our readers.

1

THE MODERN APPROACH TO THE DIAGNOSIS OF OCCUPATIONAL DISEASE

RAYMOND D. HARBISON AND JEFFREY H. MANDEL

BACKGROUND

An understanding of the health effects that may occur from occupational exposures is critical in terms of the potential human toll and an industry's success and sustainability. The diagnosis of workplace-induced diseases is necessary if the disease in question is to be prevented. In the context of modern medicine, the diagnosis of an occupational disease is a multidisciplinary process and includes input from professionals in occupational medicine, nursing, industrial hygiene, toxicology, epidemiology, engineering, and others. Though physicians are primarily responsible for making an individual diagnosis, the remaining disciplines are critical parts of the process for establishing the nature and cause of the disease(s). It is the collective group that has become paramount to the understanding and control of occupational disease within modern societies. The diagnosis of an occupational disease may be understood in the context of a public health model, which incorporates the interplay between the agent, the host, and the disease. With this approach, the agent may be physical, chemical, or biological and has the potential to cause harm depending on its characteristics (e.g., corrosive, pathogenic, and carcinogenic), the exposure concentration and duration, and the ability to target organs in exposed individuals. The host is the individual or population exposed to the agent. The disease results from the interaction of these two factors. The host in this model includes healthy individuals as well as susceptible individuals (e.g., genetic predisposition and life stage). With acute or chronic high-level exposures, host susceptibility generally increases, due to a variety of mechanisms, including saturation of detoxification reactions and increased bioactivation. Manufacturing

facilities control exposures through engineering controls, personal protective equipment, chemical substitution, area monitoring, personal monitoring, hazard communication, and employee training and education.

Despite the vast number of professionals involved, the diagnosis of an occupational disease is complicated by important factors. First, many diseases that occur as a result of workplace exposures (e.g., asthma from isocyanates) may also occur from non-workplace exposures to the same compounds or may be caused by other agents (nonspecificity). Second, disease manifestation is often idiopathic and may be attributed to the workplace purely on the basis of the disease preceding employment. Third, the majority of chemicals in commerce either have not been tested in experimental animals or have been tested but lack data on the mode of action and human relevance of adverse effects. The absence of this type of information complicates extrapolations from animal studies to workers. Finally, many tests used in clinical medicine are not specific for identifying exposures to an agent of interest. For example, a blood test that reveals high carboxyhemoglobin (COHb) levels only confirms an internal dose of carbon monoxide. It does not confirm whether the source exposure was to carbon monoxide, methylene chloride, or some other causative agent. Similarly, chest radiograph findings that suggest interstitial lung disease do not confirm exposures to a specific causative agent (e.g., wood dust). Testing of workers is subject to each test's sensitivity, specificity, and positive and negative predictive value. To complicate matters, many tests do not have established "gold standards" to which they may be compared. All of these issues may potentially compromise the accuracy of diagnoses.

As alluded to in the above examples, a multilevel assessment is needed in the diagnosis of an occupational disease. The exposure in question must be assessed in terms of what is known about it, whether the worker's complaints are consistent with this exposure, and insights into the actual work environment are the initial necessary perspectives needed. These are followed by a detailed account of the individual's illness, the person's medical history, occupational history, physical findings, laboratory findings, and a review of the epidemiological literature involving this person's exposure–disease relationship. Finally, some type of assessment of causation is necessary to determine whether there is adequate information to suggest that an exposure could produce the disease in question. This assessment typically involves a comprehensive review of the existing epidemiological literature on the topic. All this is theoretically needed before an occupational disease can be considered. Each of these will be considered in greater detail in the subsequent paragraphs.

COMPONENTS OF THE DIAGNOSIS

The History of Illness

The worker's disease history is often the only information available to the team of professionals assigned to determine the etiology of the disease. In some cases, associations with the workplace are based entirely upon this history, hence its importance. Accordingly, the trained interviewer attempts to have as much of this as possible iterated directly in the worker's own words. A description of the worker's symptoms is the basis of this history, but there needs to also be a focus on the occupational aspects of the illness. Identification of the illness occurring temporally with the workplace is helpful since exposure–disease associations may become worse during the workday, the workweek, often with improvement after work, or on weekends away from the job. It is also important to clarify the duration of the exposure and whether coworkers with similar jobs have had health problems. Since some illnesses have long latencies, the examiner must determine the prior work history of an individual. The practitioner may also use other sources of information, including the employer, incident reports, the state or federal Occupational Safety and Health Administration (OSHA), and an industrial hygienist familiar with the workplace controls, practices, and safety data sheets (SDSs). The history should include the following:

- 1. Occupational Factors.* Occupational factors must be assessed and understood. These include insights into the agent (exposure) in question as well as the involved work area. Part of this understanding is obtained through an evaluation of processes, engineering

controls, personal protective equipment, employee training and compliance, and the identification of potential causative agents (e.g., which materials or chemicals are used?) and opportunities for exposure. The chemicals used must be understood in terms of the potential routes of exposure (e.g., inhalation of volatile organics), toxicokinetics (i.e., absorption, distribution, metabolism, and elimination), and toxicity.

- 2. Nonoccupational Factors.* Many diseases that may originate from exposures to a causative agent in the workplace may also occur outside of the workplace. Asthma, for example, may be triggered by occupational or consumer exposure to certain isocyanates, but it may also be triggered by exposure to cat dander. Lung cancer may be related to asbestos exposure, smoking, or both. Few diseases have only an occupational basis. In fact, estimates of 5–10% of all cancers have been attributed to exposures in the occupational setting (Doll, 1984). The vast majority of cancers are not associated with occupational exposures and are thought to be multifactorial in origin (e.g., environmental exposures, lifestyle choices/hobbies, and genetic predisposition). In particular, attention must be given to these factors in the assessment of occupational disease. Especially important are exposures that occur to individuals with preexisting diseases, since these may complicate an illness resulting from an exposure. For example, an individual with underlying chronic bronchitis may have a reduced capacity for pulmonary clearance, which may predispose this individual to an adverse outcome following exposure to specific types of agents (e.g., fibers or insoluble particles).

The Physical and Laboratory Examinations

The physical and laboratory examinations are regarded as means of verifying what is already suspected following the history of illness. A skilled examiner is able to combine these two areas with a high likelihood of an accurate diagnosis, without any additional evaluation. The occupational physical examination, such as the history of illness, needs to focus on the organ where known toxicity occurs. If the worker has breathing difficulties and has exposure to a lung irritant, the examination will need to focus on the respiratory system. Other organ systems are evaluated for the sake of being thorough and to identify additional potential areas of abnormality.

Following the physical examination, the examiner may need to verify the disease suspected with the use of specific tests. In the above case, it would be appropriate to perform a pulmonary function test (e.g., spirometry) to evaluate the worker's inhalation and exhalation during normal breathing

to assess air volume and air flow. It may also be helpful to obtain a chest radiograph. There are an infinite array of tests available, each costly and with their own inherent risks. These have to be weighed against the benefit of the information to be obtained. Most of the common laboratory tests have significant benefits, without much risk. Even so, caution must be used in subjecting workers to these tests unnecessarily, as all tests have—as a disadvantage—the possibility of false positive or negative findings. These may result in additional, more risky tests in the case of the former or missed diagnoses in the case of the latter.

Use of Toxicology, Risk Assessment, and Risk Characterization Information

All chemicals, even everyday, seemingly benign substances, can produce an adverse effect at some level and duration of exposure. The adverse effect may be an alteration of normal function or even death. For example, at a certain level and duration of exposure, carbon tetrachloride may cause reversible effects, such as drowsiness and loss of motor function; however, at higher levels of exposure, this chemical can produce irreversible liver damage and respiratory arrest.

Every chemical can produce a spectrum of toxicological effects. The effects vary and all chemicals are toxic at some dose (Table 1.1); that is, all chemicals are capable of altering some function or causing death in some biological organism. Though this may seem to be stating the obvious, it serves to emphasize the basis for risk assessment, which is identifying those circumstances and conditions under which an adverse effect can be produced. As Emil Mrak, chancellor at the University of California at Davis, stated years ago, “There are no harmless substances; there are only harmless ways of using substances.” A chemical is toxic and does harm only within prescribed conditions of usage.

Toxicology is the study of the harmful effects of chemicals on the living system. To identify and characterize chemical-induced disease or injury, the practitioner must understand both the chemical reactions and interactions with tissues and cells and the biological mechanisms of cytotoxicity. The vastness and rapid gains in this area have stimulated many new controversies over chemical-induced injury and workplace safety. However, certain

principles of toxicology apply to a large number of chemicals, and an understanding of these principles is essential to the development of insightful toxicological judgment.

Risk assessment is the process of determining whether a chemical will produce harm under specified conditions of exposure. Safety, the reciprocal of risk, is the probability that a chemical will not produce harm under specified conditions of exposure. Thus, in determining the risk or safety of a chemical, the critical factor is not necessarily the intrinsic toxicity of the chemical *per se*, but rather the likelihood that the level of exposure to the chemical is sufficient to allow the expression of its intrinsic toxicity.

Risk is determined by evaluating the exposure required to produce toxicity. The evaluation of human risk associated with chemical exposure requires an assessment of the human epidemiological and animal testing data. When available, the following data should be evaluated:

- Breadth and variety of toxic responses reported.
- Species variation or consistency in toxic responses.
- Possible proposed mode(s) of action or mechanism(s) of action.
- Validity of tests performed and their relevance for extrapolation to humans.
- Dosage used in animal tests compared with the expected level of human exposures.
- Outcomes of poisonings and long-term occupational exposures, which may serve as a guide to the expected human consequences and as validation of the human relevance of animal testing data.

Modern science, including medicine, continues to evolve as a result of the accumulation of knowledge and experience. This process of accumulation and evolution of knowledge has resulted in new principles, concepts, and treatments of disease. Discoveries have been made in medicine and toxicology that have changed medical thinking and practice in the past decade.

As a result of the evolution of regulations to protect public health, large numbers of animal tests have been conducted that have produced massive amounts of new information for the practitioner as well as the worker. A safety data sheet used for hazard communication contains the results and

TABLE 1.1 Normal and Lethal Doses of Common Substances

Substance	Normal Dose	Lethal Dose	Safety Factor
Water	1.5 qt.	15 qt.	10
Aspirin (salicylic acid)	2 tablets	90 tablets	45
Beer (ethyl alcohol)	1 beer	33 beers	33
Salt (sodium chloride)	3 tsp	60 tsp	20
Lima beans (cyanide per serving)	1.18 mg	106 mg	90

classification of animal testing data that must be appropriately interpreted and communicated to employees.

Voluntary and enforceable occupational exposure levels are considered the benchmark for determining whether a disease or injury resulted from chemical exposure. These values cannot, however, be used to determine the cause of a disease or ailment. Rather, they provide guidance for protecting workers from harmful levels of exposure. In short, occupational exposure levels protect; they do not predict. Because safety factors and other margins of safety are incorporated into these standards, exceeding the exposure level does not indicate the likelihood of harm. However, when the exposure level is exceeded, harm can occur at some point. Because all chemicals cause harm at some level of exposure, the principles of the dose-response relationship form the basis for workplace protection against chemical-induced injury.

Exposure and Dose An individual's risk of an adverse health effect is determined by evaluating exposure(s) and dose(s). Exposures must be considered based on the likely route(s) of exposure (i.e., ingestion, inhalation, and dermal/ocular). The concept of dose is different from exposure. Exposure is the opportunity to contact and absorb a chemical; this generally means that the individual and the substance are in some physical proximity. Exposure must occur to receive a dose. As used herein, the term dose refers to the actual amount of a substance absorbed by the individual, but it may also be considered in terms of the dose received at the point of contact (e.g., dermal exposure to corrosive agents). Exposure varies according to the source of the chemical, the distance from the source of contamination, and the concentration of the chemical. Even when individuals have the same or similar exposures, the actual dose received will depend on a number of variables (Table 1.2).

Duration of Exposure With some substances, even brief exposures may be harmful; with others, adverse health effects may be manifested only after chronic exposures. Exposures vary between individuals, even those working in the same areas, based on the duration of the exposure. For example, a worker exposed for 3 h in the workplace does not receive the same dose as a worker exposed for 8 h in the workplace. This necessarily varies by a number of factors, including environment. For example, a person who has lived in an area with measurable levels of specific chemicals all his or her life certainly has a different exposure duration from someone who has recently moved to the area.

Type of Contact The opportunity for contact (e.g., inhalation, ingestion, and dermal/ocular) may determine whether the exposure gives rise to adverse health effects, and if so, the nature and severity of these effects. For example, certain chemical compounds may be harmful if inhaled but are relatively harmless if swallowed.

TABLE 1.2 Variables Determining Degree of Exposure^a

Route of Exposure	Variables
Inhalation	Inhalation absorption coefficient
	Exposure period outdoors
	Vapor concentration outdoors
	Respiratory rate indoors
Dermal	Vapor concentration indoors
	Dermal absorption coefficient
	Vapor concentration outdoors
	Vapor concentration indoors
Ingestion	Exposure period outdoors
	Exposure period indoors
	Exposed body surface outdoors
	Exposed body surface indoors
	Oral absorption coefficient
	Water ingestion rate
	Soil ingestion rate
	Food ingestion rate
	Water concentration indoors and outdoors
	Soil concentration outdoors and indoors
	Food concentrations

^aTotal daily dose, micrograms/day, determined by all routes of exposure.

Level of Exposure The effect of a chemical varies with the amount of the dose. For example, even oxygen can be dangerous to human health in very high concentrations. Potential differences in exposure result from a wide range of different workplace controls and practices as well as from lifestyle choices.

Environmental Exposure Considerable attention has been focused on environmental causes of diseases in recent years, partly because of publicity and partly because of increasing concern over industrial pollution. In the eighteenth century, it was common for children of a mercury miner to develop mercury poisoning and infants in families that used leaded pottery to suffer from central nervous system damage. In Japan during the 1960s, a disease was reported that was caused by industrial methylmercury pollution of fish used for food, a disorder called Minamata disease, after the bay into which the waste was dumped (Matsumoto et al., 1965). Recently, a painful bone disease in rice field workers in Japan, a condition known as Itai-Itai disease, resulted from cadmium pollution by nearby mines that produced zinc and lead (Kobayashi, 1971).

In the United States, a dramatic example of environmentally induced disease involved 60 cases of chronic beryllium poisoning suffered by women, children, and a few men, none of whom had entered a beryllium-using plant (Hardy et al., 1967). Beryllium in nearby community air from factory stacks was one source; clothes brought from the workplace into the home proved to be a more serious source; and it is likely that soil heavily contaminated with beryllium

may be an important cause of long-delayed cases of chronic toxicity. Another example of environmentally induced disease is provided by reports of the hazards of asbestos exposure. Wagner et al. (1960) published their finding that correlated 32 cases of malignant mesothelioma with neighborhood asbestos exposure. Native women and children who lived in the South African villages close to plants that refined asbestos from nearby mines were the main victims. Newhouse and Thompson (1965) reported a series of fatal cases of mesothelioma among residents of a dwelling adjacent to a London asbestos factory. As with the beryllium industry experience in the United States, both proximity and contaminated work clothes were etiological factors in these cases. Kiviluoto (1960) found radiographic evidence of pleural calcification in a significant number of inhabitants of a geographically limited area in Finland, with no other evidence of disease. Further study demonstrated that dust from a neighboring asbestos plant was responsible for the radiographic findings.

It cannot be overemphasized that correct diagnosis, rational treatment, and the prognosis of occupational disease rest mainly on the knowledge of workplace and/or incidental exposure. In some cases, assaying blood, urine, or tissue samples may lead to the diagnosis of industrial illness; in other cases, it may simply create confusion, because the findings reflect only exposure or levels also found in individuals who were not industrially exposed. The scientific method must be used to determine the chemical cause of a disease. Failure to use this method may result in incorrect associations and conclusions.

DETERMINING THE CAUSE OF OCCUPATIONAL DISEASE

Causal Inference

The issue of whether a particular chemical exposure causes disease in humans may be approached in different ways. Details of the exposure and the disease must be thoroughly understood. With this information, the existing scientific literature may be used to determine whether an individual's illness is related to a particular exposure. In addition to the consideration of an individual's circumstances, it is also necessary to determine if there is additional general information in the scientific literature to support a chemical-disease relationship. There are several ways of doing this. In some approaches, a more theoretical approach with causal factors described as having multiple forms (sufficient, component) and with causal inference described as a part of the more general process of scientific reasoning is used (Rothman and Greenland, 1998). In other approaches, multiple factors (biologic plausibility, strength of association, exposure response, consistency, specificity, coherence, experimental

evidence, analogy, and temporality) have received consideration (U.S. Surgeon General's Report on Smoking, 1964; Hill, 1965).

The multiple-factor approach to causation has limits, since there may be exceptions to nearly all of the factors even though an exposure-disease relationship may exist. For example, lung cancer is strongly related to cigarette smoke, but cigarette smoke is not specific to the association with lung cancer. With this approach, biologic plausibility may include an assessment of results from toxicity (animal) testing. Animal studies often exist in the absence of epidemiological data or may exist with it. In either case, the interpretation of animal data is complicated by the fact that different species process chemical and material exposures differently in terms of their absorption, distribution, metabolism, and elimination. Second, animal studies often involve the administration of high doses to elicit an effect. Once this is established, it becomes challenging to establish an exposure (dose) where no effect is present. This is often a contentious and complicated process with considerable uncertainty involved in the extrapolation of animal toxicity testing results to human beings (Green et al., 2011).

Causal inference in epidemiology relies on hypothesis testing in order for appropriate conclusions to be made between the relationship of an exposure and a disease. Because of a general lack of specific details concerning occupational/environmental epidemiological hypotheses and the subsequent difficulty in performing hypothesis testing, often the "null hypothesis" approach is used in the scientific process. The null hypothesis is used to focus on a negative association between an exposure and a disease (i.e., the exposure is not related to the disease). If an association is observed, the null hypothesis is rejected (subject to control for bias and chance) and an alternative hypothesis is considered (i.e., the exposure is related to the disease) (Rothman and Greenland, 1998). The use of the null hypothesis approach implies that studies are designed and performed where hypothesis testing is possible. In occupational epidemiology, the two designs where this is most feasible are the cohort and case-control designs (Rothman and Greenland, 1998; Elwood, 2007).

As a general rule, a causative relationship is more likely to be present if the statistical relationship is strong and if the relationship occurs in multiple hypothesis testing studies that include multiple populations where sample selection, sample size, bias, and confounding have been adequately assessed. Regardless of the approach to establishing *causation*, the practitioner must answer a series of questions satisfactorily to determine whether an *association* is present. These include the following:

1. Has the patient been exposed to the chemical?
2. Has the exposure resulted in a dose?

3. Is the dose sufficient to cause an effect?
4. Is the effect consistent with the chemical's known effects?
5. Is there objective medical evidence demonstrating a disease or illness?
6. Is the onset of the disease temporally related to the exposure?
7. Is the effect biologically plausible?
8. Have all other confounding or contributing factors been considered or eliminated?

It is apparent from these questions that the practitioner must be knowledgeable about human toxicology in combination with clinical medicine and existing epidemiological studies. The strongest and most appropriate evidence for establishing the cause of human illness comes from human epidemiological studies. In the absence of reliable human data, results from animal studies may be needed with the above caveats.

Epidemiology and Statistical Considerations

In addition to the consideration of association and possibly causation, diseases from chemicals can also be assessed based on the existing epidemiology and statistical relationships in the medical literature. Epidemiology is the study of the distribution and determinants of health-related conditions and events in specified populations along with the application of this information to the control of health problems. It uses a variety of approaches to understand diseases. Some of these approaches are common in the study of occupational groups. Occupational study types and basic statistical terminology are briefly reviewed.

There are two general measures commonly used in epidemiological investigations, incidence and prevalence. Incidence rate refers to the number of people within a specified population who become ill during a period of time (usually 1 year). This number effectively defines the "risk" of that disease within the specified population. Incidence is contrasted with prevalence or the percentage of individuals with disease in a population at a specified point in time. Prevalence is not a good estimate of risk.

There are several types of scientific investigations seen in the medical literature that involve worker populations. The most common types include cohort mortality, case-control, and cross-sectional studies. Case reports also occur in the literature. These typically involve the combination of a unique exposure and a unique disease in a person. Though they may be important in the recognition of a new disease or the exposure-disease relationship, by themselves they are unable to formally test a scientific hypothesis. The case report may occur as a series of individual reports, also known as the case series.

In the cohort mortality study, the investigator determines mortality rates within an exposed population and compares this number with the adjusted mortality rate in a non-exposed population, usually adjusted for age and gender. The ratio of the exposure-specific mortality rate in the exposed population to the standard population (usually adjusted by age, race, and gender) is referred to as the standardized mortality ratio (SMR). If the ratio is greater than 100 (also stated as 1.0), the implication is that there are more deaths in the exposed population than expected. If it is less than 100, the implication is that the death rate is less than expected. If it is equal to 100, it implies that there is no difference between the mortality rates in the exposed and the comparison populations. Cohort studies may be very helpful as they can account for the complete enumeration of all individuals within the group (cohort) along with the length of time they were exposed.

Generally, the larger the number of study participants, the better the statistical capability of determining whether there is a relationship between exposure and disease, if one truly exists. This is referred to as study "power." Power is the ability of a study to detect a true significant association between exposure and outcome. Epidemiologists can be more confident that an association does or does not exist between an exposure and an outcome when the findings are based on large studies rather than small ones.

Another type of common epidemiological investigation within occupational settings is the "case-control" study. In this type of investigation, cases include people who have the disease of interest and the other group (controls) does not have the disease but is ideally similar in all other respects. Data regarding past exposures in both groups are obtained and compared. Exposure status is unknown at the time of defining cases and controls. In this study type, the measure of risk is referred to as an "odds ratio" (OR). The OR is the comparison of odds for cases having been exposed versus the odds of controls having been exposed.

Both SMRs and ORs provide an estimate of relative risk or the risk of disease in an exposed group relative to the risk in an unexposed group. The strongest association between exposure and disease occurs when incremental exposures result in incremental disease (exposure-response). Relative risks must be interpreted within the context of bias, sample size, sample selection, and study design, as these factors may artificially increase or decrease the estimation of risk.

Cross-sectional studies evaluate the presence of diseases and exposures at one point in time. They are usually not useful in the determination of causative relationships, since it is not possible to determine which of these came first, the exposure or the disease.

If risk estimates (SMRs or ORs) are increased (>1.0), the epidemiologist (or the diagnostician) must determine if these represent true or false positive findings. Several things may affect study findings. First, due to the effect of probability on

risk estimates, it is possible that findings may be due to chance alone and not to an exposure or factor of interest. One way epidemiologists express this chance is by the *p*-value. The significance level is usually set to 0.05. If a statistical test has a *p*-value less than this, it is considered statistically significant, by convention.

Another way to consider the likelihood of a positive finding (positive risk estimate) is to determine confidence intervals around the estimate. Confidence intervals are a reflection of a study's size and express the range of possibilities for the risk estimate. Typically, confidence intervals are expressed at the 95th percentile, which provides a range in which the "true" relative risk will occur, upon repeated testing, 95% of the time. When the study's sample size is large enough, the confidence interval will be expressed as a narrower interval. This provides assurance to the epidemiologist that findings are statistically more stable. A wide interval suggests uncertainty in the estimate of relative risk. When the interval excludes 1.0, the findings are considered "statistically significant." When the interval includes 1.0, the findings are not statistically significant and may have occurred as a chance finding more than 5% of the time (Green et al., 2011).

Since SMRs and ORs (risk estimates) are calculated without taking bias into consideration, these issues must be assessed before interpretation of results. Bias refers to anything that results in nonrandom error in the design, conduct, or analysis of an investigation. There are dozens of different types of bias. Three common types are selection (how people were selected for participation), information (access to information may differ for different groups under study), and classification (groups in the study may be classified differently with an impact on relative risk). Another important term that can impact the interpretation of epidemiological findings (risk estimates) is confounding. Confounding refers to a factor that is related to both the exposure and the disease of interest, but is unaffected by the exposure. An example is that alcohol has been determined to be related to lung cancer risk. However, since people who drink are more likely to smoke, it is really the smoking that is the true risk for lung cancer. In other words, smoking confounds the relationship between alcohol and lung cancer.

The use of *p*-values and confidence intervals, along with the consideration of the study's size, sample selection, and an assessment of the potential for bias and confounding, are all critical considerations in the determination of whether study findings are likely to be true or false (Green et al., 2011).

REGULATORY INFORMATION

Direct extrapolation of animal data to identify human hazards is common and is done to develop voluntary and enforceable

occupational exposure levels. It is a common practice for the incorporation of uncertainty/variability factors when human data are not available for developing these levels. Thus, occupational exposure levels are not bright lines for identifying safe versus harmful levels of exposure, but rather they are levels of exposure that are intended to protect against adverse health effects.

Although it is a current regulatory practice to assume that a chemical that is carcinogenic in one or more animal studies may also be carcinogenic in humans, *this is not equivalent to saying that the chemical is in fact a human carcinogen*. The determination of whether a chemical is actually a human carcinogen is made quite differently from the regulatory procedure of assuming that humans will mimic animal responses. Therefore, although animal data are useful as a surrogate for assessing human health hazards, it is scientifically inappropriate to reach definite conclusions about the cause of human disease solely on the basis of animal studies.

In the absence of adequate human data, both qualitative and quantitative assumptions must be made to estimate human risk from animal studies. Although such assumptions are implicit in any animal-to-human extrapolation, the scientific community is well aware of contradictions for some of these assumptions. This may sound as if the process is somewhat contrary to the intended purpose (i.e., a reasonably accurate assessment of the human risk). These assumptions are, however, still accepted in most cases because, as a matter of public policy, this process protects public health. Some of these public policy assumptions are as follows:

1. When human data are not adequate, adverse effects in experimental animals are regarded as indicative of adverse effects in humans.
2. Results obtained with dose-response models can be extrapolated outside the range of experimental observation to yield estimated upper bounds on low-dose risk.
3. When an appropriate standardized dosage scale is used, observed experimental results can be extrapolated across species.
4. There may be no threshold for some carcinogens, whereas there may be one for others, depending on their mode(s) or mechanism(s) of action, and threshold effects usually apply for other toxicities.
5. When dose rates are not constant, average doses give a reasonable measure of exposure.
6. In the absence of toxicokinetic data, the effective or target tissue dose is assumed to be proportional to the administered dose.
7. Risks from many exposures and from many sources of exposure to the same chemical usually are assumed to be additive.

8. In the absence of evidence to the contrary and regardless of the route of exposure, standardized absorption efficiencies are assumed across species.
9. Results associated with a specific route of exposure are potentially relevant for other routes of exposure.

Many of these assumptions are controversial when applied to evaluation of a specific health risk. Moreover, it is important to consider that the degree of uncertainty for the final risk estimate increases in a multiplicative fashion with the uncertainty of each assumption adopted. Thus, the number of assumptions made in the final risk estimate may lead to an uncertainty so great that the final estimation of risk no longer reflects reality. The consensus of the scientific and regulatory communities is that risk estimates based on animal data represent *worst-case presumptions* rather than *best estimates* of the potential risk. The real risk of cancer is not known and, in many instances, may be zero (US EPA, 1986). For this reason, risk estimates based on animal data are suitable only for regulatory purposes, for setting an upper boundary on the potential risk posed by a chemical, or for ranking the relative risks posed by a number of animal carcinogens (OTA, 1981). The *actual* human risk associated with a particular level of exposure cannot be established with any degree of medical or scientific certainty, without a complete evaluation of the available database, including information on mode(s) of action and human relevance (OTA, 1981; US EPA, 1986). The risk estimates are, however, useful for setting upper limits of exposure that will not result in adverse health effects.

OCCUPATIONAL EXPOSURE LIMITS

Permissible exposure limit (PEL), recommended exposure limit (REL), and threshold limit value (TLV) are occupational exposure limits developed by OSHA, the U.S. National Institute for Occupational Safety and Health (NIOSH), or the American Conference of Governmental Industrial Hygienists (ACGIH), respectively. These values express the concept that there is a level below which no exposed worker will become ill. Such levels usually refer to exposures during a 40 h workweek over a working lifetime, except in a few instances when exposure restrictions are specified. An extreme position against these limits is taken by some who believe that no amount of evidence can assure that any exposure will be harmless for all workers. This position is not biologically or medically plausible.

PELs, RELs, and TLVs have been published for a large number of chemicals. PELs are the legally enforceable standards, which have been revised in some cases to adopt NIOSH RELs. Individual states also publish such lists of occupational exposure limits, which often defer to OSHA.

In the absence of formally developed values by OSHA, NIOSH, or ACGIH, manufacturers will often develop their own recommended occupational exposure limits.

The evidence that forms the basis for the PELs and TLVs, the safe-dose levels, currently in use is derived from occupational experience and animal testing. The development of a PEL for benzene (C_6H_6) has such a history. Benzene is a widely used solvent and was important in the manufacture of explosives during World War I. Unprotected workers exposed to as much as 1000 parts per million (ppm) or more died of the chemical's narcotic effect. At lower levels of exposure, benzene's unique action on the hematopoietic system caused fatal aplastic anemia. A number of workers who were exposed to benzene escaped these outcomes but at a later date developed acute myelogenous leukemia. As information on this experience with benzene toxicity was collected and publicized, the worker protective level was reduced to 25 ppm; it is now set at 1 ppm.

The experience with benzene illustrates an important point in understanding and characterizing specific chemical hazards. Toluene and xylene, which are structurally related to benzene, do not elicit the same toxic responses except for narcosis at high levels. In general, a toxic effect likely to be produced by an unknown chemical cannot always be predicted from its chemical likeness to a compound of known toxicity.

Though accidental or unanticipated human exposures provide information on toxicity, a systematic study of toxicity may require studies with animals. Whether a material is nearly inert or potentially harmful may be assessed by experimental animal studies. However, the difficulties involved in studying low-level, long-term effects and the variation in response from species to species create additional obstacles to extrapolating from animal exposure to humans.

Some of these problems are illustrated by the animal studies done to assess beryllium toxicity. Despite experience with chronic illness in 800 beryllium workers, some authorities believe that failure to reproduce the disease in animals ruled out beryllium as a cause. Rabbits exposed to beryllium compounds develop osteogenic sarcomas, whereas rats develop pulmonary tumors—a difference that illustrates the difficulty of predicting a response from one species to another.

CONTROLS OF OCCUPATIONAL DISEASES

DANIEL A. NEWFANG, GIFFE T. JOHNSON, AND RAYMOND D. HARBISON

BACKGROUND, SCOPE, AND PURPOSE

As presented in Chapter 1, from the early recognition of lead poisonings by Hippocrates (460–370 B.C.) through the Age of Enlightenment (Ramazzini being noted as the “Father of Industrial Hygiene”), the contributions of physicians such as Thackrah, McCready, Hamilton, and Hardy to name a few as well as the many unnamed modern, global contributors have been recognized and used to shift to a more holistic and a proactive approach to risk management and addressing occupational and environmental health issues. Specific methodologies, models, and global trends as well as a greater ability to transfer knowledge using technology, these all contribute to new approaches for the strengthening of assessing and controlling occupational risk. Note that there still are limitations on the time-tested classic approaches (i.e., anticipate, recognize, evaluate, and control) as well as evolving new principles (e.g., hazard assessments, risk assessments, control and exposure banding, generalized harmonization of risk assessment tools, etc.), which still demand the requirement for sound professional judgment. As a final thought, *it needs to be stated* with the start of the twenty-first century well behind us now, risk assessment/exposure strategies are indeed integral parts of almost every traditional and nontraditional profession, craft, trade, or industry in highly developed industrial countries. Who would have ever thought that there would be exposure guidelines for deployed military, humans living and working in low earth orbit as well as beyond our planet? But there are still very traditional occupational health and safety hazards in developing countries with economies in transition. These concerns for human health will most likely increase due to regulatory infancy, the lack of governmental infrastructure, or by the sheer volume

of chemicals being introduced into commerce with minimal test data. The need for partnerships between the regulators, manufacturing/production leadership, industrial hygienist, safety professional and toxicologist, and occupational medical team is critical in the management to prevent or reduce the onset of occupational risk, diseases, and disorders.

REGULATING BODIES AND PROFESSIONAL ORGANIZATIONS

There are many regulating bodies and mature authoritative advisory organizations throughout the industrialized world sharing information on health and safety programs and management. Additionally there are too many specific states and countries to form a comprehensive list (such as the MAK limits from Germany, WELs from the UK, etc.). Therefore, some of the more prominent entities are listed below. Be sure to check with your local government to identify under whose control and what standards need to be followed.

US EPA: While one may think of the United States Environmental Protection Agency (EPA) as directing environmental regulations, it also establishes health-based risk criteria standards and guidance for the *general public (including sensitive subgroups) during a lifetime of exposure* such as screening levels (SLs), EPA’s Integrated Risk Information System (IRIS), National Ambient Air Quality Standards (NAAQS), and Safe Drinking Water Act. The Acute Exposure Guideline Levels (AEGL) exposure index is also developed and published by the EPA.

http://www.epa.gov/reg3hwmd/risk/human/rb-concentration_table/faq.htm

<http://www.epa.gov/iris/index.html>
<http://www.epa.gov/air/criteria.html>
<http://water.epa.gov/drink/contaminants/index.cfm#List>

US ATSDR: The United States Agency for Toxic Substances and Disease Registry (US ATSDR) is a federal public health agency of the U.S. Department of Health and Human Services that serves the public by using the best science, taking responsive public health actions, and providing trusted health information to prevent harmful exposures and diseases related to toxic substances. The agency publishes an Internet web portal that provides comprehensive access to the best science, the latest research, and important information about how toxic substances can affect health (e.g., minimal risk levels, MRLs; ToxGuide, etc.).

<http://www.atsdr.cdc.gov>

US OSHA: Under the US Occupational Safety and Health Act of 1970 (a.k.a. The OSH Act), employers are responsible for providing a safe and healthful workplace. The United States Occupational Safety and Health Administration's (OSHA) mission is to assure *safe and healthful workplaces* by setting and enforcing standards, and by providing training, outreach, education, and assistance. Employers must comply with all applicable OSHA standards. Employers must also comply with the General Duty Clause of the OSH Act, which requires employers to keep their workplace free of serious recognized hazards. The OSHA publishes permissible exposure limits (PELs) that are legally enforceable workplace exposure limits.

<https://www.osha.gov/index.html>

US NRC: Although radiation is naturally present in our environment, it can have either beneficial or harmful effects, depending on its use and control. For that reason, the US Congress charged the United States Nuclear Regulatory Commission (US NRC) with protecting people and the environment from unnecessary exposure to radiation as a result of civilian uses of nuclear materials. Toward that end, the US NRC requires nuclear power plants; research reactors; and other medical, industrial, and academic licensees to use and store radioactive materials in a way that eliminates unnecessary exposure and *protects radiation workers and the public*.

<http://www.nrc.gov/about-nrc/radiation.html>

US CDC: From the food you eat, to the air you breathe, to staying safe wherever you are, the United States Centers for Disease Control and Prevention (US CDC) mission touches all aspects of *daily life*. The US CDC researchers,

scientists, doctors, nurses, economists, communicators, educators, technologists, epidemiologists, and many other professionals all contribute their expertise to *improving public health*.

<http://www.cdc.gov>

EU: The European Union (EU) offers a wide variety of community measures in the field of *safety and health at work* based on Article 153 of the Treaty on the Functioning of the EU (ex: Article 137 TEC). European directives are legally binding and have to be transposed into national laws by the member states. There are numerous directives, guidelines, and standards as well as other practical documents on safety and health from member states or European institutions (e.g., occupational exposure limits (OELs); acceptable operator exposure limits (AOELs); derived no effects levels (DNELs), etc.).

<http://osha.europa.eu/>

ILO: The International Labour Organization (ILO) is a unique structure of the United Nations that globally gives an equal voice to workers, employers, and governments to ensure that the views of the social partners are closely reflected in labor standards and in shaping policies and programs in the area of *safety and health at work*.

<http://www.ilo.org/>

<http://www.hc-sc.gc.ca/ahc-asc/legislation/index-eng.php>

Military, Space, etc.: Most US federal installations will reference either the American Conference of Governmental Industrial Hygienists (ACGIH) guidance or US OSHA regulation, whichever is more stringent. At times, the agency might have a lower exposure limit published within its organization. As of this publishing date, some examples are as follows:

Department of the Army EM 385-1-1 (Sept 2008):

<http://www.usace.army.mil/safetyandoccupationalhealth.aspx>

The US Army Center for Health Promotion and Preventative Medicine, Chemical Exposure Guidelines for Deployed Military Personnel (USACHPPM Technical Guide 230, 2013 Revision):

<http://phc.amedd.army.mil/Pages/Library.aspx?Series=PHC+Technical+Guide>

NASA-STD-3001, NASA Space Flight Human System Standard, Volume 1:

<http://www.nasa.gov/centers/johnson/slsd/about/divisions/hefd/standards/>

Department of Defense, Human Engineering Design Data Digest (April 2000):
[http://www.dtic.mil/cgi-bin/GetTRDoc?
 AD=ADA467401](http://www.dtic.mil/cgi-bin/GetTRDoc?AD=ADA467401)

US NIOSH: The United States National Institute for Occupational Safety and Health (US NIOSH) is the U.S. federal agency that conducts research and makes recommendations (e.g., recommended exposure limits (RELs)) to prevent worker injury and illness. The NIOSH is part of the US CDC in the U.S. Department of Health and Human Services.

<http://www.cdc.gov/niosh/>

ACGIH®: The ACGIH® is a member-based organization that advances occupational and environmental health. Examples of this include annual editions of the threshold limit values (TLV®) and biological exposure indices (BEIs®) work practice guides.

<https://www.acgih.org>

AIHA: The American Industrial Hygiene Association (AIHA) was founded in 1939; AIHA is a nonprofit organization devoted to achieving and maintaining the highest professional standards for its members. More than half of 10,000 members are certified industrial hygienists (CIHs), and many hold other professional designations. A professional designation of CIH identifies an individual as having met the professional challenge of illustrating competency through education, experience, and examination. The AIHA administers comprehensive education programs that keep occupational and environmental health and safety (OEHS) professionals current in the field of industrial hygiene. The AIHA is one of the largest international associations serving OEHS professionals practicing industrial hygiene and is a resource for those in large corporations, small businesses, and who work independently as consultants. The mission is to create knowledge to protect worker health keeping a vision of eliminating workplace illnesses. Exposure indices such as Workplace Environmental Exposure Levels (WEELs) and Emergency Response Planning Guidelines (EPRGs) are developed and published by the AIHA.

[https://www.aiha.org/](https://www.aiha.org)

ASSE: Founded in 1911, the American Society of Safety Engineers (ASSE) is the world's oldest professional safety society. The ASSE promotes the expertise, leadership, and commitment of its members while providing them with professional development, advocacy, and standards development. It also sets the occupational safety, health, and environmental community's standards for excellence and

ethics. A professional designation of certified safety professional (CSP) identifies an individual as having met the professional challenge of illustrating competency through education, experience, and examination.

<http://www.asse.org/>

ROLE OF OCCUPATIONAL HEALTH PROFESSIONALS

Technological gains have been impressive over the past number of decades, which translate into productivity improvements. With these gains, the sustainability of the world's resources is critical in order to maintain health and wellness for our most valuable resource, the human capital. The roles of the different occupational health professionals in proactively controlling exposures and diseases in the workplace are described below and should be used as best as one can. Obvious to the working health professionals, the need for a safe and healthy work environment requires the control of physical, chemical, biological, psychosocial, illnesses, injury, etc. Not so obvious though are the needs to establish organizational/management systems to assertively and proactively address early recognition and response to work-related health/safety risks critical to preserving the human element and building a sustainable workforce. Hence, a multidisciplinary occupational health and safety team approach is needed.

The goal of a multidisciplinary occupational health and safety team is to design, implement, and evaluate a comprehensive health and safety program, which will maintain and enhance health, improve safety, and increase productivity. Such programs often provide similar results for the families of workers, with resultant financial and other benefits for the corporation. Occupational health and safety professionals include occupational and environmental health nurses, occupational medicine physicians, industrial hygienists, safety professionals, and occupational health psychologists. Other related members of the multidisciplinary team are ergonomists, toxicologists, epidemiologists, human resource specialists, and organizational psychologists (in an attempt to name a few).

Occupational medicine professionals (i.e., physicians, physician assistants, registered nurses including nurse practitioners) include health care professionals qualified to design, manage, supervise, and deliver health care in occupational settings. These professionals have usually completed an additional occupational medical training or acquired an on-site experience. Completion of additional training (residency or otherwise) and further practice in occupational medicine enable them to pursue certification in occupational medicine after meeting rigorous qualifying standards and successfully completing an examination in

occupational medicine. Many times, these team members will be charged with developing and *managing* the safety and health programs.

Occupational technical team (professional level) includes industrial hygienists, safety engineers, professional engineers in the traditional disciplines such as civil, electrical, environmental, chemical, mechanical, etc. Toxicologists, health physicists, ergonomists, health educators, dieticians, dentists, physiologists, psychologists, and professionals from other disciplines are involved directly or indirectly with the prevention of occupational disease. These are key team members who may be employed full time or on call, as and when needed. On the professional level, these team members should have completed a minimum of a bachelor's degree from an accredited university. Advanced degrees; master and doctorate and professional credentials (CIH, CHMM, CSP, PE, DABT, BOHS-COC, etc.) are desirable because these certifications show an accomplished level of education, measurable amount of knowledge, and experience.

Occupational technical team (technical level) includes technicians, production, and many other personnel that are full or part time dedicated to *delivering* the elements of the health and safety programs to the operating or manufacturing environment. Typically these roles are staffed with team members that haven't completed formal university training (i.e., bachelor's or advanced degrees), but their importance on the occupational health team is critical to any type of success. These technicians are the heroes of the team and often overlooked. Their role places them directly where the work is being performed and they're typically well received through their relationships with their coworkers performing the work. The knowledge, experience, and execution capabilities these technicians offer to the health and safety program are invaluable.

Research, engineering, and design team includes team members who participate in researching, designing, developing, engineering, and constructing the manufacturing/production equipment and environment. It is critical that these team members are aware of the potential hazards and risks their processes can produce so that they can eliminate or mitigate them through design. A gold standard approach would be to have an occupational health team member be an active contributing member of the research, engineering, and design team who will enable education opportunities to the other members of the team as well as contribute to focused health and safety input into any designs.

Production leadership team is composed of team members who manage and supervise the production/manufacturing environment. It is *only* by acceptance and approval from these team members that any health or safety control is implemented into the production or manufacturing environment. As with the research, engineering, and design team, a gold standard approach would be to have an occupational health team member as an active contributing member of the production leadership team who will enable education

opportunities as well as contribute to focused health and safety input into any production decisions.

CONTEMPORARY STRATEGIES FOR CONTROLLING EXPOSURES AND DISEASES

Over the past number of centuries, strategies for occupational disease control, managing workplace illnesses and injuries have changed. Historically, the concept of asking the injured person what their occupation was to help identify the "cause of their illness" has now developed into the AIHA's anticipate, recognize, evaluate, and control strategy, which is continuing to mature into newer principles for occupational risk assessments. While some of the more seasoned concepts and principles such as reducing the risk of occupational injury and illness by designing the risk out (e.g., US NIOSHs Prevention through Design, (PtD)) will always be relevant, newer holistic and comprehensive methods are being developed. Some of the more generally accepted strategies are described below.

Current approaches: The AIHA, US OSHA, US EPA, Canadian Centre for Occupational Health and Safety, UK Health and Safety Executive (HSE) as well as other well-established entities discuss many successful strategies for managing occupational exposures via the science of anticipating, recognizing, evaluating, and controlling the workplace conditions. Some of the more germane concepts are as follows:

Regulatory OELs are established by government statute (e.g., US OSHA PELs) and have been established for a limited number of chemicals in commerce. These exposure limits *do consider technical and economic feasibility* thereby have inherent limitations. Many health professionals state the OEL development and setting process/infrastructure is labored, which results in out-of-date standards.

Authoritative OELs (*also referred to as OELs*) are established by research or consensus organizations based on health criteria (e.g., US NIOSH RELs, ACGIH TLVs®, AIHA WEELs®, US EPA Reference Dose (RfD), etc.) and *do not consider economic or technical feasibility*. The developing entity uses professional judgment, elimination mechanisms, and the significance of adverse health outcomes. Additionally, typically the exposure limit is derived based on no-effect-levels or a set ratio of other toxic end points.

Internal OELs are set by private organizations as per their internal policies, guidelines, corporate risk tolerance, and data.

Working OELs are set by the industrial hygienist based upon their professional judgment, knowledge, personal risk tolerance, and experience.

Control banding (CB) is a methodology that germinated in 1988 by the US NIOSH, AIHA, ACGIH, ILO, International Occupational Hygiene Association (IOHA), and

World Health Organization (WHO) describing a system that matches a control measure (e.g., ventilation, engineering controls, containment, etc.) to a range or “hazard band” of hazards and exposures (e.g., skin/eye irritation, very toxic, carcinogenic, etc.). The CB system groups chemicals according to similar physical or chemical characteristics, how the chemical will be handled or processed, and what the anticipated exposure is expected to be. This system then determines a set of useful controls that will prevent harm to workers. The methodology uses performance-based criteria for chemicals that do not have established exposure limits but similar hazards to already studied or known chemicals, the idea being to follow the existing control strategy that the “studied or known” chemical is using.

Occupational exposure bands (OEBs) is the application of both hazard banding and CB methods in the assessment and management of workplace risks.

Similar exposure groups (SEGs) NOTE: This approach was previously referred to as homogeneous exposure groups (HEGs). Similar exposure groups is a risk assessment strategy sponsored by the AIHA that focuses on the concept of similarly exposed workers. It is a method for considering the exposure of a limited number of workers in a group to be representative of everybody in the group. This allows for limited resources to be better used in characterizing the many exposures that are present in the workplace. The approach is intended to identify workers having the same general exposures/exposure profile due to their similarity and frequency of work tasks, same use of materials and processes. Benefits from using the SEG methodology are: with limited resources, it will quickly identify what hazard(s) need to be prioritized and urgently addressed in a complex facility where many hazards exist; and help identify what “control banding” principles for selecting a control technology can be put into place to eliminate or mitigate the exposures. Finally, it is acceptable to provide professional judgment and estimate exposure level, severity of health effects, and the uncertainty associated with the available information.

Comprehensive exposure assessments methods involves a continual process of collecting as much health and safety information as you can, prioritizing controls, and gathering follow-up information to manage the hazards and risks in the workplace.

Qualitative exposure assessment methods can be used when exposure-monitoring data are *not* available or not required, modeling techniques have become accepted. A qualitative exposure assessment may be initially used to assess exposures from an upcoming task. A critical component though is to have the assessment performed by an industrial hygienist who is familiar with the operation or process being evaluated.

Hierarchy of controls is a widely accepted system used to eliminate or minimize workplace exposures. The concept has been a core foundation for decades in many health and

safety organizations and is also drafted into many standards throughout the industrialized world such as ISO 12100-1, ISO 14121/EN 1050, ANSI/ASSE Z244.1, ANSI B11.TR3, ANSI/RIA R15.06, SEMI S2-0200, MIL-STD-882D, ANSI/AIHA Z10, ANSI/PMMI B155.1 . . . just to cite a few. The concept presents hazard controls in the event that the hazard cannot be eliminated altogether. Some methods are more effective than others and typically the solution is to use a combination of one or more of the five approaches. The controls are presented in the order of decreasing effectiveness:

Elimination (eliminating the hazard and removing it is the most effective method of control)

Substitution (the second most effective method, replace the hazard with something that is less hazardous to the workers)

Engineering controls a.k.a. safeguarding technology (the third most effective method is to design a control strategy to protect the worker from the hazard such as ventilation, noise dampening, mechanical lifts, or machine guards)

Administrative controls a.k.a. training and procedures (the fourth most effective method is to change the way the work is performed through policy changes, training, warning alarms, signage, etc.)

Personal protective equipment (PPE) (the fifth and the least desirable method of control is by placing protective equipment directly on the workers’ bodies. This is referred to as *the least desirable* because the management of the safety device is solely up to the worker performing the work. There is a high potential for the PPE to not be worn correctly or at all. Examples are hard hats, goggles, earplugs, and protective clothing.)

Prevention through Design is a concept being presented by the US NIOSH that focuses on reducing the risk of occupational injury and illness by integrating decisions affecting safety and health in all stages of the design process. To further elaborate, the concept of PtD can be defined as: Addressing occupational safety and health needs in the design process to prevent or minimize the work-related hazards and risks associated with the construction, manufacture, use, maintenance, and disposal of facilities, materials, and equipment. *This is why it is critical* to have a safety and health team member involved on the research, engineering, and design team as discussed earlier in this chapter in the “Role of Occupational Health Professionals” section.

With the changing global regulatory environment, there is an ever-increasing expectation for proactive risk management, use of more control/hazard banding when OELs are lacking *plus* the fact that only a small number of chemicals are either regulated by a government statute or have a traditional OEL. We must recognize that OELs *are just one* of the components of a larger body of occupational benchmarks and guidance values, which help in the risk assessment process. The future challenges are when a

regulatory OEL or authoritative guidance value does not exist or cannot be derived easily, what alternative risk assessment method should be used? New risk management tools are designed around the globalization of risk issues and enhanced abilities for information transfer. There is no doubt that greater expectations for occupational risk assessments will need to be addressed in a systemic manner for a growing list of chemicals being used in the workplace. The future will see developments such as the hierarchy of OELs model, further harmonization of OELs and DNELs at the European Level, US OSHA providing annotated references as a supplement to their health-based PELs, US NIOSH refining and harmonizing their hazard banding techniques, and AIHA and US NIOSH working jointly with OEL experts to categorize OEBs based on the Globally Harmonized System for Classification and Labeling of Chemicals (GHS) within the REACH regulation.

CONCLUSIONS

Updating OELs is a continuing process based on new discoveries and advances in science.

We know:

That the dose makes the poison (Paracelsus)

A hazard is defined as the potential to cause harm posed by some material or situation.

Risk is the probability, or chance, that it actually will harm someone.

And there are still occupational illnesses, injuries, and fatalities happening on a daily basis.

Continued vigilance, learning through scientific advancement, passion, and humility are needed by all involved in the protection of the worker whether terrestrial bound or working in outer space. The health and safety team member's dedication to humanity is admired and appreciated. The future for occupational safety and health risk management is ever changing and will prove to be as challenging as its history has shown it to be.

SECTION II

METALS AND METALLOIDS

SECTION EDITOR: RICHARD V. LEE

3

INTRODUCTION

RICHARD V. LEE

One of the defining events in the cultural and biological evolution of our species, *Homo sapiens sapiens*, was the refining and use of metals and metalloids. These elements have shaped human history by their malleability, desirability, and toxicity, properties determined by their physical chemical properties and the fashions and passions of their human artisans. Ancient gold jewelry, blue and green copper salts for eye makeup in Egypt, lead-based wine additives and wig powders in the seventeenth and eighteenth centuries, and iron alloys in contemporary steel superstructure construction constitute only a small segment of the history of metallic progress. Although 80 of the 105 elements listed in the periodic table have been labeled as metals, fewer than 30 are documented human toxins.

The oldest toxins recognized by our species were probably derived from foods, from the plants, and flesh our forebears ate. The toxicity of metals was recognized after the working of metals became more than an occasional event. Metals were the first industrial toxins. Gold, copper, lead, silver, tin, and arsenic were the earliest metals systematically extracted and worked into ornaments, tools, and weapons (Table 3.1).

Copper workings have been found in the Middle East dating from 3000 to 4000 b.c. By 2000 b.c., bronze, an alloy of copper and tin, became the dominant useful metal. By 1400 b.c., iron was smelted and worked simultaneously with copper and bronze, and rapidly supplanted them as the preferred material for tools and weapons. About the same time, brass, an alloy of copper and zinc, was created and became a popular material for coins, ornaments, and sculpture.

Early observers of medicine, natural history, and industry described the preparation of metals and metal objects and

some of the health consequences of such work. Hippocrates described abdominal colic in a metal worker in the fourth century b.c. Arsenic and mercury products were mentioned by Theophrastus of Erebis (370–287 b.c.) and Pliny the Elder (a.d. 23–79). In *De Medicinaria*, Celsus (25 b.c.–a.d. 30) described medicaments containing antimony, lead, mercury, iron, copper, zinc, arsenic, and aluminum.

Many of the metals that cause concern for health are of recent discovery and application (Angerer and Heinrich, 1988; Abrams and Murrer, 1993). Cadmium was identified in 1817. Many of the lanthanides were purified only in the twentieth century. In 1845, Robert Christison's *Treatise on Poisons* devoted 120 pages to arsenic, 73 pages to mercury, 65 pages to lead, 27 pages to copper, 15 pages to antimony, 6 pages to zinc, 4 pages to iron, 2 pages each to tin, bismuth, silver; and a collection of "rarer metals" (osmium, platinum, palladium, iridium, rhodium, molybdenum, manganese, uranium, cobalt, cadmium, nickel, tungsten, titanium, and cerium); and 1 page each to chromium and gold. Contemporary technology is finding novel uses for many metals and metalloids that were thought to be only curiosities. Information about their toxicities will be developed as their applications become more common (Underwood, 1977; Beijer and Jernelov, 1986; Friberg et al., 1986; Seiler and Sigel, 1986; Angerer and Heinrich, 1988; Abrams and Murrer, 1993; Elinder et al., 1994).

The characteristic properties of metals are a shiny crystalline surface and the ability to conduct heat and electricity better than nonmetals. Metals are distinctive because they have freely movable electrons, the so-called conduction electrons. The intrinsic toxicity of metals is determined by the properties of the atom. As a general rule, within the vertical groups of the periodic table, greater toxicity is

TABLE 3.1 Ancient Metallurgy

Period	Smelting and Refining	Alloying and Working
Before 4000 b.c.	Occasional use of native gold and copper and of meteoritic iron	Hammering to shape and to harden copper annealed without melting (about 4000 b.c.)
4000–3000 b.c.	Reduction of oxidized ores of copper and lead	Melting and casting of nearly pure copper, followed by creation of copper–arsenic and copper–tin alloys (made from ores)
	Creation of copper–arsenic alloys by smelting of natural mixed ores, followed by creation of bronzes from intentionally mixed copper and tin ores (ca. 3500 b.c.)	Creation of permanent molds of stone and metal
3000–2000 b.c.	Roasting and smelting of sulfide ores of copper	Invention of lost-wax process for complicated castings Use of native silver and gold Use of native gold–silver alloys Soldering with copper–gold and lead–tin alloys Most jewelry techniques developed before 2500 b.c. (e.g., inlay, stamping, <i>repoassé</i> , raising, soldering, riveting, granulation, surface coloring)
	Smelting of tin (perhaps earlier), which becomes important trade good Cupellation of lead to extract silver and of gold and silver for purification	Golf leaf
2000–1000 b.c.	Bellows used in furnaces by 1800 b.c.	Wire made by cutting sheet Experimental production of sponge iron Bronze made from metallic tin and copper (perhaps much earlier), high tin bronze (speculum metal) for mirrors, leaded bronzes for statuary
	Wrought iron becomes important by 1600 b.c. (directly reduced from ore as sponge iron and forged without melting)	Brass produced from copper and zinc oxide ores (not important before 2000 b.c.) Steel regularly made by carburization in hearth, perhaps hardened by quenching (1200 b.c.) Vast expansion in production of iron, common nonferrous metals, gold and silver
1000–0 b.c.	Cast iron (China only) Cast steel (India only) Gold purified by sulfide process Mercury distilled from ores Amalgamation of gold ores	Iron and steel welded into composite tools and weapons Stamping of coins (700 b.c.) Gilding of bronze and silver with gold amalgam Assay by cupellation, cementation, touchstone, and density

associated with increasing atomic weight or atomic number (Venugopal and Luckey, 1978). For example, heavy metals tend to form stable, irreversible complexes with biological macromolecules, thus altering their biological characteristics. Toxicity is proportional to the electropositivity and the solubility of metal cations in water or in lipids. The relatively nontoxic properties of the lighter metallic elements (sodium, magnesium, potassium, and calcium) must have determined their ubiquity and importance in the life of virtually all living creatures. The chemical form of the metal determines solubility, absorption, cellular uptake, and excretion (Underwood, 1977; Venugopal and Luckey, 1978; Beijer and

Jernelov, 1986; Friberg et al., 1986; Seiler and Sigel, 1986; Angerer and Heinrich, 1988; Abrams and Murrer, 1993; Elinder et al., 1994; Goyer, 1995). Soluble compounds are more readily absorbed by the mucosa and skin and usually are more rapidly excreted. Insoluble compounds may coat mucosal surfaces and become entrapped in mucus or phagocytosed by polymorphonuclear leukocytes and macrophages. Thus the dose of a metal depends on factors other than just the magnitude or site of the exposure.

The biological processing of metals—absorption, distribution, and excretion—is another determinant of toxicity. The toxic effects of metals are the result of the interactions

between free metal ions and a susceptible cellular target. Prolonged contact between target and metallic toxin enhances toxicity. The biological half-life therefore is a major factor in metal toxicity. Lead and cadmium have 20- to 30-year biological half-lives. Insoluble nickel compounds have a much longer half-life than soluble nickel salts, which dictates the differences in their biological effects. The concept of "dose" must be expanded beyond the size of the inoculum to include the duration of the substance in the host. The inoculum of a metal with a prolonged biological half-life may be substantially smaller than the inoculum of a biologically short-lived metal to produce the same toxic effects (Furst and Haro, 1969).

The metallic elements have a wide range of toxic potentials. Direct injury to cellular processes is a consistent effect that can result in necrosis, acute inflammation, and enhanced susceptibility to secondary infection or injury because of loss of the host's defense mechanisms. Indirect injury results from an alteration in molecular configuration, as in the creation of immunogenic haptens and the stimulation of cell-mediated immunity. For example, platinum, cobalt, and chromium can illicit type I anaphylactic/immediate hypersensitivity reactions; gold can illicit type II cytotoxic hypersensitivity; mercury and gold can illicit type III immune-complex hypersensitivity; and nickel, chromium, beryllium, zirconium, titanium, and aluminum can illicit type IV cell-mediated hypersensitivity. Carcinogenesis and mutagenesis are complex, multistep processes in which metal ions act as conspirators with other physical or chemical events (Table 3.2).

TABLE 3.2 Carcinogenic Potential of Some Common Metals^a

Metal	Evidence for Carcinogenesis	
	Humans	Animals
Arsenic	Sufficient	Limited
Beryllium	Sufficient	Sufficient

^aAs determined by the International Agency for Research on Cancer.

Considering their ubiquity in the natural and manmade environments, the truly remarkable feature of the metals and metalloids is how uncommon serious toxicity has become. One of the major success stories of occupational medicine has been the striking reduction in serious occupational metal intoxication in contemporary industry. However, serious environmental consequences from the metal working and industrial revolution of the past two millennia remain. The quantity of environmental lead in the Greenland ice cap has risen dramatically over the past two millennia in synchrony with the growth in the industrial use of lead and lead compounds (Ng and Patterson, 1981).

A major contemporary ecological problem is the existence of large residues of potentially toxic metallic waste at mining, refining, and manufacturing sites, many of which were in operation before enactment or enforcement of industrial hygiene and environmental codes. There is always the danger that old lessons are forgotten as new discoveries and novel applications dominate the interests of research and industry. Even with the explosion in technology and the use of toxicologically unfamiliar metals and metalloids, ancient metals such as lead, mercury, copper, and iron are still produced and used, and the health and environmental safety routines developed for them must continue to be applied. Moreover, the basic principles of industrial hygiene and environmental safety developed for old metals and metallurgy are applicable to the emerging industries using new techniques and novel applications for a variety of metallic elements and should be followed until guidelines for the safe handling of newer metals and processes are established.

ALKALI COMPOUNDS

STEVE MORRIS AND ANN LURATI

Target organ(s): Respiratory system, skin, eyes, mucous membranes

Occupational exposure limits: See individual compounds

Reference values: See individual compounds

Risk/safety phrases: Caustics, bases, explosives

BACKGROUND AND USES

Alkali compounds comprise a diverse group of corrosive chemicals with the common characteristic of a pH > 7.0. This group of chemicals comes in a variety ranging from gaseous (anhydrous ammonia) to solids (calcium lime). Alkalies include the hydroxides of sodium, potassium and ammonia; sodium carbonate; calcium and barium oxide; calcium chloride; the sulfides of sodium, calcium and arsenic; and alums. Their uses in the workplace are widespread and can easily reach exposure levels requiring interventions, from the production of explosives to the formation of reagents in clinical chemistry tests to the mixtures of common cleaners in the office workplace. Alkali exposures can also reach actionable levels at atypical occupational locales such as ammonia buildup in animal containment houses.

In general, most alkali usage causes mild to moderate skin and eye irritations. However, some of the more caustic alkalies can be considered significant threats to worker health and safety. Inhalation of concentrated anhydrous ammonia mists may be lethal. Alkalies produce injury to the soft tissue through a process called “liquefaction necrosis” that causes loosening of tissue and allows a deeper penetration of the chemical (Palao et al., 2009). Sodium hydroxide (lye) can cause blindness or death after ingestion or extensive skin and

eye contact. Lime (calcium oxide, calcium hydroxide, or similar mixtures with magnesium) can cause severe skin burns and eye injuries. Because of their potential toxicity and widespread use in industry, these three are discussed in further detail later in the section.

PHYSICAL AND CHEMICAL PROPERTIES

Alkalies manifest as all forms of matter, from gases to solids. Their definitive common trait is their elevated pH and their corrosivity, the degree of which is determined by their composition and concentration. They are also water soluble and commonly exist in solution. Alkalies can form salts and anhydrides, which maintain the same chemical properties of the original compound. Because of their reactivity, these compounds should be stored in glass or plastic containers rather than metal or rubber ones (Sullivan and Kreiger, 2001).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Few regulatory environmental assessments have been done on these compounds, most likely due to their ability to be neutralized to innocuous compounds over time. For example, while any discharge of lime risks immediate adverse effects to the stability of the environment, time does reduce its toxicity. Calcium oxide will rapidly convert to calcium hydroxide in the presence of moisture, which then reacts with carbon dioxide to reduce pH and precipitate to calcium carbonate. Thus, in time cement and concrete lose their

alkalinity and present little corrosivity risk to the surrounding environment. Of course, spills and other unplanned releases can have a devastating effect on the surrounding flora and fauna until the neutralization process is complete.

Ammonia has a distinct impact in environmental studies, but is difficult to assess by degree since it is also a natural by-product of bacterial decomposition. The alkalis can form salts that are common to environmental locales. Therefore, it is the quantity of these agents in the environment that is a factor.

CHEMICAL PATHOLOGY

Alkali injuries are both heat and chemical generated. Heat results from the exothermic chemical reactions. Typically, lipid emulsification and saponification and protein dissolutions result from the oxidation-reductions of available oxygen species (Sullivan and Kreiger, 2001).

MEDICAL MANAGEMENT

Alkalies generally cause more damage than acids when in contact with body tissues, especially when the compound's pH exceeds 11. Unlike most acids, alkali damage to body tissue is a twofold problem. The heat generated from the alkali hydration from body moisture causes heat damage, while the oxidation of the compound causes chemical damage to the surrounding molecules. Additionally, the mechanism of acid burns tends to result in the formation of eschars, which then serve somewhat of a protective function. Alkalies cause liquefactive necrosis, leaving softened tissues, so no protective layer is formed—leaving the tissue subject to both heat and chemical damage (Sullivan and Kreiger, 2001). This liquefaction of tissue also allows deeper penetration of the injurious substance, compounding the determination of the extent of injury and treatment thereof. In fact, alkali injuries can appear deceptively minor in the preliminary stages of contact (Riffat and Cheng, 2009; Maguina and Busse, 2011).

Alkali burn injury detection is further complicated by the varying nature of each compound and thus different ways of exposure can occur. Gaseous ammonia exposure can be through dermal absorption or through inhalation, while ammonium salts can be ingested. Eye exposures and inhalation are perhaps the most dangerous of all exposures due to the fragile systems involved, but this in no way diminishes the potential lethality of ingestion exposures.

In studies of children and ingestion of caustic substances, little correlation was found between the presence of oral lesions and the degree or even presence of esophageal injury (Riffat and Cheng, 2009; Arici et al., 2012). Thus medical

follow-up should be sought in any case of possible alkali exposure, especially ingestion, regardless of whether visible injury is present.

Ocular exposures have additional risks when the alkalis are in particulate form, as the embedded particle continues to cause continuing chemical damage to the sensitive cornea until the particle itself is removed. Excessive ocular exposure to alkali usually destroys the corneal epithelial and stromal cells, often severely damaging or killing the corneal endothelial cells. Repair and regeneration of these tissues are extremely slow or impossible. Alkali injury is often followed by degeneration and sloughing of the tissue, ending finally in perforation of the globe, endophthalmitis, and ultimately the loss of the eye (Records, 1979). The importance of ocular alkali burns thus lies not only in the large number of patients seeking care for eye injuries, but also in the total disability that often results and the difficult management problems created. Uniocular injuries generally result in prolonged time off from work, and with binocular injuries, the worker must usually leave the workforce (Pfister and Koski, 1982).

Alkali damage to the esophagus can result in strictures at best and perforation at worst. Although not held in total consensus, induction of vomiting in the case of alkali ingestion is generally discouraged to prevent further damage and potential rupture of the esophagus (Riffat and Cheng, 2009).

Alkalies have not yet been found to have a clear association as carcinogens or teratogens. Cancers have been found in higher incidence with some workers exposed to alkalies, but there is no definitive study that links it to the alkali itself and not to dysfunctions in damaged tissue repair. Some studies have suggested a link between potash mining and lung cancer. Some have speculated a link between the miners and diesel fumes, but Pahwa and McDuffie (2008) conducted a study of 1435 males and found a correlation of potash mining to a higher incidence of lung cancer without regard to diesel exposure. However, the authors noted that they neither measured radon, nor personal levels of potash or diesel exposure.

In the event of an exposure, proper medical management is imperative. Delay in treatment can have significant negative consequences later on. Maguina and Busse (2011) discuss the case study of a 30-year-old male who had recurrent ulcerations and necrotic tissue patches for 2 years after an industrial sodium hydroxide accident resulted in chemical burns to his forearms. The authors stated that immediate irrigation of an affected area until a tissue pH of 7–7.5 is called for; irrigation is of little use when offered after delays. Effective irrigation for exposure to strong alkalis may take several hours before a normal pH is resumed. Thus “adequate knowledge of first responder treatment of alkali burns is of the utmost importance to their initial treatment and final outcome” (Maguina and Busse, 2011).

AMMONIA

Occupational exposure limits:

OSHA: PEL: 50 ppm, 35 mg/m³ TWA (General Industry and Maritime)

ACGIH: TLV: 25 ppm, 17 mg/m³ TWA; 35 ppm, 24 mg/m³ STEL

NIOSH: REL: 25 ppm, 18 mg/m³ TWA; 35 ppm, 27 mg/m³ STEL; IDLH: 300 ppm

Reference values: IRIS: RfC = 1×10^{-1} mg/m³ (UF = 30)

BACKGROUND AND USES

Ammonia (CASRN 7664-41-7) is a common chemical of production, holding a third place in world production (Makarovskiy et al., 2008). The large-scale use of ammonia is facilitated by large-scale storage tanks containing millions of gallons of anhydrous ammonia with a network of piping for off-loading to train or truck. Industrial exposures come from its use in fertilizers, explosives, intermediary in chemical productions, metallurgy, paper/pulp manufacturing, and refrigeration (Makarovskiy et al., 2008).

PHYSICAL AND CHEMICAL PROPERTIES

At atmospheric pressure, ammonia is a colorless gas with a characteristic pungent odor, which is extremely irritating to the eyes and upper respiratory tract. It is approximately half as dense as air and thus rises readily. With pressurization, 13 cubic feet of ammonia vapor can be condensed into 1 cubic foot.

MAMMALIAN TOXICOLOGY

Acute Effects

The irritating effects of high concentrations of ammonia vapor usually prompt exposed individuals to leave the area before significant pulmonary injury occurs (Summer and Haponik, 1981). With an odor typically described as “pungent” and reminiscent of urine, gaseous ammonia is typically detectable by odor at levels as low as 5 parts per million (ppm). The strong odor was thought to be its own safety alarm for the worker; however, later studies ruled this safety factor out as olfactory fatigue occurs readily and thus odor is not a reliable warning system (Makarovskiy et al., 2008). Experimental studies show that short-term exposure to 50–100 ppm causes moderate eye, nose, and throat irritation in most people, but acclimation to these effects can occur after 1–2 weeks. Below 50 ppm no significant effects are

noted, even though the odor of ammonia may be detectable (Swotinsky and Chase, 1990).

Acute inhalation injuries have been seen as two distinct clinical presentations. The first, associated with very high exposure levels, is tracheobronchitis with massive swelling of the upper airways and possible laryngospasm (Montague and Macneil, 1980). This is thought to be a protective response to shield the lower airways. Of the patients who can be revived with endotracheal intubations (tracheostomy if necessary), many survive without any severe pulmonary sequelae (Close et al., 1980). People exposed to a lesser concentration of ammonia may remain conscious and continue to breathe in the mist for a longer period. These patients do not manifest acute respiratory distress; rather, they gradually develop obstructive symptoms or pulmonary edema.

Dermal, ocular, or mucous membrane exposure to ammonia often results in significant airway involvement. Superficial injury to the esophagus also has been reported with ingestion of ammonia. These patients typically respond to conservative therapy and do not have permanent injuries (Sugawa and Lucas, 1989).

Mixtures of household ammonia and bleach (sodium hypochlorite) form chloramines, which are released as an unstable, respirable gas. The gas produced is less soluble than ammonia and is not readily absorbed by the mucous membranes of the upper airways. As a result, it reaches the alveoli, where it hydrolyzes to ammonia and hypochlorous acid. Chloramines exert a direct toxic effect that is described as a toxic pneumonitis (Reisz and Gammon, 1986).

Chronic Effects

Although cases of acute exposure to high levels of ammonia are well documented, one study by Rahman, Bratweit, and Moen (2007) suggested that long-term exposure to ammonia may result in obstructive and restrictive respiratory disease. It is not considered carcinogenic or teratogenic (Makarovskiy et al., 2008). In one study a group of workers exposed to airborne ammonia at levels generally below 25 ppm and not above 50 ppm were compared with controls. No differences were found in symptoms, sense of smell, or lung function (Holness et al., 1989).

DIAGNOSIS AND TREATMENT

If the victim with an inhalation injury reports a pungent odor, the clinician should consider ammonia as a causative agent. Obtaining ammonia levels is of little value due to a poor correlation with the victim’s clinical presentation (Burgess, Pappas, and Robertson, 1997). There are no biomarkers available to identify ammonia exposures (Center for Disease Control, 2004). Chest X-rays appear to offer little help in assessing the immediate status of lung involvement

(Montague and Macneil, 1980). Initial chest X-rays and early blood gas values also correlate poorly in predicting the future clinical course of patients who suffer acute ammonia inhalation. The presence or absence of abnormal chest findings on physical examination is the best prognostic factor (Arwood et al., 1985). There may be a need to establish baseline spirometry with future monitoring (Rahman, Bratveit, and Moen, 2007).

First aid treatment consists of removing the patient from the source of exposure and basic life support measures. If possible, an attempt should be made to remove the ammonia from the eyes and skin by irrigating with copious amounts of water, and affected clothing should be removed. Ammonia causes eye and skin injuries identical to those of other caustic alkalis (O’Kane, 1983). If ammonia is ingested, do not induce vomiting, and consider consulting for an upper and lower endoscopy to assess the injury (Burgess, Pappas, and Robertson, 1997).

SOURCES OF EXPOSURE

Occupational

Exposures to anhydrous ammonia for fertilizer production generally occur during transfer operations (Greenberg et al., 1985). Ammonia used in refrigeration is typically stored under pressure, which means that leaks will disperse ammonia at greater pressures and larger areas than non-pressurized systems. Contact with the leaking liquid at normal atmospheric pressure brings an addition hazard of frostbite, since its temperature then runs about -28°F .

Ammonia is an additional risk factor in animal management facilities. A by-product of bacterial decomposition, ammonia (as well as other gases) can be produced by decomposing animal wastes. Employee fatalities result from oxygen depletion and toxic gas exposure from cleaning manure pits in animal facilities (Greenberg et al., 1985).

Amshel reported a 28-year-old male that sustained a 45% total body surface area burn due to an anhydrous ammonia explosion (Amshel et al., 2000). It was concluded that the injured worker had not received any formal training regarding the hazardous nature of the anhydrous ammonia, and the company was unprepared to meet the demands for immediate first aid.

LIME (CALCIUM OXIDE; CALCIUM HYDROXIDE)

Occupational exposure limits: OELs are for the specific constituents:

Calcium Oxide:

OSHA PEL: 5 mg/m³.

NIOSH REL: 2 mg/m³;

NIOSH IDLH: 25 mg/m³

Calcium Hydroxide:

OSHA PEL: 15 mg/m³ (total); 5 mg/m³ (resp)

NIOSH REL: 5 mg/m³

BACKGROUND AND USES

Lime (calcium oxide CASRN 1305-78-8 and calcium hydroxide CASRN 1305-62-0), produced from the heating of mined limestone, is an important industrial product for metal manufacturing, building and construction, and chemical processing. Almost 20 million tons of lime is produced from 29 states and Puerto Rico, with most of it being used for purification processes in steel manufacturing (EPA, 2011).

“Lime” as a general term refers to calcium oxide, calcium hydroxide, or magnesium–calcium oxides or hydroxides (dolomites). Calcium oxide (also known as quicklime, unslaked lime, or burnt lime) is a white to gray hygroscopic crystalline solid. Calcium hydroxide (also known as slaked lime or caustic lime) is a white odorless powder formed from the addition of water to calcium oxide (“slaking”). The hydration process is quite an exothermic process and creates a strongly alkaline product (pH ≈ 12.4).

Workers in the construction industry often sustain dermal injuries from foundation work with cement or concrete, accounting for 1.8% of burns treated in adults (Sherman and Larkin, 2005). The alkalinity of cement comes from calcium oxide, which constitutes 60–70% of cement. Cement acquires its industrial properties when water is added to “slake” the lime, increasing cement strength as the amount of free water declines through progressive hydration and evaporation. The hydration process increases the alkalinity to a pH typically exceeding 12. However, exposure to air allows the calcium hydroxide to react with ambient carbon dioxide, resulting in an inert calcium carbonate and a more neutral pH.

Reports of occupational injuries from lime or cement burns are as varied as the number of occupations themselves. Ng and Koh (2011) presented a case study of contact dermatitis after a worker dispensed calcium oxide in a cloud seeding procedure for a meteorological operation. The case study presented sound arguments for the use of full-face respirators when working in areas with the potential for lime dust. Tindholdt,

Danielsen, and Åbyholm (2005) described a worker who sustained 3% TBSA (total body surface area) burns from placing newly molded flagstones in the rain. The 90 min of work he performed resulted in multiple medical procedures, an 8-day hospital stay, and a 6-week absence from work.

Sherman and Larkin (2005) discussed the case of a cement worker who sustained cement burns from standing in cement in tennis shoes for roughly 4 h, despite his awareness of the potential burn risks. The worker sustained burns on his lower extremities that required skin grafts and 10 days hospitalization. The authors suggested that despite warnings, these types of burns will most likely reoccur in an industry where workers choose to ignore the need for protective equipment. Rigorous education and required adherence to safety policies are perhaps the best prevention for incidents as these.

MAMMALIAN TOXICOLOGY

Acute Effects

Cain et al. (2004) studied 12 human subjects exposed to selected chemical dusts for 20 min and found that the subjects had a “chemesthetic” response to calcium oxide dust at concentrations of 2–5 mg/m³.

In a series of reported eye injuries, lime was the agent most responsible for burns. The lime in cement reacts avidly to form calcium hydroxide solution, a concentrated solution of which can have a pH of 12.4–12.7 (Benmeir et al., 1993). Lime also differs from the previously discussed agents because, since it is a solid, its particles tend to adhere and continue to damage the area until they are removed.

Cement can damage the skin in several ways. It can act as a primary irritant that causes dermatitis by means of the alkalinity of the material or by the gritty particles, or both, and it also can be a sensitizer that causes a contact allergic dermatitis in workers who become sensitized to the chromium present in many cements (mostly from Europe). Cement can cause burns similar to those caused by other alkalis with two major differences: the cement particles can adhere to the skin, and the injury can go unnoticed for some time (Vickers and Edwards, 1976). The lower legs area is most commonly injured because workmen kneel in wet cement or it splashes inside their work boot. Benmeir et al. (1993) reported on two soccer players who suffered burns to the groin and upper legs when lime powder that was used to line the field penetrated their clothing.

However, the most innocuous of uses can provide a source for injurious exposures to lime. Neubauer et al. (2000) described a rare case of pulmonary injury sustained from a diver’s exposure to soda lime (a mixture of calcium hydroxide, sodium hydroxide and potassium hydroxide.) through a failure in his closed circuit rebreather.

Chronic Effects

Cement particles may be a source of occupational asthma as well as other obstructive and restrictive lung diseases (Bauer et al., 2013). It is noted that the use of dust exposure control methods prevents a decrease in lung function (Tungu et al., 2014).

INDUSTRIAL HYGIENE

With the strong alkalinity and hygroscopic nature of lime products, care must be exercised to avoid exposures, especially to moist areas such as eyes and airways. At a minimum, protective clothing and eyewear should be worn and eyewashes and quick drench facilities should be readily available to workers. The National Institute of Occupational Safety and Health (NIOSH) recommendations for respirators should be consulted for those working with calcium oxide.

Spills of solid lime must be handled with care. Unslaked lime, for example, reacts violently with water and so the dry product should be removed as completely as possible before any washing of the area commences.

SODIUM HYDROXIDE

Occupational exposure limits:

NIOSH REL: (ceiling) 2 mg/m³; IDHL: 10 mg/m³

OSHA PEL: 2 mg/m³ TWA

ACGIH TLV: (ceiling) 2 mg/m³

BACKGROUND AND USES

Sodium hydroxide (NaOH; CASRN 1310-73-2) is commonly available as an aqueous solution known as caustic soda, soda lye, or simple as lye. It has various uses, including neutralization of acid; the manufacture of paper, textiles, plastics, corrosives, dyestuffs, paint, paint remover, and soap; refining of petroleum; electroplating; metal cleaning; laundering; and dish washing. A burgeoning use has been in the illegal manufacture of methamphetamine.

PHYSICAL AND CHEMICAL PROPERTIES

Sodium hydroxide is a white, odorless, nonvolatile alkaline material marketed in solid form as pellets, flakes, clumps, or sticks. Its solubility in water is 111% by weight and a vapor pressure of 0 mmHg (NIOSH, 1994).

It can react with trichloroethylene (TCE) to form flammable dichloroacetylene and with metals to form hydrogen gas (OEHHA, 1993). Its reactivity with metals should be considered in regards to storage units and containers.

TOXICOLOGY

Acute Effects

Sodium hydroxide dusts generally are without odor; therefore, the corrosivity of the dust reacting with moist tissue can be the only preliminary sign of exposure. Concentrations as low as 0.5 mg/m³ can elicit mild to moderate feelings of respiratory irritation (OEHHA, 1993).

A total of 25–50% solutions can cause immediate and overt damage to the skin, while several hours may pass before the damage from exposures to 4% or lower solutions manifests (OEHHA, 1993).

It has been shown that 4% lye solution has an initial anesthetic effect on intact skin and that hours can elapse before a sense of irritation occurs; by comparison, with a 25% solution, the sense of irritation occurs in 3 min. Because of this initial insensitivity, medical attention may not be sought until sometime after the thermal burn occurs and progressive skin destruction has occurred (Harper and Dickson, 1994).

It is recommended that the eyes be flushed for at least 15 min with copious amounts of water (Wax and Young, 2013). Due to the excessive amount of hydrochloric acid that is produced, a patient with a history of gastroesophageal reflux may need treatment for this condition (Messner et al., 1996).

Chronic Effects

Sodium hydroxide has not been determined to be carcinogenic. While some studies have associated esophageal cancer with damage from sodium hydroxide exposure, the general belief is that the cancer arises from mutations in the repairing tissue rather than exposure to the sodium hydroxide itself.

Chemical Pathology

Winemaker et al. (1992) found that irreversible damage to the skin by sodium hydroxide is proportional to the concentration when above 1% and pH when above 11.5.

INDUSTRIAL HYGIENE

The ACGIH and the NIOSH have set the TLV and REL, respectively, with a ceiling of 2 mg/m³. OSHA has set the PEL for sodium hydroxide at 2 mg/m³ for an 8-h, time-weighted average (TWA). Respiratory protective equipment should be worn when working with NaOH mists.

ALUMINUM

GIFFE T. JOHNSON

Target organ(s): Dermis, lungs, nervous system

Occupational exposure limits: TWA: 5 mg Al/m³ from ACGIH (TLV) [United States] inhalation (pyro powders, welding fumes); TWA: 10 mg Al/m³ from ACGIH (TLV) [United States] inhalation (metal dust)

Reference values: RfD/RfC: N/A (USEPA); MRL: 1 mg Al/kg/day (ATSDR)

Risk/safety phrases: Combustible dust

BACKGROUND AND USES

Occurring naturally in the soil, aluminum makes up 8% of the earth's surface, although higher concentrations may be found in the soil surrounding associated industries. Aluminum is used to make items such as antiperspirants, antacids, cooking utensils, soda cans, aluminum foil, and construction materials.

Transportation accounts for an estimated 40% of aluminum usage in the United States, mostly for automotive applications, with the remaining amounts consumed by packaging (28%), building (13%), consumer durables (7%), electrical (5%), and other applications (7%) (USGS, 2007).

Various aluminum compounds are also found in a diverse number of industrial processes and consumer products. Aluminum chloride, anhydrous form, is used as an acid catalyst to provide a chemical intermediate for other aluminum compounds, in the cracking of petroleum, in the manufacture of rubbers and lubricants, and as an antiperspirant. The hexahydrate form is used as a wood preservative, for disinfecting stables and slaughterhouses, in deodorants and antiperspirants, in cosmetics (such as topical astringents), in refining crude oil, dyeing fabrics, and manufacturing parchment paper (O'Neil et al., 2001). Aluminum chlorohydrate is

an ingredient in commercial antiperspirant and deodorant preparations and is also used for water purification and treatment of sewage and plant effluent (Lewis, 2001).

PHYSICAL AND CHEMICAL PROPERTIES

Aluminum (also aluminum metal, aluminum powder, or elemental aluminum) is a silvery-white, odorless metal that is malleable and ductile; its Chemical Abstract Service (CAS) number is 7429-90-5. Aluminum has a vapor pressure of approximately 0 mmHg and is insoluble in water. It is a combustible solid, and as a finely divided dust, it ignites easily and can cause explosions.

MAMMALIAN TOXICOLOGY

Acute Effects

Aluminum may cause death (as observed in laboratory animals) only from exposures that are extremely high compared to what a human might normally encounter. The LD₅₀ for aluminum bromide in Sprague-Dawley rats and Swiss Webster mice have been reported as 162 and 164 mg Al/kg, respectively (Llobet et al., 1987). The chloride form has produced LD₅₀ values of 370, 222, and 770 mg Al/kg in Sprague-Dawley rats, Swiss Webster mice, and male Dobra Voda mice, respectively (Llobet et al., 1987; Ondreicka et al., 1966). The LD₅₀ for aluminum sulfate in male Dobra Voda mice has been reported as 980 mg Al/kg (Ondreicka et al., 1966).

Acute toxicity in humans associated with aluminum is rare, although aluminum may cause local contact dermatitis. Vaccines absorbed to aluminum have been used for many

years for immunization (Böhler-Sommeregger and Lindemayr, 1986). This procedure is thought to prolong the absorption process and enhance the immunological response. Böhler-Sommeregger and Lindemayr report a case of a 3-year-old boy who received routine triple vaccinations. The mother reported a strong local skin reaction with intense redness after each injection. The development of nodular or granulomatous reactions, or both, after injection with an aluminum adjuvant is not uncommon. However, in this child the effects persisted until age 10. Fawcett et al. (1985) also reported such injection-site granulomas, but those reactions did not persist beyond a few weeks.

Fischer and Rystedt (1982) reported other cases of contact dermatitis. Positive patch tests were found with aluminum chloride and aluminum hydroxide. Cases of contact dermatitis, as well as positive skin reactions, arising from exposure to aluminum filings, have been reported among aircraft workers. Meding et al. (1984) described a similar contact allergy, but they point out that the condition is rare considering the common exposure to aluminum.

Chronic Effects

Neurotoxicity has been linked to exposure to aluminum in both humans and laboratory animals. Aluminum has been documented to accumulate in the central nervous system (brain nuclei and spinal cord) when bound to citrate and administered to laboratory mice (Oteiza et al., 1993). Accumulated tissue concentrations were shown to be dose dependent. Banks and Kastin (1983) also demonstrated that aluminum increases the permeability of the blood-brain barrier to labeled N-Tyr-delta sleep-inducing peptide (DSIP) and beta endorphin. Laboratory rats injected intraperitoneally with aluminum demonstrated this effect. Analysis of variance showed a statistically significant effect resulting from this treatment. These authors suggested that the increase in permeability to the test compounds produced by aluminum may provide a theoretical mechanism by which changes in brain biochemistry that lead to neurotoxicity may occur.

Some epidemiological studies have supported the finding of an association between aluminum and neurotoxicity though a causal relationship has not been clearly established. The results of a cross-sectional study undertaken at an aluminum plant in Norway suggested an increased risk of visuospatial organization and a tendency toward decline in psychomotor tempo as a result of long-term, low dose exposure to aluminum (Bast-Pettersen et al., 1994). As well, it has been hypothesized that increased aluminum levels in the brain and the incidence of Alzheimer's disease may be linked. Crapper et al. (1973) were the first to identify increased levels of aluminum in subanatomical regions of the brain in patients who had suffered from Alzheimer's disease. However, this hypothesis has been subsequently refuted by an abundance of publications. It is difficult for

any research group to have access to a sufficient number of patients with Alzheimer's disease and proper controls. Also, a significant amount of the controversy can be attributed to the detection methodologies used to evaluate neurofibrillary tangles and senile plaques, which are the hallmarks of Alzheimer's disease (Savory et al., 1996). Two case-control studies examining occupational exposure to aluminum dust or fumes and the risk of Alzheimer's disease found no significant association (Graves et al., 1998; Salib and Hillier, 1996). A study of former aluminum dust-exposed workers (retired for at least 10 years) found some impairment in some tests of cognitive function; however, the data did not link the exposure to the diagnosis of Alzheimer's disease (Polizzi et al., 2002).

Osteomalacic dialysis osteodystrophy was identified 20 years ago by Ward et al. (1978). It was recognized that many patients suffered from this disease in areas with tap water that had a high concentration of aluminum. Subsequently, the medical records of patients who had been dialyzed with softened or untreated water were compared with those of patients who had been dialyzed with deionized water. The findings from this comparison supported the original observation. Later, more quantitative studies were undertaken using bone biopsies from subjects known to have been exposed to contaminated drinking water in, which a high level of aluminum was one of the contaminants (Eastwood et al., 1990). These subjects were exposed to aluminum concentrations ranging from 30 to 620 mg/l, although regulatory drinking water standards in the geographical area were established at 0.2 mg/l. The bone biopsies revealed a period of high gastrointestinal absorption, probably because of the high acidic conditions of the contaminated drinking water. Bone biopsies in hemodialysis patients from other studies have revealed almost pure osteomalacia (Gratwick et al., 1978; De Verneuil et al., 1982). These experiments support some of Ward's original observations of 20 years ago.

In animal models, repeated exposure to high levels of aluminum has been suggested to adversely affect the hematological system of rats and mice. Significant decreases in hemoglobin, hematocrit, and/or erythrocyte osmotic fragility were observed in rats exposed to 420 mg Al/kg/day as aluminum citrate in drinking water for 15 weeks, mice exposed to 13 mg Al/kg as aluminum citrate administered via gavage 5 days/week for 22 weeks, rats exposed to 230 mg Al/kg/day as aluminum citrate in drinking water for 8 months, and rats exposed via drinking water to 54.7 mg Al/kg/day as aluminum sulfate in a sodium citrate solution for 18 months (Garbossa et al., 1996; Farina et al., 2005; Vittori et al., 1999).

Mechanism of Action(s)

A predominant mechanism for the uptake of aluminum has yet to be described (Exley et al., 1996). The primary route of

uptake is believed to be via the small intestine. It serves as a formidable barrier; however, only about 1% of an oral dose of aluminum is absorbed into the body. The absorption of aluminum depends on the intraluminal pH (McKinney, 1993). In addition, certain cofactors increase and limit the absorption of aluminum. Aluminum complexes with oxygen donor ligands, especially phosphates, allowing the formation of compounds such as insoluble aluminum phosphate, which reduces free Al³⁺ and facilitates elimination of aluminum from the body. Citrate, on the other hand, actually is known to increase the bioavailability of aluminum by forming the neutral compound aluminum citrate, which can readily pass through membranes (Oteiza et al., 1993). Aluminum would also be expected to bind with other oxygen donor ligands such as phosphate groups, nucleotides, and polynucleotides. The relationships between aluminum and donor ligands may be especially significant because some of these donors (phosphate and citrate) are known to activate brain hexokinase enzymes (Martin, 1986).

Inhalation of aluminum dust may result in some absorption across lung epithelia and also passage to the gut. Inhalation of the dust also may cause deposition of aluminum in the lungs, and these mucociliary pathways may be the reigning mechanism by which aluminum becomes systemic (Exley et al., 1996).

The mechanisms for neurotoxic effects have not been elucidated. Strong et al. (1996) have suggested that because aluminum is transported to the brain primarily by means of transferrin, toxicity may occur through the transferrin-mediated receptor system. The aluminum complexation with nucleoside phosphates (adenosine triphosphate [ATP] and adenosine diphosphate [ADP]) and binding proteins has also been examined. The coordination chemistry of Al³⁺ demonstrates a preference for binding to negatively charged oxygen atoms. Because of this characteristic, the phosphate and oxygen atoms of ATP may act as a dominant binder of Al³⁺ in some cells (Martin, 1994). This is of great interest to human biochemistry as we require ATP for a variety of cellular metabolic activities. In addition, many nucleoside phosphate reactions involve Mg²⁺, and Al³⁺ is an effective surrogate for Mg²⁺ (Nelson, 1996).

Chemical Pathology

No specific target organ or mechanism has been conclusively described for aluminum toxicity (Shi et al., 1993). It seems that aluminum has varying effects on different organs associated with different exposure routes. Studies suggest that aluminum may be associated with many neurodegenerative disorders, including reduced cognitive function, impaired psychomotor function, and dialysis encephalopathy (Bast-Pettersen et al., 1994). Altmann et al. (1989) suggested that reduction of psychomotor function occurs as a result of inhibition of the brain enzyme dihydropteridine reductase.

McDermott et al. (1978) found increased concentrations of aluminum in the brain in seven patients suffering from dialysis encephalopathy. These results suggest a correlation between increased levels of aluminum and untreated or softened dialysis water.

Neurofibrillary degeneration has been found in cats and rabbits similar to that observed in patients with Alzheimer's disease (McDermott et al., 1978). Banks and Kastin (1983) found that when rats were injected with aluminum chloride (AlCl₃), the aluminum increased the permeability of the blood-brain barrier to small peptides. However, specific dose-dependent pathways to disease remain unclear.

SOURCES OF EXPOSURE

Occupational

Occupational exposure to aluminum occurs during the refining of the primary metal and industries that use aluminum products, including the aircraft, automotive, and metalwork industries. Exposure to aluminum may also occur from aluminum welding (Nieboer et al., 1995).

In the aluminum refining process, exposure is primarily to aluminum hydroxides and aluminum oxides from the initial extraction and purification process. Aluminum oxide and aluminum fluoride exposure may occur in the potroom, an area that also produces tar-pitch volatiles such as PAHs, which are important confounding exposures when examining the potential health effects from exposure of aluminum (Drablos et al., 1992; IARC, 1984; Nieboer et al., 1995). Most studies of occupational exposure to aluminum have dealt with inhalation of aluminum-containing dust particles, in combination with other dust constituents. Rarely is a worker exposed solely to aluminum-containing dust; exposure to mixtures of aluminum with fine respirable particles or other potentially toxic chemicals is more prevalent.

A great variety of industries employ workers potentially exposed to aluminum and aluminum compounds, including the plumbing, heating, and air conditioning industry; the masonry and stonework industry; electrical workers; machinists; metal and wire production; general medical and surgical hospitals; industrial building construction; and industries that use special dyes, tools, and fixtures (NIOSH, 1991).

Environmental

Aluminum is the most abundant metal in the earth's crust and the third most abundant element making up about 8.8% by weight. It is found in most rocks in the form of aluminosilicate minerals (Lide, 2005; Staley and Haupin, 1992). Aluminum enters the environment naturally through the weathering of rocks and minerals, and through anthropogenic releases from air emissions, waste water effluents, and the solid waste

generated from aluminum refinement and production. The aluminum released through natural weathering processes far exceeds the contribution of releases to air, water, and land associated with human activities (Lantzy and MacKenzie, 1979).

The use of alum (aluminum sulfate) as a flocculent in water treatment facilities is a potential source of aluminum in treated water (Letterman and Driscoll, 1988; Miller et al., 1984). However, the concentration of aluminum in surface and groundwater is modulated by the acidity of the water. Higher concentrations of aluminum are typically limited to water with a pH < 5; as a result, aluminum concentrations in most surface water are very low.

Chronic exposure to aluminum is found primarily in patients undergoing dialysis treatment with softened or untreated water. In a study by McDermott et al. (1978), 7 of 19 patients receiving dialysis treatment experienced dialysis-associated encephalopathy. In all seven patients, the aluminum concentration in the brain was significantly higher than in other patients who were uremic but not dialyzed. Abreo et al. (1990) have demonstrated exposure to aluminum by means of inadequately treated domestic water sources containing high concentrations of the metal.

Another source of chronic exposure to aluminum is aluminum-containing phosphate binders. Randall (1983) reported a case of an 11-month-old girl who was not undergoing dialysis but who received aluminum-containing phosphate binders. The child subsequently died of a progressive encephalopathy, and increased levels of aluminum were found in the serum and cerebrospinal fluid. It is now well established that iatrogenic exposure to aluminum, such as through hemodialysis or administration of phosphate binders, may cause encephalopathy, bone disease, and anemia (Flaten et al., 1996).

INDUSTRIAL HYGIENE

Aluminum has been used in the industry for more than 100 years. Electrolytic reduction of aluminum was developed in 1886 by Hall and by Héroult in France. Aluminum has many uses, either alone or alloyed with other compounds such as copper, magnesium, manganese, silicon, and zinc. These alloys are used in industries such as construction materials, communications, laboratory and diagnostic studies, paper, printing, glass, water purification, and textiles.

Industrial health hazards are largely associated with electrolytic reduction of aluminum oxide, also known as alumina, aluminum trioxide, or bauxite. Health hazards may exist as a result of exposure to condensed pitch volatiles (tars), which are produced during the reduction process by burning the anode in the electrolytic cell (Gibbs, 1985). Gibbs conducted a cohort study on aluminum reduction plant workers between 1950 and 1977. The study found a slight increase in mortality

from respiratory disease among some of the men occupationally exposed to tars during this time period. However, no adjustment was made for lifestyle factors, such as smoking or for other personal traits that might contribute to respiratory disease.

Many early reports describe inhalation of aluminum as a dust to be hazardous to workers. German literature from World War II describes the cases of workers who had inhaled aluminum and who subsequently exhibited X-ray changes much like those seen with silicosis. The workers complained of dyspnea and the development of spontaneous pneumothorax.

These findings are compatible with those of Shaver and Riddell (1947), who described the first identified cases of what has since been called Shaver's disease. This disease is characterized by dyspnea, coughing, substernal pain, weakness, and fatigue. X-ray films show bilateral lace-like shadowing, more frequently in the upper halves of the lungs and with increasing intensity toward the lung roots, and varying degrees of pneumothorax. Outstanding features at autopsy are advanced emphysema and interstitial pulmonary fibrosis.

Currently, the National Institute of Occupational Safety and Health (NIOSH) classifies aluminum compounds as nuisance dusts and sets exposure limits at 10 mg/m³ total and respirable dusts, and 5 mg/m³ respirable dusts. The NIOSH also sets exposure limits for aluminum pyropowders and welding fumes at 5 mg/m³ and for soluble salts and alkyls at 2 mg/m³. Atomic absorption spectrometry can be used to monitor aluminum levels (NIOSH, 1994).

MEDICAL MANAGEMENT

Two important risk groups for aluminum toxicity exist for, which emergency management may be required: those with renal insufficiency and those with excessive and prolonged aluminum exposure, which produce clinical symptoms, including altered mental status, anemia, or osteoporosis.

Treatment of aluminum toxicity includes elimination of aluminum from the diet, total parenteral nutrition, elimination of aluminum from dialysate, medications or antiperspirants, and elimination of any occupational exposure that may be present. An attempt at elimination and chelation of the element from the body's stores may be prescribed depending on the severity of the exposure.

Elimination by chelation is accomplished through the administration of deferoxamine. Patients with serum levels >20 mcg Al/dl may require chelation therapy though symptomatic patients with serum levels >50–60 mcg Al/dl generally indicate that chelation therapy is necessary. Deferoxamine therapy typically ranges from 2.5 to 5 mg/kg/wk (Kan et al., 2010). Chelation therapy is typically conducted in consultation with a nephrologist and a medical toxicologist.

ANTIMONY

MARIE M. BOURGEOIS

First aid: Eye: irrigate immediately; skin: water flush promptly; breathing: respiratory support; swallow: medical attention immediately

Target organ(s): Eyes, skin, respiratory system, cardiovascular system

Occupational exposure limits: NIOSH REL: 0.5 mg Sb/m³ TWA, OSHA PEL: 0.5 mg Sb/m³ TWA, 1993–1994 ACGIH TLV: 0.5 mg Sb/m³ TWA

Reference values: Oral RfD of 40,000 mg/kg/day (confidence is low), IDLH: 50 mg Sb/m³

Risk phrases: R34-51/53-20/22-36/37/38-36/38

Causes burns. Toxic to aquatic organisms, may cause long-term adverse effects in the aquatic environment. Harmful by inhalation and if swallowed. Irritating to eyes, respiratory system, and skin. Irritating to eyes and skin

Safety phrases: S60-61-36/37/39-26

This material and its container must be disposed of as hazardous waste. Avoid release to the environment. Refer to special instructions/safety data sheet. Wear suitable protective clothing, gloves, and eye/face protection. In case of contact with eyes, rinse immediately with plenty of water and seek medical advice.

BACKGROUND AND USES

Antimony (CASRN 7440-36-0, EINECS 231-146-5) is a metal with synonyms, including antimony black; elemental antimony; antimony metal; metallic antimony; stibanylidy-nestibane; antimony ingot; antimony powder; antimony regulus; stibium and stibium metallicum. It has multiple industrial applications. The trioxide form has primarily been used as a

flame retardant in items such as automobile and aircraft upholstery, toys, and clothing (NRCNA, 2008). It also is used in ceramics to achieve hardness and opacity and in glassware to remove bubbles and stabilize color. The trisulfide and pentasulfide forms are used as a pigment to make rubber tires black and as pigment stabilizers in pavement paint. A small amount is also used as a fining agent to remove bubbles in the glass of computer monitors and television picture tubes (Butterman and Carlin, 2004). Antimony trisulfide is an important component of pigments and munitions primers. Metallic antimony is a minor strengthening component in lead and tin alloys used for cable coverings and solder. Unalloyed antimony is used infrequently, principally in doping semiconductor wafers.

Antimony has been used medicinally as an emetic, expectorant (e.g., potassium antimony tartrate and antimony dimer-captosuccinate) and antiparasitic agent in schistosomiasis, trypanosomiasis, and leishmaniasis for centuries (Lizarazo-Jaimes et al., 2014). Meglumine antimoniate and sodium stibogluconate, forms of pentavalent antimony (Sb(v)), have been the drugs of choice for leishmaniasis for more than 60 years (Garcerant et al., 2012). Antimony plays no important role in nutrition (Beliles, 1979; Squires et al., 1993). Intake has been reported as being between 23 and 1250/ag per week (Dickerson, 1994). Beliles (1979) cites an average body burden of 90 mg.

PHYSICAL AND CHEMICAL PROPERTIES

A natural element, antimony (symbol Sb; CASRN 7440-36-0) occurs in valence states of 3, 5, and –3 and has both metallic and nonmetallic properties (Table 6.1). It is commercially

TABLE 6.1 Chemical and Physical Properties of Antimony

Characteristic	Information
Chemical name	Antimony
Synonyms/trade names	Antimony black; elemental antimony; antimony metal; metallic antimony; stibanylidynestibane; antimony ingot; antimony powder; antimony regulus; stibium; and stibium metallicum
Chemical formula	Sb
CASRN	7440-36-0
Molecular weight	121.76 g/mol
Melting point	630 °C
Boiling point	1635 °C
Vapor pressure	0 mmHg (approx)
Density/specific gravity	6.69 g/ml at 25 °C
Flashpoint	Not applicable
Water solubility at 25 °C	Insoluble
Explosion limits	No data available
Octanol/water partition coefficient ($\log K_{ow}$)	0.73 (estimated)
Henry's law constant	No data available
Odor threshold	No data available
Conversion factors	1 ppm = 3.082 mg/m ³ 1 mg/m ³ = 0.324 ppm

available as a silver white lustrous solid metal or a dark gray powder (HSDB, 2005; Budavari, 1989). The amount in the earth's crust is <1 parts per million (ppm); its most common ore is stibnite (CASRN 1345-04-6). Antimony trisulfide (symbol Sb₂S₃; CASRN 1317-86-8), is a chemical form of antimony (Beliles, 1979). In the soils of the conterminous United States, it occurs at a geometrical mean of 0.48 ppm (Shacklett and Boerngen, 1984).

Because antimony is a group VA element, it has many of the same chemical and toxicological properties as arsenic and lead. For example, the toxicity of pentavalent antimony compounds is less than that of trivalent compounds (DeWolff and Edelbroek, 1994). The suggested descending order of toxicity is metalloid antimony (particularly stibine gas), the trisulfide, the pentasulfide, the trioxide, and the pentoxide.

ENVIRONMENTAL FATE AND BIOACCUMULATION

In water, antimony occurs primarily as suspended particulate, although some may occur as products of hydrolysis. It likely accumulates in sediments, and, although some bioconcentration has been observed in some freshwater and marine invertebrates (most likely from methylated forms), antimony does not biomagnify (USEPA, 1985, 1988; Wilson et al., 2010; Feng et al., 2013).

In most soils the trioxide form prevails and persists as a result of precipitation and of the element's lack of reactivity, its stability, and its low vapor pressure (USEPA, 1985; Dragun, 1988; Wilson et al., 2010). Antimony can be found on the 2007 Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) priority list of hazardous substances (Padilla et al., 2010; Ren et al., 2014).

ECOTOXICOLOGY

Quantitative information on antimony in the environment is not available. Toxicity assessment can be further complicated because antimony and arsenic are frequent environmental co-contaminants (Gebel, 2000). There is limited information on persistence, degradability, bioaccumulative potential, and mobility in soil. Environmental hazard in the event of a spill cannot be ruled out.

MAMMALIAN TOXICOLOGY

Antimony is poorly absorbed from the gastrointestinal tract but more readily absorbed through the respiratory tract. It is distributed in a rather unspecific manner, although trivalent compounds tend to react with red blood cells and the liver, and the pentavalent form tends to remain in plasma. The metabolism of antimony is similar to that of arsenic. Unlike arsenical compounds, antimony does not appear to be methylated *in vivo* (Bailly et al., 1991). Antimony tends to bind to sulfhydryl groups of respiratory enzymes. Antimony is excreted in both bile and urine as a glutathione conjugate (Bailly et al., 1991; NRCNA, 2008). Pentavalent antimony tends to be excreted more rapidly.

Acute Effects

Acute poisoning is rare but can result in death within several hours (Beliles, 1979). The symptomatology is similar to that for the arsenicals: vomiting, colic, diarrhea, and a metallic taste. Acute inhalation can induce rhinitis and pulmonary edema. Potassium antimony tartrate at a dose of 0.53 mg Sb/kg produced vomiting (Dunn, 1928). Inhalation of antimony dust by factory workers produced gastrointestinal irritation, probably the result of antimony dust transported via the mucociliary escalator and swallowed (ATSDR, 1992). No acute dermal effects have been reported.

Chronic Effects

Workers exposed to airborne antimony and antimony compounds can develop dermatitis, eye irritation, obstructive lung changes, and emphysema with increased pneumoconiosis (Cooper et al., 1968; Schroeder et al., 1968; Potkonjak and

Pavlovich, 1983). Transient “antimony spots” also may appear in individuals who are chronically exposed; these spots appear to be the result of internal changes rather than external effects (Sundar and Chakravarty, 2010). The pustular eruptions occur most frequently in areas of sweating. Otherwise, the only skin effect is dermatitis (White et al., 1993). A single study appears to indicate an increase in the number of spontaneous abortions and menstrual cycle disturbances among women workers exposed to antimony aerosols; however, this observation has not been reported elsewhere (Balyaera, 1967). There is limited evidence of carcinogenic, mutagenic, and teratogenic risks of antimony compounds, although additional investigation of pregnancy outcomes in women treated for leishmaniasis with antimony compounds may be indicated (Leonard and Gerber, 1996). Exposure to antimony may induce some cardiac effects, including arrhythmia (Brieger et al., 1954; Huang et al., 1958; Berman, 1988).

The federal Environmental Protection Agency (EPA) has established an oral reference dose (RfD) for antimony (40,000 mg/kg/day) based on a chronic oral bioassay in which 5 ppm of potassium antimony tartrate was administered to rats in their drinking water. The primary study used 100 rats (Schroeder et al., 1970). Confidence in the principal study is considered low because only one species and one dose level were used; a “no observed adverse effects level” (NOAEL) was not documented; and gross pathology and histopathology were not well described. Confidence in the database, and consequently the RfD, is low because no adequate investigations of oral exposure have been done. In 1994, the EPA has established a limit of 145 ppb in surface waters and 0.006 ppm in drinking water. EPA requires reports for environmental discharges of antimony exceeding 5000 pounds. The Agency for Toxic Substances and Disease Registry (ATSDR) has not derived acute, intermediate, or chronic oral minimal risk level for antimony due to insufficient data (NRCNA, 2008).

Existing data suggest that antimony may be an animal carcinogen; however, the data are not sufficient to justify a quantitative estimate of cancer potency at this time. In laboratory rats, inhalation of antimony dust can increase the risk of lung cancer. However, there is no evidence of an increased risk of cancer in animals that eat food or drink water containing antimony. The International Agency for Research on Cancer (IARC) concluded that antimony trioxide is a possible carcinogen in humans (Group 2E) and that the trisulfide form is not classifiable (IARC, 1989).

Mechanism of Action(s)

The primary targets in antimony poisoning are the gastrointestinal and respiratory tracts, and the effects in these regions have been documented in humans and animals. Other targets observed in animals include the cardiovascular system, the blood, and the liver (Goi et al., 2003; Newkirk et al., 2014). Renal toxicity (histological changes) has also been observed

in animals. Only limited data are available which indicate that occupational exposure to antimony may adversely affect the reproductive system of women.

SOURCES OF EXPOSURE

Exposure to antimony in humans can occur through inhalation, ingestion, and eye or skin contact (Majestic et al., 2012; Felix et al., 2013).

Occupational

Prior to automation and improved working conditions, antimony process workers exhibited an increased risk of lung cancer (Schnorr et al., 1995; McCallum, 2005). Excessive exposures may still occur in electrorefining. Smoking enhanced this association (Cooper and Harrison, 2009). Occupational exposures to antimony may occur in battery industries where antimony is alloyed with lead and zinc. In this case, workers are typically exposed to antimony hydride (SbH_3) (Cooper and Harrison, 2009). Also known as stibine, SbH_3 is produced when antimony reacts with an acid in the presence of a reducing agent such as zinc. Workers in semiconductor industries, where antimony is used as a dopant, can be exposed to stibine. Antimony exposure may also occur when antimony replaces lead in soldering (Fowler et al., 1993).

Environmental

Antimony is also a ubiquitous urban air pollutant, which occurs at an average concentration of $0.001/\text{mg/m}^3$ (Beliles, 1979; Smichowski, 2008). Antimony commonly is released into the air through combustion of fossil fuels and their by-products and of products containing antimony (Hodzic et al., 2012; Tian et al., 2012; Sun et al., 2014). The resultant form most likely is the trioxide, although the tetroxide and pentoxide forms are possible. Rapidly condensed on suspended particulates, the residence time of antimony in the air is thought to range from 30 to 40 days.

INDUSTRIAL HYGIENE

Both proper industrial hygiene and personal hygiene are important. The approaches used to limit exposure to arsenic apply to antimony as well (Table 6.2). The Occupational Safety and Health Administration (OSHA), the National Institute for Occupational Safety and Health (NIOSH, 2013), and the American Conference of Governmental Industrial Hygienists (ACGIH, 2013) have set the permissible exposure limit (PEL), the recommended exposure limit (REL), and threshold limit value (TLV) for antimony compounds (as Sb) at 0.5 mg/m^3 for an 8-h workday, 40-h

TABLE 6.2 NIOSH Recommended Respiratory Protection for Workers Exposed to Antimony

Condition/Airborne Concentration of Antimony	Minimum Respiratory Protection
Up to 5 mg/m ³	(APF = 10) Any particulate respirator equipped with an N95, R95, or P95 filter (including N95, R95, and P95 filtering facepieces) except quarter-mask respirators. The following filters may also be used: N99, R99, P99, N100, R100, P100.
Up to 12.5 mg/m ³	(APF = 10) Any supplied-air respirator (APF = 25) Any supplied-air respirator operated in a continuous-flow mode (APF = 25) Any powered, air-purifying respirator with a high efficiency particulate filter.
Up to 25 mg/m ³	(APF = 50) Any air-purifying, full facepiece respirator with an N100, R100, or P100 filter. (APF = 50) Any supplied-air respirator that has a tight-fitting facepiece and is operated in a continuous-flow mode (APF = 50) Any powered, air-purifying respirator with a tight-fitting facepiece and a high efficiency particulate filter (APF = 50) Any self-contained breathing apparatus with a full facepiece (APF = 50) Any supplied-air respirator with a full facepiece
Up to 50 mg/m ³	(APF = 1000) Any supplied-air respirator operated in a pressure-demand or other positive-pressure mode
Emergency or planned entry into unknown concentrations or IDLH conditions	(APF = 10,000) Any self-contained breathing apparatus that has a full facepiece and is operated in a pressure-demand or other positive-pressure mode (APF = 10,000) Any supplied-air respirator that has a full facepiece and is operated in a pressure-demand or other positive-pressure mode in combination with an auxiliary self-contained positive-pressure breathing apparatus
Escape	(APF = 50) Any air-purifying, full facepiece respirator with an N100, R100, or P100 filter. Any appropriate escape-type, self-contained breathing apparatus

workweek. The ACGIH has listed antimony trioxide production as a suspected source of human carcinogenicity (A2).

MEDICAL MANAGEMENT

Treatment for antimony poisoning follows the same management as that for arsenic intoxication, primarily chelation with British antilewisite (BAL) for extreme exposure, as well as mercaptans such as dimercaptosuccinic acid or dimercaptopropane sulfonic acid (Aaseth, 1983). Stibine intoxication should be treated as arsine exposure.

ARSENIC

JANICE S. LEE AND SANTHINI RAMASAMY

First aid (inorganic and organic arsenic): Eye—irrigate immediately; skin—soap wash immediately; breathing—respiratory support; swallow—medical attention immediately

First aid (arsine): Eye—frostbite; skin—frostbite; breathing—respiratory support

Target organ(s): Liver, kidneys, skin, lungs, lymphatic system (inorganic arsenic); kidneys, liver, thyroid, gastrointestinal tract (organic arsenic)

Occupational exposure limits: OSHA PEL: 0.010 mg/m³ (inorganic arsenic); OSHA PEL: TWA 0.2 mg/m³ (arsine); OSHA PEL: TWA 0.5 mg/m³ (organic arsenic); ACGIH TLV: TWA 0.01 mg/m³ (inorganic arsenic and inorganic arsenic compounds); ACGIH TLV: TWA 0.02 mg/m³ (arsine); NIOSH REL: 0.002 mg/m³ (15 min) (inorganic arsenic and arsine)

Reference values

Inorganic arsenic: EPA MCL: 0.010 mg/l; EPA MCLG: 0; EPA RfD: 0.0003 mg/kg/day; EPA oral cancer slope factor: 1.5 per mg/kg/day; EPA inhalation unit risk: 0.0043 per µg/m³; ATSDR acute oral MRL: 0.005 mg/kg/day; ATSDR chronic oral MRL: 0.0003 mg/kg/day; RIVM TDI: 1.0 µg/kg/day for chronic oral exposures and 1.0 µg/m³ for chronic inhalation exposures; Cal EPA acute RELs: 0.2 µg/m³; Cal EPA chronic RELs: 0.015 µg/m³; Cal EPA inhalation unit risk: 3.3 per µg/m³; Cal EPA inhalation slope factor: 12.0 per mg/kg/day

Arsine: EPA RfC: 0.05 µg/m³; WHO provisional guidance criteria: 0.05 µg/m³; Cal EPA acute RELs: 0.2 µg/m³; Cal EPA chronic RELs: 0.015 µg/m³

Organotin compounds: EPA RfD: 0.03 mg/kg/day for MMA and 0.014 mg/kg/day for DMA; ATSDR intermediate oral MRL: 0.1 mg/kg/day for MMA; ATSDR chronic oral MRL: 0.02 mg/kg/day for DMA

Risk phrases: 23/25-50/53

Toxic by inhalation and if swallowed. Very toxic to aquatic organisms, may cause long-term adverse effects in the aquatic environment

Safety phrases: 20/21-28-45-60-61

When in use, do not eat, drink, or smoke. In case of accident or if you feel unwell, seek medical advice immediately (show the label where possible). This material and/or its container must be disposed of as hazardous waste. Avoid release to the environment. Refer to special instructions/safety data sheets.

BACKGROUND AND USES

Arsenic (As; CAS #7440-38-2) is a brittle solid with a metallic coloring that ranges from silver to gray. It is a naturally occurring element found in the earth's crust, and it cycles rapidly through water, land, air, and living systems. Exposure to it occurs through ingestion, inhalation, and dermal contact.

Arsenic is a metalloid that can exist in the -3, 0, +3, and +5 oxidation states. Arsenic as a free element (0 oxidation state) is rarely encountered in the environment (HSDB, 2005). Compounds that contain arsenic are ranked according to their relative toxicities, depending on the form. Inorganic forms of arsenic, such as arsine gas, are considered more

toxic than its organic forms, such as tributylarsine. These different forms of arsenic determine the solubility of the compound and its vapor pressure.

The arsenic metalloid is used for hardening copper and lead alloys (HSDB, 2005). It is also used in glass manufacturing as a decolorizing and refining agent, as a component of electrical devices in the semiconductor industry, and as a catalyst in the production of ethylene oxide. Arsenic compounds are used as a mordant in the textile industry, for preserving hides, as medicinals, pesticides, pigments, and wood preservatives. The production of chromate copper arsenite (CCA), a wood preservative, accounts for approximately 90% of the domestic arsenic consumption (ATSDR, 2007). However, production of this preservative is being phased out. The uses of inorganic arsenical compounds (e.g., lead arsenite) as pesticides were voluntarily cancelled by the industry during late 1980s and early 1990s. A majority of organoarsenicals are used on cotton and turf as herbicides. Disodium methanearsenite (DSMA), monosodium methanearsenite (MSMA), and calcium methanearsenite (CAMA) continue to be used as contact herbicides.

Arsenic naturally comprises approximately 3.4 parts per million (ppm) of the earth's crust, where it is the twentieth most abundant element (ATSDR, 2007; The Merck Index, 1989). Arsenic leaches from the natural weathering of soil and rock into water; and low concentrations of arsenic are found in water, food, soil, and air. However, industrial activities such as coal combustion and smelting operations release higher concentrations of arsenic into the environment (Adams et al., 1994). The highest background arsenic levels found in the environment are in soils, with concentrations ranging from 1 to 40 ppm (ATSDR, 2007). Food typically contains total arsenic concentrations of 20–140 parts per billion (ppb), with inorganic arsenic levels being much lower (ATSDR, 2007). The majority of surface and ground waters contain <10 ppb (although levels of 1000–3400 ppb have been reported, especially in areas of the western United States) (ATSDR, 2000). The average arsenic content in drinking water in the United States (U.S.) is 2 ppb with 12% of the water supply from surface water in central portions of the United States and 12% of groundwater sources in western portions of the United States exceeding 20 ppb (ATSDR, 2007). Mean arsenic concentrations in ambient air have generally been found to range from 1 to 2000 ng/m³ (ATSDR, 2007).

PHYSICAL AND CHEMICAL PROPERTIES

Arsenic (As) is the third element in Group VA of the periodic table. Elemental arsenic can be found in two solid forms: yellow and gray or metallic, with specific gravities of 1.97 and 5.73, respectively (CRC, 1999). Gray arsenic is the

ordinary stable form. Arsenic compounds can be categorized as inorganic and organic. Inorganic compounds do not contain an arsenic–carbon bond while organic compounds do. Chemical and physical properties of inorganic arsenic and selected organic arsenic compounds are listed in Table 7.1.

MAMMALIAN TOXICOLOGY

Acute Effects

The effect of acute exposure to arsenic in an industrial setting is local irritation on the skin, mucous membranes, and conjunctivae, wherever the dust is deposited. Tissue necrosis may also occur. Moist surfaces such as the lips, nares, eyelids, pharynx, and scrotum suffer the most. Another manifestation of acute arsenic exposure is the latent appearance of horizontal white bands, called Mee's lines, across the nails as a result of injury to the nail bed. Mee's lines may be visible in the fingernails several weeks to months after acute arsenic poisoning (Rossman, 2007).

Other exposures often are associated with ingestion of contaminated food, usually intentional. Major symptoms of this type of exposure are gastrointestinal inflammation and irritation with possible hemorrhage. Signs and symptoms include abdominal pain, vomiting, watery diarrhea, low blood pressure, and pulse irregularity, all similar to the signs of cholera (Landrigan, 1981). These symptoms can result in stupor, convulsions, coma, and death. Franzblau and Lilis (1989) described two cases of acute arsenic poisoning caused by contaminated well water. In addition to gastrointestinal effects, some neurological and hematopoietic effects were observed.

After acute ingestion, a delayed sensorimotor peripheral neuropathy may occur. Electrophysiological studies in cases that followed a single exposure showed axonal degeneration (Le Quesne and McLeod, 1977). Common symptoms include numbness and tingling of the hands and feet in a stocking-and-glove symmetrical distribution. Motor weakness of the distal extremities may develop and is distinguishable from the effects of lead poisoning by the severe neuralgic pain. Neuropathy may develop whether exposure is inhalation, ingestion, or cutaneous absorption.

Arsine The principal effect of arsine poisoning is intravascular hemolysis. Varying periods of time elapse after inhalation of the gas before the destruction of red cells results in clinical manifestations. Such intervals have been reported as ranging from 6 to 36 h or longer, depending on the severity and length of exposure. The initial symptoms of headache, malaise, weakness, dizziness, and dyspnea are followed by abdominal pain, nausea, and vomiting (Fowler and Weissberg, 1974). These acute symptoms are followed in 4–6 h by the passage of dark or bloody urine, often the first symptom

TABLE 7.1 Chemical and Physical Properties of Inorganic Arsenic and Selected Organic Arsenic Compounds

Properties	Arsenic	Dimethylarsinic Acid	Methanearsonic Acid	Disodium Methanearsonate	Sodium Methanearsonate
Molecular weight	74.9216	138.00	139.97	183.93	161.95
Color	Silver-gray or tin-white	Colorless	White	White	White
Physical state	Solid	Solid	Solid	Solid	Solid
Melting point	817 °C (triple point)	195 °C	160.5 °C	>355 °C	130–140 °C
Boiling point	603 °C (sublimes)	>200 °C	—	—	—
Density	5.778 g/cm ³	—	—	1.04 g/cm ³	1.55 g/ml
Odor	Odorless	Odorless	—	—	Odorless
Solubility:

—: No data.

that alarms the victim. Jaundice appears later, after 24–48 h, and the red cell count may fall below 2 million. Jones (1907) described the triad of abdominal pain, hemoglobinuria, and jaundice as characteristic of arsine poisoning. Findings during the physical examination include fever, tachycardia, tachypnea, jaundice, and abdominal tenderness, especially of the enlarged liver. Hemolytic anemia is evidenced by the low hemoglobin values and by the presence of reticulocytosis, red cell fragments, and ghost cells. Toxic granules may be found in the leukocytes. Plasma hemoglobin may be present at concentrations as high as 2 mg/dl. Urinalysis reveals the presence of both hemoglobin and arsenic. Hong et al. (1989) demonstrated similar effects in mice exposed to low concentrations of arsine gas. A decline in the red cell count and hemoglobin level correlated with increasing concentrations.

Arsine intoxication is differentiated from acute poisoning with nitro and amido derivatives of benzene by the absence of methemoglobin formation and cyanosis. A valuable observation that confirms the direct toxic action of arsine on the cardiac muscle has been provided by the reports of lowered T waves or inversion of T waves on the electrocardiogram (Weinberg, 1960). Such changes may persist for 2 months after apparent recovery.

The pulmonary edema that occurs secondary to the effects of arsine on cardiac muscle and the dilation of the heart caused by anemia resulting from hemolysis require heroic measures. Early death after acute arsine poisoning may be the result of myocardial failure accompanied by massive pulmonary edema that precedes the onset of renal failure.

Organotoxins MSMA, DSMA, CAMA, and DMA have moderate to low acute toxicity via the oral, dermal, and inhalation routes ($LD_{50} \sim 2000$ mg/kg and above; $LC_{50} > 2$ mg/l). They have slight or negligible irritant properties to the eye and skin and are not sensitizers (USEPA, 2006).

Chronic Effects and Cancer

Arsenic has been associated with a number of health hazards, including several cancers, skin lesions, cardiovascular disease, diabetes mellitus, anemia and other hematological changes, neurological symptoms, respiratory changes, and immunotoxicity. Chronic occupational and environmental contact with arsenical compounds has been associated with dermatitis (Holmquist, 1951). Chronic oral arsenic exposure is associated with hyperpigmentation, depigmentation, keratosis, and peripheral vascular disorders (NRC, 1999). One

report by Juhlin and Ortonne (1986) links chronic arsenic exposure in a vineyard worker to the darkening of scalp hair from reddish to dark brown. High levels of arsenic were also detected in the vineyard worker's hair. With several compounds and possible exposure routes available for arsenic, the chronic toxicity of this element varies by organ. Cancers of the skin, bladder, liver, and lung can also result from chronic arsenic exposure, in addition to cardiovascular and neurological diseases.

Occupational studies have reported excess risk of lung cancer from inhalation of arsenic (Enterline et al., 1987; Jarup et al., 1989; Lee-Feldstein, 1986; Ott et al., 1974; Taylor et al., 1989). Data from these studies suggest that the risk of lung cancer after inhalation of inorganic arsenic compounds increases with higher concentrations (NRC, 1999). Respiratory disease is also a common hazard in the smelting of metals, in which arsenical compounds are released. Lundgren et al. (1951) studied 1500 Swedish smelter workers exposed to both arsenic trioxide and sulfur dioxide. These researchers described the occurrence of Rönnskär disease, a worker illness named for the location of the smelter. In contrast to the controls, the exposed men suffered chronic upper respiratory tract disease. A hoarse voice is characteristic of an arsenic worker, and a perforated nasal septum is an occupational sign of the worker who handles arsenic trioxide. After short periods of exposure, the workers notice nasal obstruction, with consequent mouth breathing, and usually some inflammation in the pharynx and larynx, soreness of the tongue, and excessive salivation. Sloughing of the mucous membrane and necrosis of the nasal cartilage may follow. The bony septum is not involved. Inflammation and noncancerous lesions may occur in chronically exposed workers, although cancer mortality is the most studied chronic effect of the respiratory system.

One of the first studies to link arsenic exposure to lung cancer was reported by Lee and Fraumeni in 1969. This study examined 8047 white male smelter workers exposed to arsenic trioxide and found they were three times more likely to develop respiratory cancer than the general population. More recent studies have found similar associations with respiratory cancers in populations of workers in the gold and copper smelting industries (Enterline et al., 1995; Kabir and Bilgi, 1993; Simonato et al., 1994; WHO, 2001). In addition to respiratory cancers, exposure of smelter workers to arsenic has been associated with cancers of the kidney, digestive tract, and lymphatic and hematopoietic systems. Glass workers, hat makers, and pesticide workers exposed to arsenic also have reported excesses of lung and skin cancer (IARC, 1973, 1980).

There are many regions in the United States and abroad that have arsenic in their drinking water at concentrations >100 µg/l. Parts of Maine, Michigan, Minnesota, South Dakota, Oklahoma, and Wisconsin have widespread arsenic concentrations exceeding 10 µg/l (Welch et al., 1999). Populations in Taiwan, Mexico, India, and Chile who consumed

drinking water with high levels of arsenic had high rates of skin cancer (Tseng et al., 1968; Cebrian et al., 1983; Chakraborty and Saha, 1987; Zaldivar, 1974). Elevated rates of liver cancer deaths were found in an area of southwestern Taiwan with high levels of arsenic in the artesian well water supply (Chen et al., 1988; Wu et al., 1989). Elevated rates of lung cancer were found in areas of Argentina with high levels of arsenic in drinking water (Tello, 1986; Biagini et al., 1978). Chen et al. (1988) also found an increase in bladder and kidney cancer with increasing arsenic concentrations. In addition, a few studies have suggested that exposure to arsenic in drinking water is associated with prostate cancer in men and nasal cancer in both men and women (Cantor, 1997).

Neurological effects associated with chronic arsenic exposure may involve a peripheral neuropathy, which may evolve into a sensorimotor distal axonopathy. Mayers (1954) reported a case of peripheral neuropathy in a worker exposed for 20 years to inhalation and skin contact of Paris green. Heyman et al. (1956) reported arsenical neuropathy in seven farm workers exposed occupationally to arsenate sprays or dust. Peripheral and subclinical neuropathies were also noted in arsenic smelter workers by Feldman et al. (1979) and Blom et al. (1985). An assessment of workers chronically exposed to inorganic arsenic found lower motor nerve conduction velocity among the workers compared to the nonexposed control group (Lagerkvist and Zetterlund, 1994). The authors concluded that arsenical neuropathies are dependent on long-term exposure. Recovery from neurological effects from chronic exposure to arsenic may take years.

Vascular effects associated with arsenic have not been seen among occupationally exposed groups. Characteristic vascular effects include peripheral vascular disease (e.g., blackfoot disease), cardiovascular-related mortality, atherosclerosis, QT abnormalities, and elevated blood pressure.

Hematopoietic effects, most often involving a reversible bone marrow suppression with pancytopenia, are noted with chronic exposure. Anemia, leukopenia, eosinophilia, thrombocytopenia, and basophilic stippling also are common hazards in this type of exposure (Ringenberg et al., 1988). Aplastic anemia followed by acute myelogenous leukemia has also been reported (Kveldsberg and Ward, 1972).

The developmental toxicity associated with arsenic has been reviewed, and, although arsenic is teratogenic in some experimental animals, occupational exposure levels and routes of exposure have not been linked to human teratogenic effects (Domingo, 1994). However, drinking water studies in humans have shown an association between arsenic in drinking water and congenital heart defects (Engel and Smith, 1994; Zierler et al., 1988).

Arsine Chronic exposure to arsine has been reported in workers employed in the cyanide extraction of gold (Bulmer et al., 1940). These workers showed a progressive reduction

in erythrocyte levels and hemoglobin values, marked basophilic stippling, and an elevation of urine arsenic. They had exertional dyspnea and the weakness typical of anemia. These chronic effects are similar to those associated with acute exposure to arsenic.

Organoarsenicals No human studies have been found in the literature relating to organoarsenical poisoning. Animal studies suggest the target organs following oral exposure to MMA (MSMA, DSMA, CAMA) as the gastrointestinal tract, particularly the large intestine, and kidney (USEPA, 2006). The target organs following oral exposure to DMA (cacodylic acid) are believed to be the bladder and thyroid in animals (USEPA, 2006). The IARC classifies MMA and DMA as “possibly carcinogenic to humans” (Group 2B) (Straif et al., 2009).

Mechanism of Action(s)

The metabolism of inorganic arsenic in humans occurs through alternating steps of reduction and oxidative methylation mostly to DMA^V. Less toxic species (i.e., As^V, MMA^V, and DMA^V) can be converted to more toxic species (i.e., As^{III}, MMA^{III}, and DMA^{III}). The trivalent species have been found to be more cytotoxic, genotoxic, and more potent inhibitors of enzyme activity (Thomas et al., 2001). The trivalent methylated metabolites, such as MMA^{III} and DMA^{III}, may play a role in arsenic-mediated health effects along with inorganic arsenic.

Although arsenic has been associated with altering numerous key events (e.g., reactive oxygen species (ROS), changes in genes/proteins, proliferation, or apoptosis), no specific mode of action (MOA) has been identified for any of the noncancer effects. However, the various effects associated with arsenic exposure indicate possible multiple MOAs. The MOA for arsenic carcinogenicity has not been established (NRC, 1999). Possible MOAs for arsenic carcinogenesis include chromosome abnormalities, oxidative stress, altered growth factors, cell proliferation, promotion and/or progression in carcinogenesis, altered DNA repair, p53 gene suppression, altered DNA methylation patterns, and gene amplification (Kitchin, 2001). The MOAs for arsenic may depend on the following biochemical events: (1) binding of trivalent arsenicals to tissue targets such as sulfhydryl groups and/or selenium atoms; (2) formation of superoxide, hydrogen peroxide, and other ROS; and/or (3) hypomethylation of DNA (Kitchin and Conolly, 2010). It is not clear which arsenic species and key events are most important in the target organs because mechanisms of arsenic carcinogenesis in the organs may be quite different.

Chemical Pathology

Arsenic exposure is associated with skin pathology, including hyperpigmentation, hyperkeratosis, and skin cancers

(Centeno et al., 2000; Heyman et al., 1956). Liver pathology, not as well described, includes noncirrhotic portal hypertension (Nevens et al., 1990), hepatic enlargement, hepatocellular carcinoma (Centeno et al., 2000), and liver angiosarcoma (Neshiwat et al., 1992). Long-term arsenic exposure has also been found to be associated with peripheral vascular diseases (Yu et al., 2002).

Hyperpigmentation of the skin in patches is a common occurrence with arsenic toxicity. The patch is dark brown with lighter brown spots. Arsenical hyperkeratosis manifests itself as small, corn-like lesions that typically are benign but that may become precancerous and resemble lesions associated with Bowen’s disease. Persistence of the skin lesions with hyperpigmentation may result in a basocellular carcinoma or arsenical keratosis even after exposure has been eliminated (Alain et al., 1993).

Three distinct cancers of the skin have been associated with chronic exposure to arsenic, namely, Bowen’s disease, basal cell carcinoma, and squamous cell carcinoma. These are all thought to develop secondary to arsenical keratoses (Landrigan, 1981).

Although chronic ingestion of arsenic has been reported to lead to cirrhosis of the liver and to noncirrhotic portal hypertension (Huet et al., 1975; Morris et al., 1974; Cowlishaw et al., 1979), there are a few documented cases of liver cirrhosis that occurred as a result of industrial exposure to arsenic. Jhaveri (1959) reported a case of primary liver carcinoma associated with liver cirrhosis in a man who had handled arsenous oxide and sodium arsenate for more than 20 years in a chemical plant.

Blackfoot disease, an arterial disease with dry gangrene of the lower extremities due to chronic arsenic poisoning, has been endemic in Taiwan. It has been associated with the ingestion of high concentrations of arsenic in drinking water. The pathology of blackfoot disease includes thickening and fibrinoid necrosis of subcutaneous arterioles.

SOURCES OF EXPOSURE

Occupational

Unlike the environmental exposures, where the health concerns are mainly to arsenite/arsenate from oral exposures (e.g., drinking water, food), occupational exposures can occur from many types of arsenic compounds introduced via inhalation and dermal contact. Dermal exposure has been reported from application and handling of pesticides containing arsenicals (e.g., copper chromated arsenic-treated wood). Differences in the exposure routes, metabolism, disposition, and toxicity of these various arsenical compounds in occupational settings (inorganic arsenic oxides, organoarsenicals, arsine, arsenides) must be considered in evaluating the health concerns of the workers (Carter et al., 2003).

U.S. production of arsenic compounds (e.g., arsenic trioxide) ceased in 1985, thus now all arsenic consumed in the United States is imported. Arsenic is imported mainly from China and to some extent from other countries. In 2005, the United States remained the major consumer of arsenic compounds. About 65% of domestic consumption of arsenic trioxide was used for the production of CCA used in wood preservatives. The remainder was used for the production of agricultural chemicals, including herbicides and insecticides (ATSDR, 2007). The use of arsenic compounds as pesticides has been reduced in the past few years due to voluntary cancellation of residential uses of CCA-treated wood (USEPA, 2008). However, copper chromated arsenic-treated wood is still used in industrial and agricultural settings. The United States Environmental Protection Agency (EPA) has also made restrictions on herbicidal uses of organoarsenicals (USEPA, 2006). With the increased use of arsenic in electronic industries, occupational exposures from arsenide (e.g., gallium arsenide) are likely; however, the toxicities of these arsenides are not well studied.

Exposures to arsenical compounds are commonly monitored by measuring total or speciated arsenicals in urine. Speciated arsenicals are preferred in exposure assessment to differentiate background arsenic exposures from food (e.g., arsenobetaine in seafood) to that introduced by occupational exposures. Arsenical exposures are also measured in blood to a limited extent. Because inorganic arsenic binds to sulphydryl groups, keratin-rich tissues such as skin, hair, and nails, may also serve as indicators of arsenic exposures. However, external contamination may pose a problem in interpretation of the results (ATSDR, 2007).

The World Health Organization (WHO) reported a wide range of airborne arsenic concentrations in various departments of smelter operations (WHO, 2001). The exposure levels may vary depending upon the departments, the operations, and industrial hygiene measures. Farmer and Johnson (1990) measured total and speciated arsenic in urine samples collected from workers in different types of United Kingdom industries. Mean urinary arsenic (total arsenic) concentrations ranged from 4.4 µg/g creatinine for controls to <10 µg/g for those in the electronics industry, 47.9 µg/g for timber treatment workers applying arsenical wood preservatives, 79.4 µg/g for a group of glassworkers using arsenic trioxide, and 245 µg/g for chemical workers engaged in manufacturing and handling inorganic arsenicals. The speciation measurements of arsenic in urine samples for the most exposed groups indicate 1–6% As(V), 11–14% As(III), 14–18% monomethylated metabolite, and 63–70% dimethylarsinic acid. In another study conducted in the United Kingdom, evidence of increased urinary levels of total inorganic arsenic from timber treatment workers exposed to CCA wood preservatives were reported, after adjusting for seafood intake, compared to control subjects (Cocker et al., 2006). The urine and blood arsenic concentrations were also increased in

incinerator workers compared to control subjects (Chao and Hwang, 2005).

In addition to urinary arsenic measurements, other urinary biomarkers have been examined in arsenic-exposed workers. These other biomarkers may not be specific to arsenic since other pollutants may influence these effects. For example, increased urinary excretion of porphyrins (uroporphyrin and coproporphyrin) has been reported in 84 smelter workers (Feldman et al., 1979; Telolahy et al., 1993). Also, 8-oxodGuo (e.g., 8-oxo-7,8-dihydro-2'-deoxyguanosine), biomarker of oxidative DNA damage, was found elevated in urine samples from 50 smelter workers compared to 40 unexposed workers (Blom et al., 1985; Hu et al., 2006). In this study, Hu et al. (2006) demonstrated a positive correlation between 8-oxodGuo and monomethyl arsenic acid in urine as well as primary methylation index, supporting the existing evidence that accumulation of monomethyl arsenic may play a significant role in arsenic-mediated adverse effects. A positive association between blood arsenic levels and DNA damage in leukocytes and increased frequency of micronuclei in buccal cells was reported in glass workers (Vuyyuri et al., 2006). The measurement of biomarkers of oxidative damage is less commonly used in biomonitoring compared to measuring urinary arsenic and its metabolites in workers.

Environmental

Arsenic occurs naturally in a wide range of minerals in soils. It is the main constituent of more than 200 mineral species, and the most common of the arsenic minerals is arsenopyrite. It has been estimated that about one-third of the atmospheric flux of arsenic is of natural origin. Volcanic action is the most important natural source of arsenic, followed by low temperature volatilization. Mining, smelting of nonferrous metals, and burning of fossil fuels are the major industrial processes that contribute to anthropogenic arsenic contamination of the air, water, and soil. Concentrations of arsenic in air in remote locations range from <1 to 3 ng/m³, but concentrations in cities may range up to 100 ng/m³. Arsenic levels in groundwater average about 1–2 µg/l, except in areas with volcanic rock and sulfide mineral deposits where arsenic levels can range up to 3400 µg/l (Ferreccio et al., 2000). Surveys of arsenic concentrations in rivers and lakes indicate that most values are below 10 µg/l (WHO, 2010). Concentrations of arsenic in open ocean water are typically 1–2 µg/l. Drinking water in the United States generally contains an average of 2 µg/l of arsenic. Natural levels of arsenic in soil range from 1 to 40 mg/kg, with a mean of 5 mg/kg, with much higher levels occurring in mining areas, at waste sites, near high geological deposits of arsenic-rich minerals, or from pesticide application (ATSDR, 2007). Sediments in aquatic systems often have higher arsenic concentrations than that of water. Most sediment arsenic concentrations reported for

rivers, lakes, and streams in the United States range from 0.1 to 4000 mg/kg, with higher levels occurring in areas of contamination (Franzblau and Lilis, 1989). Arsenic concentrations of <10,000 mg/kg (dry weight) were found in surface sediments near a copper smelter (ATSDR, 2007; WHO, 2001). Arsenic is also found in many foods at concentrations ranging from 20 to 140 µg/kg. Total arsenic concentrations may be substantially higher in certain seafoods. The general impression in the literature is that about 85 to >90% of the arsenic in the edible parts of marine fish and shellfish is organic arsenic (e.g., arsenobetaine, arsenocholine, dimethylarsinic acid) and that approximately 10% is inorganic arsenic (USEPA, 2003).

Environmental Fate and Bioaccumulation

In soil there are many biotic and abiotic processes controlling arsenic's overall fate and environmental impact. Arsenic in soil exists in various oxidation states and chemical species, depending upon the soil pH and oxidation-reduction potential (ATSDR, 2007). It is largely immobile in agricultural soils and tends to remain in upper soil layers (ATSDR, 2007). However, reducing conditions form soluble mobile forms of arsenic and leaching is greater in sandy soil than in clay loam (ATSDR, 2007). Mobility of arsenicals is typically very low to intermediate and sorption is higher in soils with higher percentage of clay or with more iron or aluminum content (USEPA, 2006).

Transport and partitioning of arsenic in water depends upon the chemical form of the arsenic and on interactions with other materials present (ATSDR, 2007). Under normal conditions in water, arsenic is present as soluble inorganic As^V because it is thermodynamically more stable in water than As^{III}. Soluble forms may be carried long distances through rivers, but arsenic may also be adsorbed from water onto sediments or soils, especially clays, iron oxides, aluminum hydroxides, manganese compounds, and organic material (USEPA, 1979, 1982b; Welch et al., 1988). Groundwater arsenic concentrations are usually controlled by adsorption rather than by mineral precipitation under oxidizing and mildly reducing conditions (ATSDR, 2007).

High temperature processes, such as coal and oil combustion, smelting operations, and refuse incineration, contribute to most of the anthropogenic arsenic emitted into the atmosphere (Pacyna, 1987). These fine particles, with a mass median diameter of about 1 µm, can reside in the atmosphere for about 7–9 days and be transported thousands of kilometers by wind and air currents until they are returned to earth by wet or dry deposition (Pacyna, 1987). Atmospheric fallout can also be a significant source of arsenic in coastal and inland waters near industrial areas (ATSDR, 2007).

Terrestrial plants may accumulate arsenic by root uptake from the soil or by absorption of airborne arsenic deposited on the leaves (USEPA, 1982a). Pitten et al. (1999) found that

when plants were grown on soils high in arsenic, the arsenic level taken up by the plants remained comparably low. Arsenic speciation affects arsenic accumulation in plants. Arsenic uptake increases with increasing arsenic concentration, with organic arsenicals showing higher upward translocation than the inorganic arsenical (Burlo et al., 1999; Carbonell-Barrachina et al., 1999).

Arsenic bioaccumulation depends on the environmental setting, organism type, trophic status within the aquatic food chain, exposure concentrations, and route of uptake (Williams et al., 2006). Bottom-feeding and predatory fish can accumulate arsenic found in water, with arsenic mainly accumulating in the exoskeleton of invertebrates and in the livers of fish (ATSDR, 2007).

Organoarsenicals Unlike other pesticides that degrade over time, MSMA, DSMA, CAMA, and cacodylic acid (DMA) contain elemental arsenic that does not degrade. The extent and speed of transformation and redistribution of the organic arsenical herbicides in soil is highly variable and depends mostly on the localized environmental conditions. Thus, persistence of applied organic arsenical herbicides can range from days to years, depending on the soil properties and ambient conditions such as soil moisture, temperature, chemical concentration, bacterial population, and amount of organic matter. Environmental fate studies show that organic arsenicals are stable and do not degrade by hydrolysis or by aquatic or soil photolysis. However, soil microorganisms could convert the organoarsenicals to inorganic arsenic and add to the background arsenic levels in the environment (USEPA, 2006).

Potential metabolites of applied organic arsenicals include volatile alkylarsines and inorganic arsenic (as arsenate or arsenite) along with carbon dioxide. Transformation to volatile alkylarsines is the only metabolism route that would directly reduce soil arsenic loading. This transformation has been shown to be possible in certain circumstances but is generally not expected to be a major route of dissipation.

Ecotoxicology

Acute Effects and Chronic Effects In general, inorganic arsenicals are more toxic than organoarsenicals, and arsenite is more toxic than arsenate. Arsenic compounds cause acute and chronic effects in individuals, populations, and communities at concentrations ranging from a few micrograms to milligrams per liter, depending on species, time of exposure, and end points measured. These effects include lethality, inhibition of growth, photosynthesis and reproduction, and behavioral effects (USEPA, 1985; IPCS, 2001).

The mode of toxicity and mechanism of uptake of arsenate differ greatly from organism to organism (WHO, 2001). This may explain why there are interspecies differences in organism response to arsenate and arsenite. The primary

TABLE 7.2 Permissible and Recommended Exposure Limits for Arsine and Arsenic Compounds

Arsenic Compounds	CAS Number	PEL	TLV/BEI	REL/IDLH	ERPG
Arsine	7784-42-1	0.2 mg/m ³ (OSHA, 2014a)	TLV 0.02 mg/m ³ (ACGIH, 2010)	REL: 0.002 mg/m ³ IDLH: 3 ppm NIOSH, 2007	ERPG(1) N/A; ERPG(2) 2.00 mg/m ³ (without serious, adverse effects); ERPG(3) 6.00 mg/m ³ (not life threatening) each up to 1 h exposures (AIHA, 2014)
Arsenic and inorganic arsenic compounds	7440-38-2	0.01 mg/m ³ (OSHA, 2014b)	TLV 0.01 mg/m ³ BEI: 35 µg As/l in urine (ACGIH, 2010)	REL: 0.002 mg/m ³ IDLH 5 mg/m ³	N/A
Organic arsenic compounds*		0.5 mg/m ³ (OSHA, 2014a)	N/A	N/A	N/A

PEL: permissible exposure limit; TLV: threshold limit value; REL: recommended exposure limit; IDLH: Immediately Dangerous to Life or Health; ERPG: Emergency Response Planning Guidelines; OSHA: Occupational Safety and Health Administration; ACGIH: American Conference of Governmental Industrial Hygienists; AIHA: The American Industrial Hygiene Association; *: Value for organic arsenic is based on inorganic arsenic.

mechanism of arsenite toxicity is considered to result from its binding to protein sulphhydryl groups. Arsenate is known to affect oxidative phosphorylation by competition with phosphate. In environments where phosphate concentrations are high, arsenate toxicity to the biota is generally reduced. As arsenate is a phosphate analog, organisms living in elevated arsenate environments must acquire the nutrient phosphorous yet avoid arsenic toxicity (IPCS, 2001).

The freshwater residue data indicate that arsenic is not bioconcentrated but that lower forms of aquatic life may accumulate higher arsenic residues than fish (USEPA, 1982b). Recently, Culioli (2009) reported that the accumulation of arsenic decreased with increasing trophic level after testing the macroinvertebrates, bryophytes, and fish tissues.

INDUSTRIAL HYGIENE

ACGIH (2010) classifies elemental arsenic and inorganic arsenic compounds as confirmed human carcinogen (A1). NIOSH (2009) classifies elemental arsenic and inorganic arsenic compounds as potential occupational carcinogen. Table 7.2 lists the permissible and recommended exposure limits for arsine and arsenic compounds.

RISK ASSESSMENTS

The regulatory levels as well as the toxicity values determined for inorganic and organoarsenical compounds by various government agencies and organizations are listed below.

U.S. EPA

Inorganic Arsenic The U.S. EPA published the maximum contaminant level (MCL) of 0.01 mg/l (10 ppb) and maximum contaminant level goal (MCLG) of zero for arsenic on January 22, 2001 (USEPA, 2001). The MCL for arsenic was set at the level at which lung and bladder cancer reduction benefits were maximized at a cost that was justified by the benefits.

The reference dose (RfD) for inorganic arsenic for oral exposure is 0.0003 mg/kg/day, and this is based on hyperpigmentation, keratosis, and possible vascular complications in a large number of southwest Taiwanese subjects from blackfoot disease endemic area for arsenic (USEPA, 1993). The EPA concluded that inorganic arsenic is a human carcinogen from oral and inhalation exposures. An oral cancer slope factor for inorganic arsenic of 1.5 per mg/kg/day was derived based on skin cancers observed in a large Taiwanese cohort exposed to arsenic via drinking water (USEPA, 1993). A chronic reference (RfC) concentration for arsenic exposure via inhalation was not provided. The inhalation unit risk was determined as 0.0043 per µg/m³ based on the respiratory cancer mortality observed in smelter workers. This cancer risk estimate corresponds to the air arsenic concentration of 0.0002 µg/m³ for 1 in 1,000,000 cancer risk.

Arsine The U.S. EPA Integrated Risk Information System (IRIS) assessment indicates the chronic inhalation reference concentration of 0.05 µg/m³ based on increased hemolytic effects and spleen changes in animal models (USEPA, 1994).

Organic arsenicals The U.S. EPA Office of Pesticide Programs (USEPA, 2006) derived a chronic RfD of 0.03 mg/kg/day for MMA based on decreased body weights, diarrhea, body weight gains, food consumption, histopathology of gastrointestinal tract and thyroid in rats, and 0.014 mg/kg/day for DMA based on regenerative proliferation of the bladder epithelial tissue in rats. For carcinogenicity effects, EPA determined that there was “no evidence for carcinogenicity” for MMA and that DMA was “not carcinogenic at doses that do not result in enhanced cell proliferation” (USEPA, 2006).

ATSDR

No inhalation risk levels were determined for inorganic or organic arsenical compounds. However, ATSDR (2007) determined oral toxicity values for potential noncancer effects associated with exposure to inorganic and organic arsenical compounds. The acute oral minimal risk level (MRL) for inorganic arsenic was determined as 0.005 mg/kg/day based on edema of the face and gastrointestinal effects (nausea, vomiting, diarrhea) observed in humans exposed to arsenic-contaminated soy sauce in Japan. The chronic oral MRL of 0.0003 mg/kg/day was based on skin lesions (hyper pigmentation and hyperkeratosis) observed in southwest Taiwanese populations exposed to arsenic in drinking water. ATSDR (2007) derived an intermediate oral MRL for MMA of 0.1 mg/kg/day based on diarrhea observed in rats and a chronic oral MRL of 0.01 mg/kg/day based on progressive glomerular nephropathy observed in mice. The chronic oral MRL for DMA was derived as 0.02 mg/kg/day based on vacuolization of the urothelium in the urinary bladder in female mice.

RIVM

Baars (2001) determined the tolerable daily intake (TDI) of 1.0 µg/kg/day for chronic oral exposures and the tolerable concentration in air as 1.0 µg/m³ for chronic inhalation exposures for inorganic arsenic.

Other Standard Regulations and Guidelines

As a collaborative effort with public and private sectors in handling emergency situations, the U.S. EPA (USEPA, 2010) has derived the acute exposure guideline levels (AEGLs) for arsine and these values are presented in Table 7.3.

WHO

WHO guidance criterion for arsine was derived as 0.05 µg/m³ based on the hematological effects observed in animal models (WHO, 2002). WHO recommends a provisional

TABLE 7.3 Acute Exposure Guideline Levels (AEGLs) for Arsine

Arsine Exposure Time	AEGL 1 (ppm) (Discomfort)	AEGL 2 (ppm) (Impaired Escape)	AEGL 3 (ppm) (Life Threatening/ Death)
10 min	NR	0.3	0.91
30 min	NR	0.21	0.63
1 h	NR	0.17	0.5
4 h	NR	0.04	0.13
8 h	NR	0.02	0.06

Source: USEPA (2010).

guideline for drinking water of 10 ppb because of scientific uncertainties in the assessment (WHO, 2010).

Cal EPA

The Cal EPA has determined the acute inhalation reference exposure level as 0.2 µg/m³ and the chronic inhalation reference exposure level as 0.015 µg/m³ for inorganic arsenic compounds, including arsine (CalEPA, 2008). The inhalation unit risk for inorganic arsenic is determined as 0.0033 per µg/m³. The inhalation slope factor is 12.0 per mg/kg/day based on lung tumors observed in smelter workers (CalEPA, 2009).

BARIUM

MARIE M. BOURGEOIS

First aid: Skin: Remove contaminated clothing; wash skin with plenty of water and soap. Eyes: Flush eyes with plenty of water. Inhalation: Fresh air, administer oxygen, if necessary. Ingestion: Rinse mouth; induce vomiting in conscious patients, seek medical attention immediately

Target organ(s): Respiratory system, eye, skin, immune system (allergic reactions), central nervous system, and heart

Occupational exposure limits: OSHA PEL: 0.5 mg/m³ (soluble compounds), 15 mg/m³ (barium sulfate dust), TLV: 0.5 mg/m³ as TWA A4 (not classifiable as a human carcinogen); (ACGIH, 2008). EU OEL: 0.5 mg/m³ as TWA (EU 2006)

IDHL barium chloride levels of 50 mg/m³ (NIOSH)

Reference values: 0.56 mg/kg/day with UF of 300

Risk phrases: 11–14/15

Flammable. Reacts violently with water, liberating highly flammable gases

Safety phrases: 7/8–30–43

Keep container tightly closed and dry. Never add water to this product

BACKGROUND AND USES

Barium (symbol Ba; CASRN 7440-39-3) is a dense, silver-white metal that oxidizes rapidly in air, assuming a silver-yellow color, when present in its elemental state. The TSCA inventory, established by the Toxic Substances Control Act of 1976, lists more than 270 compounds containing barium. Barium is naturally found in two minerals, barytes, or barite (“heavy spar”) (BaSO_4), and witherite (BaCO_3). Witherite is no longer mined

for commercial purposes. Some barium compounds are soluble in water (barium sulfide, barium chloride, barium hydroxide), but the more common compounds found in nature (barium sulfate and barium carbonate) are less soluble.

Barium is commonly used in the manufacture of cathode ray tubes in the form of barium–aluminum alloy evaporation getters (gas absorbers) (HSDB, 2010). Barium sulfate ore is used primarily in the petroleum industry, in which it is used for drilling muds, which act as lubricants. It also has been used in the manufacture of lithopone, a white pigment used in the paint industry. Barium is used for metal alloys (barium nickel) in spark plugs, as filler for paper, and in textiles, leather, soap, rubber, and linoleum. Compounds such as barium chloride, barium hydroxide, and barium carbonate are used in saltwater-resistant cement, in the manufacture of ceramics and glass, and in pesticides, rodenticides, and dyestuffs. Barium nitrate and barium chlorate produce a green color in pyrotechnics. Barium sulfide phosphoresces following exposure to the light making it ideal for fluorescent lamps. Wool used for stuffing mattresses is treated with barium chloride (BaCl_2), which makes the wool whiter, more elastic, and more moth resistant. Barium chloride also has been used in the electronics industry to remove gases from vacuum tubes. Barium compounds (e.g., barium sulfate) are used in the medical industry for radioimaging, because they are radiopaque, extremely insoluble, and essentially nontoxic in humans. Radioactive barium isotopes are useful as bone-scanning agents in the study of bone metabolism.

PHYSICAL AND CHEMICAL PROPERTIES

Barium is a dense alkaline earth metal in Group IIA of the periodic table found at concentrations ranging from 15 to

TABLE 8.1 Chemical and Physical Properties of Barium

Characteristic	Information
Chemical name	Barium
Synonyms/trade names	Bario, baryum, bario [Spanish], baryum [French], barium, soluble compounds, barium and soluble compounds, HSDB 4481, EINECS 231-149-1
Chemical formula	Ba
CASRN	7440-39-3
Molecular weight	137.33 g/mol
Melting point	725 °C
Boiling point	1640 °C
Vapor pressure	2 mmHg at 20 °C
Density/specific gravity	3.5 g/cm ³ at 20 °C
Flashpoint	Not available
Water solubility at 25 °C	Reacts with water; slightly soluble in ethanol
Explosion limits	Not available
Octanol/water partition coefficient (log K _{ow})	Cannot be estimated
Henry's law constant	Not available
Odor threshold	Odorless
Conversion factors	Not available

Source: NIOSH (2010).

3500 parts per million (ppm), dry weight. It is a naturally occurring component of the Earth's crust, particularly in areas rich in sandstone, shale, igneous rock, and coal. Under normal conditions, barium is present in +2 valence state. It does not occur in its free state; it is stable as an inorganic complex such as barite (barium sulfate) and witherite (barium carbonate). Selected chemical and physical properties of barium are presented in Table 8.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Barium is released to the environment from natural and anthropogenic sources. Barium is present in the air, water, soil, and food, although background levels are very low (ATSDR, 2007). For example, background barium in ambient air is approximately 0.0015 parts per billion (ppb) or less. Perturbations in pH, redox states, and the availability of oxides of metals such as aluminum, manganese, and silicon may alter environmental partitioning of elemental barium and barium compounds. The presence of sulfate and carbonate elicits similar effects. Barium may enter the environment via wet and dry deposition, leaching, natural weathering, and soil and sediment adsorption. Biomagnification in aquatic and terrestrial food chains is possible.

Research indicates that, although only a limited amount of barium accumulates in most plants, it is actively absorbed from the soil by legumes, grains, forage plants, some fir trees,

mushrooms, and legumes such as black walnut, hickory, and Brazil nuts. It does not appear that vegetation can incorporate airborne barium, although dry and wet deposition on foliage has been noted. Barium has been found in animal products such as milk and eggs. Bioconcentration factors have been calculated for some biota (soil to plants 0.4, soil to insects 0.2, and soil to rodent 0.2) but there are significant data gaps. Uptake in marine animals and plants is significantly higher and represents an important clearance mechanism in saltwater.

The primary exposure route in humans is ingestion. Barium has been detected in the blood, urine, feces, and biological tissues of humans; however, there are no data correlating exposure levels with the levels in tissues and fluids. Barium is eliminated in the urine (5%) and the feces (20%) and almost completely eliminated from the bloodstream within 24 h (HSDB, 2010). Barium metabolizes similarly to calcium and has been found to localize to the bone (IPCS, 1991). Barium preferentially deposits at the periosteal surfaces, which are the most active areas of bone growth (HSDB, 2010). The bioavailability of barium and its compounds has been studied extensively in foods, water, and air but there are limited data for soil (McCauley and Washington, 1983). This represents a significant avenue for potential exposures so more information is needed (IPCS, 2001).

ECOTOXICOLOGY

Historically, naturally occurring barium has been found in 99% of surface waters; however, far more barium is released to the groundwater so it is likely that the barium concentrations are even higher there. Most municipal and surface water contain an average of 0.03 ppm barium. Groundwater concentrations in well water may be as high as 10 ppm; this exceeds the Environmental Protection Agency (EPA) limit of 2 ppm. The primary source of barium and barium compounds in groundwater is sedimentary rock leaching and erosion.

The Toxic Release Inventory (TRI) estimated that there were environmental releases of approximately 105,000 metric tons by manufacturing and processing facilities of barium/barium compounds in 2004. This is likely an underestimate given that mandatory reporting of releases is restricted to certain kinds of facilities. These include facilities employing 10 or more full-time employees, facilities that combust coal and/or oil for the generation of electricity for commercial distribution, and businesses performing solvent recovery services for hire (EPA, 2005). Water-soluble forms of barium (hydroxides, nitrates, chlorides) typically do not persist following release unless they combine with other less soluble forms. These insoluble forms (sulfates and carbonates) can persist for a lengthy period. If insoluble forms of barium are released onto land, they will adsorb with particles of soil. Barium concentrations in soil may range from about 15 to 3500 ppm. Barium has been identified in roughly half of the

EPA's proposed National Priority List hazardous waste sites. Barium sulfate and barium carbonate are the most common forms found in the soil and water.

MAMMALIAN TOXICOLOGY

Acute Effects

The soluble barium salts may present an acute hazard, but they have not been prominent in causing occupational illness. Ingestion of barium chloride or carbonate can lead to toxic effects as low as 0.2–0.5 g (IPCS, 1991). Soluble barium compounds such as the oxide, chloride, or carbonate can cause dermal or mucous membrane irritation (Elkins, 1959). It is absorbed via the mucosal tissue in the respiratory system and gastrointestinal tract. The amount absorbed is dependent on factors, including age, solubility of the barium compound, and stomach contents. Stewart and Hummel (1984) reported that a worker who was exposed to molten barium chloride when a furnace exploded had abnormal electrocardiographic tracings for about 9 h, although no other adverse effects were associated with this accident. Barium carbonate is used as a rat poison, and accidental ingestion of this compound has resulted in gastroenteritis, electrocardiographic changes, and muscular paralysis which is possibly from severe hypokalemia (IPCS, 1991; Morton, 1945; Bowen, 2010). Barium compounds profoundly affect all muscle types, especially the heart (IPCS, 1991).

Bertarelli (1931) found that extended contact with wool that had been treated with BaCl₂ did not result in inhalation of sufficient quantities of this compound to cause toxic signs or symptoms. Doig (1976) reported a fatal case of a worker exposed for several days in the mid-1920s to dust from barium peroxide crushing operations. The baryta (BaO), BaCO₃, and the peroxide presumably were converted to the soluble chloride in the stomach. Death on the third day was preceded by abdominal pain, vomiting, tachycardia, dyspnea, cyanosis, and paralysis of the right arm and leg. Nonoccupational poisoning has resulted from accidental ingestion associated with errors in food preparation. Paralysis has been noted in inhalation of barium carbonate.

Most acute human data are the result of intentional or accidental ingestion of barium chloride and barium carbonate. Intentional ingestion of barium carbonate or barium nitrate, common rodenticides in developing countries, is relatively rare but has been used in suicide attempts (Johnson and VanTassell, 1991; Torka et al., 2009). Barium chloride has multiple industrial applications. Physical effects of ingestion of barium and barium compounds include hypokalemia, tachycardia, hypertension (or hypotension), and muscle weakness. Barium acts as a potassium channel antagonist, decreasing blood potassium levels. This shunts potassium from the extracellular to intracellular compartments. Other symptoms

include nausea, vomiting, cramping, and loose stool. Similar symptomology may occur in acute airborne exposures.

Barium sulfate is extremely insoluble, a property that has made it useful as an opaque contrast medium in radiography. Under normal conditions barium sulfate is safe enough for diagnostic X-rays during pregnancy (Han et al., 2011). If barium sulfate or other insoluble compounds enter the bloodstream through a gastrointestinal perforation, there is a chance of toxicity.

Chronic Effects

Baritosis, a benign pneumoconiosis, has been reported in workers who have inhaled barium sulfate in baryta (BaO) mines and also in lithopone workers. This condition presents no respiratory distress, but the chest X-rays show small, sharply circumscribed nodules distributed throughout the lungs. Some reports suggest that baritosis is accompanied by a significant increase in mortality from pneumonia and tuberculosis; however, exposure to fibrogenic, dust-free silica may have occurred in such cases (Chong et al., 2006; Pendergrass and Greening, 1953). Seaton et al. (1986) detected silicosis in barium sulfate miners, which suggests that in some cases other materials associated with barium mining and processing may cause illness.

Doig (1976) studied a group of workers in a barytes crushing factory and found air levels of about 22–92 mg/m³. Baritosis was detected radiographically in some cases as early as 18–21 months after initial employment. The chest X-rays were noteworthy for the “intense radiopacity of the discrete opacities,” which were profuse and evenly disseminated, and for the absence of any other abnormalities of the lungs. The radiographic opacities slowly disappeared after exposure stopped. Pulmonary function tests were essentially normal even though the X-rays indicated substantial radiopacity. Doig noted that the chest X-rays produced by well-established baritosis are similar to those obtained in cases of stannosis.

Essing et al. (1976) studied workers chronically exposed to barium carbonate dust and found no respiratory symptoms or radiographic findings associated with exposure to this material. In the same study the researchers reported that 3 of the 12 workers had elevated blood pressure and two had abnormal electrocardiographic results. These findings are consistent with those reported for accidental or intentional ingestion of barium compounds and with the results of studies of animals exposed to barium compounds, in which elevated blood pressure and abnormal electrocardiographic findings also were observed.

Overexposure to barium via the inhalation route results in characteristic X-ray findings because of the dense nature of this element. Discrete opacities are seen evenly distributed throughout the chest, and they disappear if exposure is eliminated.

Intoxication associated with barium exposure by other routes is most notably associated with increased blood pressure and electrocardiographic abnormalities (Tsai et al., 2011). One worker who was exposed to very high but unmeasured levels of barium carbonate by the inhalation route suffered a broad spectrum of adverse health effects (Shankle and Keane, 1988). The worker experienced nausea, vomiting, stomach cramps, loss of tendon reflex response, low serum potassium, kidney failure, muscle weakness, and paralysis. These findings are consistent with those associated with accidental or intentional human ingestion of barium compounds and with those seen in oral exposure studies in animals (Hicks et al., 1986; Payden et al., 2011).

Barium stimulates contraction of smooth, cardiac, and striated muscles, which may partly explain the symptoms noted. Barium levels in the body are measured in the blood, urine, feces, and bone. In the worker who was exposed to molten barium chloride from a furnace explosion, plasma barium level was 12.4 mg/l at approximately 2 h postburn. At 4, 8, 12, and 18 h postburn the plasma barium levels were 10.3, 8.2, 8.9, and 4.0 mg/l, respectively. Welders who used welding rods with barium flux for 3 hours had elevated levels of barium at the end of a 3-hour welding session and also the next morning (Dare et al., 1984; Yeo, 1986). Apart from symptomatic treatment for barium overexposure, the most important consideration is monitoring potassium levels and providing potassium supplementation if needed.

Using the EPA's 1986 Guidelines for Carcinogen Risk Assessment, barium has been classified as Group D (not classifiable as to human carcinogenicity). There have been no studies that assess the carcinogenicity of barium following chronic inhalation or dermal exposures. Several long-term studies have examined the potential carcinogenicity of ingested barium using rats and mice (NTP, 1994; Schroeder and Michener, 1975a, 1975b). These studies did not report an increased incidence of neoplastic lesions in either species. Significant data gaps exist for immunotoxicity, genotoxicity, developmental toxicity, and reproductive toxicity.

Chemical Pathology

Barium can mimic calcium and thus affect nerve impulse transmission in the nervous system as well as ventricular automaticity in the heart (IPCS, 1990). Calcium can release a neurotransmitter only after depolarization; barium does not require prior depolarization to release a neurotransmitter from the synapse (IPCS, 1990).

Hypothesized Modes of Action

The mechanism of action underlying barium toxicity has not been elucidated. It is hypothesized that exposure to high doses produces muscle weakness, paralysis, ventricular tachycardia, and alterations in blood pressure. It is thought

that these symptoms are the result of barium's action on calcium-activated potassium channels, which increases intracellular potassium. Barium stimulates contractions in muscle tissues, vasoconstriction, peristaltic activity, muscle tremors and fasciculation, and dysrhythmias. These symptoms are more common following exposures to soluble barium compounds.

SOURCES OF EXPOSURE

Occupational

The majority of occupational exposures to barium occur via inhalation in barium sulfate and barium carbonate miners and processors. Recent estimates indicated that more than 10,000 individuals were at risk of occupational exposures to barium and up to 474,000 may have been exposed to barium compounds. When individuals must work around high levels of barium compounds, engineering controls are recommended to limit exposure. Since the respiratory route is the most important occupational route, respirators are recommended if engineering controls are inadequate (Moreton and Jenkins, 1985). The irritating nature of several barium compounds indicates that protective clothing and eye wear are needed for those working with these substances. If the skin becomes contaminated with barium compounds, it should be washed as soon as is practical. Fugitive dust inhalation is a common source of occupational exposures in barium processing and mining facilities.

Environmental

Barium is the fourteenth most abundant element in the earth's crust. As previously stated, barium and barium compounds exist in varying concentrations in all environmental media (Zielinski, 2011). Studies indicate that bioaccumulation is possible. The Third National Health and Nutrition Examination Survey (NHANES) measured barium concentration in the urine of study participants 6 years and older (CDC, 2008; Padilla et al., 2010). The geometric mean for the urinary barium across all ages was 1.44 (1.31–1.58) µg per gram of creatinine. No information has been collected regarding populations living close to hazardous waste sites with high levels of barium. Recent data on barium levels in plants and ambient air, soils, and groundwater, particularly from NPL sites, are necessary to close this data gap.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration (OSHA) and the American Conference of Governmental Industrial Hygienists (ACGIH) have set the permissible exposure limit

TABLE 8.2 NIOSH Recommended Respiratory Protection for Workers Exposed to Barium Chloride

Condition/Airborne Concentration of Barium Chloride	Minimum Respiratory Protection
Up to 5 mg/m ³ (10 × PEL)	Any particulate respirator equipped with an N95, R95, or P95 filter (including N95, R95, and P95 filtering facepieces) except quarter-mask respirators
Up to 12.5 mg/m ³ (25 × PEL)	(APF = 25) Any supplied-air respirator operated in a continuous-flow mode
Up to 25 mg/m ³ (50 × PEL)	(APF = 25) Any powered, air-purifying respirator with a high efficiency particulate filter (APF = 50) Any air-purifying, full facepiece respirator with an N100, R100, or P100 filter (APF = 50). Any supplied-air respirator that has a tight-fitting facepiece and is operated in a continuous-flow mode (APF = 50) Any powered, air-purifying respirator with a tight-fitting facepiece and a high efficiency particulate filter (APF = 50) Any self-contained breathing apparatus with a full facepiece (APF = 50) Any supplied-air respirator with a full facepiece
Up to 50 mg/m ³ (2000 × PEL)	(APF = 2000) Any supplied-air respirator that has a full facepiece and is operated in a pressure-demand or other positive-pressure mode
Emergency or planned entry into unknown concentrations or IDLH conditions	(APF = 10,000) Any self-contained breathing apparatus that has a full facepiece and is operated in a pressure-demand or other positive-pressure mode (APF = 10,000) Any supplied-air respirator that has a full facepiece and is operated in a pressure-demand or other positive-pressure mode in combination with an auxiliary self-contained positive-pressure breathing apparatus
Escape	(APF = 50) Any air-purifying, full facepiece respirator with an N100, R100, or P100 filter Any escape-type, self-contained breathing apparatus with a suitable service life (number of minutes required to escape the environment)

Source: NIOSH (2010).

(PEL) and the threshold limit value (TLV), respectively, for soluble barium salts, barium nitrate, barium oxide, barium carbonate, and barium chloride at 0.5 mg/m³ (Table 8.2) (OSHA, 1996). These criteria are based on the fact that excessive exposure to these compounds may result in irritation of the eyes, nose, throat, and respiratory tract. Several of these compounds are strongly alkaline, which contributes to their irritancy. The PEL for insoluble barium sulfate is 10 mg/m³ total dust or 5 mg/m³ respirable dust. This is based on the potential for barium sulfate to cause a benign pneumoconiosis associated with very high exposure levels. The greatest potential for exposure to barium compounds exists in the mining and processing of barium-containing ores, in the production of barium compounds from barium sulfate, and in the incorporation of barium compounds into commercial products.

RISK ASSESSMENTS

Recently the EPA updated the oral RfD for barium exposure from 0.7 to 0.6 mg Ba/kg/day. The update was based on long-term animal data in the absence of long-term human data. The EPA determined that human and animals metabolize barium in similar ways; therefore, animal data present an excellent tool for modeling the acute and chronic health effects of exposure in humans. The EPA has evaluated the potential

carcinogenicity of barium and classified it as Group D (not classifiable as to human carcinogenicity).

BERYLLIUM

ALISON J. ABRITIS AND RAYMOND D. HARBISON

Target organ(s): Lung, skin, mucosal membranes

Occupational exposure limits: OSHA PEL: $2\text{ }\mu\text{g}/\text{m}^3$, TWA.
Ceiling: $5\text{ }\mu\text{g}/\text{m}^3$ STEL (30 min maximum): $25\text{ }\mu\text{g}/\text{m}^3$;
ACGIH: TLV-TWA: $0.05\text{ }\mu\text{g}/\text{m}^3$; NIOSH TWA-REL:
 $0.5\text{ }\mu\text{g}/\text{m}^3$

EPA (air emissions): $10\text{ g}/24\text{ h}$

Reference values: EPA IRIS: Rfd: $2 \times 10^{-3}\text{ mg/kg/day}$

Risk/safety phrases: Inhalation risk, irritant, sensitizer

BACKGROUND AND USES

Beryllium (Be; CASRN 7440-41-7) is the lightest structural metal known to exist at this time. It is stronger than steel by 40%, its dimensional stability, favorable stiffness-to-weight ratio, high thermal conductivity, high melting point, and effectiveness as an electrical insulator make it an ideal industrial element for use in “inertial guidance systems, turbine rotor blades, laser tubes, rocket engine liners, springs, aircraft brakes and landing gear, ball bearings, injection and blow mold tooling, electrical contacts, automotive electronics, X-ray tube windows, spark plugs, electrical components, ceramic applications, gears, aircraft engines, oil and gas industries, welding electrodes, computer electronics, and golf clubs” (Barna et al., 2003).

Golf clubs notwithstanding, the United States Department of Defense considers beryllium as a “strategic and critical material” due to its integral use in industries vital to national security (Boland, 2012). Beryllium is used in control rods for nuclear reactors, in heat shields for space vehicles, for castings of nuclear weapons, and in windows for radiographic treatments. When bombarded with alpha particles

it releases electrons. It reduces the energy of the neutrons rather than absorbing neutrons from radioactive material, and is permeable to X-rays.

At least 85% of the world’s mined resources of beryllium come from Spor Mountain, Utah (controlled by Materion Brush, Inc., originally Brush Wellman, Inc.) in the United States, with China making up much of the rest and <2% coming from numerous other countries (Boland, 2012). Beryllium is also imported as composites of other industrial commodities; Russia supplies roughly 45%; Kazakhstan, 22%; Japan, 7%; Kenya, 5%; and the remainder from various other countries (Jaskula, 2012).

Three types of beryllium products are in current use: elemental beryllium, beryllium compounds, and beryllium alloys. Elemental beryllium is too reactive to be mined as an isolated ore, and is generally recovered as bertrandite and beryl. Virtually all of the beryllium mined in the United States is of the silicate bertrandite, while beryl (an aluminosilicate) is primarily mined in Russia, Brazil, and China. The green or blue-green color characteristic to emeralds and aquamarines is due to their beryl constituent. Beryllium compounds include beryllium chlorides, fluorides, hydroxides, and oxides. Beryllium hydroxide is used in the production of elemental beryllium, Be oxides, and copper alloys (Gordon and Bowser, 2003). However, beryllium oxides are more versatile and considered as “the most important high purity commercial beryllium chemical” (ATSDR, 2002).

About 75% of the beryllium used in the United States is used for the production of beryllium alloys. These alloys are light and markedly resistant to stress and strain, and most commonly made with copper, aluminum, or nickel. Copper beryllium alloy is commercially the most important and most widely used alloy. The master alloy usually contains 4–4.5%

beryllium by weight (ATSDR, 2002) and shows good resistance to corrosion and fatigue, electroconductivity, and machining characteristics. Beryllium copper products are non-sparkling, resistant to metal fatigue, ductile, and highly electrically conductive (Day et al., 2006) making them optimal in the production of tools, manufacture of electrical equipment, and in the construction of aircraft and spacecraft. Beryllium nickel and beryllium–chromium–nickel alloys have been used for applications such as dental crowns, bridges, and prostheses. Most beryllium alloys have a low percentage of beryllium, but “lock-alloy” has 62% Be and 38% aluminum (Bruce et al., 1998).

PHYSICAL AND CHEMICAL PROPERTIES

Elemental beryllium is a hard, brittle, grey-white alkaline metal with a melting point of 2341°F (1283°C), and is insoluble in water under normal conditions. With its high charge-to-radius ratio, its behavior mimics that of aluminum more than it does of other elements in its group. Beryllium tends to form stable compounds with smaller ions such as fluoride and oxide, although beryllium fluoride is highly soluble in water while beryllium oxide is virtually insoluble. Beryllium also is likely to form covalent bonds, from which organometallics can be formed.

The solubility of a compound plays a significant role in its potential toxicity and beryllium is no different. While beryllium alloys and beryllium oxide are virtually insoluble in water, beryllium salts (e.g., fluoride, chloride, sulfate, nitrate) can be very soluble. Beryllium is amphoteric, forming positive ions in acids with pH < 5 and negative ions in pH > 8. Beryllium is reactive with oxygen and forms a superficial layer of beryllium oxide when exposed to the atmosphere. It is considered non-volatile, except it may pose an explosive hazard if present as a powder or dust.

MAMMALIAN TOXICOLOGY

Animal studies using a variety of test subjects from rodents to dogs to monkeys have been used to model beryllium toxicity. Wagner et al. (1969) exposed animals of various species to beryllium ores at concentrations of 15 mg/m³, from which they calculated the actual Be concentration to be 210 µg/m³ for the bertrandite ore exposure and 620 µg/m³ for the beryl ore exposure. They acknowledged these levels to be 105 and 310 times greater, respectively, than the existing occupational exposure limit of 2 µg/m³.

In the Wagner study, squirrel monkeys, two strains of rats, and one strain of golden Syrian hamsters were exposed on a daily basis for 6 h per day for 5 days per week. Not surprisingly considering the elevated exposures, weight loss, and mortality rates for the animals were higher than

controls. Monkeys showed similar pathologies in lung tissues for both ores, namely, “aggregates of dust-laden macrophages, lymphocytes, and plasma cells near respiratory bronchioles and small blood vessels” but “no other consistent or significant lesions,” which could be related to the inhaled particulates. No such changes were noted in the controls. The hamsters showed different responses to the bertrandite and beryl ore exposures, where the beryl ore exposures caused small areas of atypical cell proliferation akin to bronchiole alveolar cell tumors, and the bertrandite exposures produced “a few” granulomatous lesions. No such responses were observed in the control hamsters. Interestingly, both strains of rats showed multiple forms of lesions, including adenomas, adenocarcinomas, and epidermoid tumors, with all rats showing tumor formation by 17 months. The control rats while not manifesting any “neoplastic or granulomatous pulmonary lesions,” did show “moderately chronic bronchitis, which did not involve the respiratory bronchioles.” In their discussion, the authors noted that while bertrandite produced granulomatous lesions, the beryl ore exposures did not, although the beryl exposures produced certain lung histopathologies. They concluded that beryl ore exposures should be considered as “an intoxicant and, more seriously, as a pulmonary carcinogen.” They did not explore the possibility, drawn from the adverse responses of the control rats, that the exposure chamber design may have its own adverse response capability on test animals.

Grier et al. (1949) tested beryllium’s effects on alkaline phosphatase *in vitro* using rat and human serum, and concluded that Be inhibits the production of the enzyme. However, the study by Wagner et al. (1969) noted no change in the phosphatase activity of their beryllium-exposed animals and speculated that *in vivo* results may differ from *in vitro* for this response.

In a summary of animal studies performed at the Inhalation Toxicology Research Institute (ITRI), Finch et al. (1996) noted that both dogs and monkey case studies yielded results similar to those seen in case studies of humans. They found that dogs, however, showed a tendency for resolution in symptoms, which makes exposure modeling to humans unlikely. They also noted that the F344 rat strain used in their studies did not respond to Be exposure in the same way that certain mice strains do, making non-strain-specific murine modeling difficult to apply to humans.

Some human epidemiological data suggest that beryllium may be a factor in some lung cancers, although there are conflicting reports. Studies by Infante et al. (1980), Waggoner et al. (1980), Steenland and Ward (1991), and Ward et al. (1992) reported a higher risk of cancer associated with beryllium exposure. Ward et al. (1992) working under the auspices of the National Institute for Occupational Safety and Health (NIOSH), performed “retrospective cohort mortality study of seven beryllium production facilities” in Pennsylvania and Ohio. Each facility handled all or part of the

industrial processes involved in the extraction of beryllium from beryl ore or in the use of beryllium metal, oxide, and copper alloy in the manufacturing of other products. Their study found a “modest excess of lung cancer (SMR = 1.26) in a cohort of 9,225 workers.” The standardized mortality ratios (SMRs) for each of the seven plants in the study ranged from 0.82 to 1.69. Since it can be safely assumed that working in a beryllium plant would not be protective from lung cancer (i.e., SMR < 1), other factors must be in play for the determination of mortality ratios. The authors admitted to the limitations in knowledge of occupational history, degree of exposure, and nature of exposure but did include consideration of smoking history and geographic region, which they discounted as a complete explanation for lung cancer risk.

The 1992 NIOSH report was challenged by Levy et al. (2002), who, after reanalyzing the data in consideration of local statistics and adjusted smoking risks, stated that “(o)ur analyses have shown that there is no statistical association between beryllium exposure in these workers and lung cancer when using the most appropriate population cancer rates. There is, at best, an extremely fragile association when the data are corrected for smoking.” This analysis was soon countered by Schubauer-Berigan et al. (2008), who stated that average beryllium exposure correlated to a lung cancer risk while cumulative exposure did not. Levy et al. (2009) followed with a Cox proportional hazards single- and multivariate analysis to reevaluate the NIOSH study data without the inclusion of smoking as a confounder and concluded that again the link between beryllium and lung cancer was tenuous. Schubauer-Berigan et al. (2011) examined an expansion of the original data set, which now included data up to 2005, and again found an association between beryllium exposure and lung cancer: “Among these workers, lung cancer SMRs¹ were significantly elevated for workers in the highest cumulative exposure group (>10,300 µg/m³-days) and for workers having an annual maximum DWA² of 10 µg/m³ or higher.” Risks associated with smoking were included, but individual region effects were omitted.

The International Agency for Research on Cancer (IARC), referencing the Ward et al. (1992) and Schubauer-Berigan et al. (2008) analyses among other reports, stated that there “is sufficient evidence in humans for the carcinogenicity of beryllium and beryllium compounds. Beryllium and beryllium compounds cause cancer of the lung. There is sufficient evidence in experimental animals for the carcinogenicity of beryllium and beryllium compounds. Beryllium and beryllium compounds are carcinogenic to humans (Group 1)” (IARC, 2012). Similarly, in their Report of Carcinogens (2011), the National Toxicology Program (NTP) states that beryllium and beryllium compounds “are known to be human carcinogens”

based on human studies performed by Steenland and Ward (1991) and Ward et al. (1992) (NTP, 2011).

The EPA, however, has not changed their assessment of the Be’s carcinogenicity since 1998 and still rates it as B1: a *probable human carcinogen* (Bruce et al., 1998). They address IARC’s categorization of Be as a human carcinogen and counter that “the U.S. EPA, however, considers that the issues of incomplete smoking data and exposure to other potential lung carcinogens are not completely resolvable with the data currently available, and therefore concludes that the evidence of carcinogenicity of beryllium and compounds is limited in humans.” Indeed, the epidemiological studies conducted on occupationally exposed workers show a lack of identification and isolation of other carcinogens that may have been present in the industrial settings in which the workers spent their work period. Adhesives, fossil fuels, and even asbestos may be a part of the manufacturing and processing process (Goldberg, 2006), all of which may be potential contributors to carcinogenicity in an exposed worker.

Acute Effects

Since the advent of occupational exposure and community air regulations, the incidence of acute beryllium disease (ABD) has been almost completely eliminated. Acute beryllium disease is a chemical irritant condition from which the patient can recover if the damage is not too extensive. It is usually associated with an isolated high concentration exposure (>1 mg Be/m³) of soluble forms of beryllium (ATSDR, 2002; Wambach and Laul, 2008) such as seen in an accidental release rather than a continuous exposure. The solubility of the compounds allows beryllium clearance from exposed tissues, usually before damage becomes irreparable.

Signs and symptoms of ABD from inhalation exposures are generally similar to a chemical irritant reaction. Coughing, weight loss, shortness of breath, labored breathing, swelling and inflammation of the respiratory tract, and pneumonitis may occur. Dermal exposures usually are associated with the soluble salts and can result in dermatitis, although skin granulomas have occurred from an immune-mediated reaction (ATSDR, 2002). If the patient survives the acute overexposure, the signs and symptoms of acute beryllium disease usually disappear after removal from the exposure source, although sometimes remission can take months for full recovery.

There has been limited speculation that ABD may actually be a preliminary phase in a “continuum of hypersensitivity reactions” leading to chronic beryllium disease (CBD) (Cummings et al., 2009). However, the case studies were limited and involved either repeated exposures or exposures to insoluble forms of beryllium, which may have accounted for the continued low level exposure associated with the development of the chronic form of the disease.

¹ Standardized mortality rates.

² Daily weighted average.

Chronic Effects

Beryllium exposure is known to result in two forms of chronic effects: beryllium sensitization (BeS) and CBD. Both conditions arise from an immune-mediated response to beryllium exposure, and CBD will not occur without BeS being initiated. It is also speculated to play a role in the development of lung cancer, although there remains some controversy over this finding.

Beryllium sensitization is a condition of a body's immune system's over-response to beryllium exposure. Unlike ABD and CBD, BeS is not dependent upon the length or extent of exposure, but is merely dependent upon the exposure occurrence. As the initial immune response may be minimal, BeS is generally asymptomatic (Day et al., 2006). There is no known dose-response curve for the onset of BeS; neither is there a time frame between exposure and sensitization response (CBAE, 2008). Various studies show a prevalence ranging from 0.47 to 14.9%, varying with the nature of the occupational exposure by profession and product (Kreiss et al., 1997; McCanlies et al., 2003; Day et al., 2006; Taiwo et al., 2010).

Previously, BeS was screened by use of a "beryllium patch test," whereby a patch of soluble beryllium salts was affixed to the test subject's skin and the nature of an inflammatory response was evaluated. However, the test fell out of favor as it was suspected as its own source of induced BeS (Donovan et al., 2007). The current "standard of care" in employee monitoring and screening for BeS and CBD is the Beryllium Lymphocyte Proliferation Test (BeLPT) (Newman et al., 2005).

The Beryllium Lymphocyte Proliferation Test measures the proliferation of tritiated thymidine-marked lymphocytes in three different concentrations of beryllium salts and two different time periods for culturing. The ratio between a test sample and its control is called a stimulation index (SI); six SIs are then produced for each test. Two (or more) SIs of 3.0 or more are considered as an abnormal result, one SI of 3.0 or more is considered borderline, and no SIs meeting or exceeding 3.0 is considered a negative test result (Barna et al., 2003; Middleton et al., 2006). It bears noting that some test protocols may use SIs as low as 2.0 as the "normal limit" (Kreiss et al., 1993; US Department of Energy, 2001). Roughly 10% of workers in beryllium industries are considered to have BeS based on the test results (Cullen, 2005).

While BeLPT use in screening and diagnosis has become common, it is not without its limitations. Although the Department of Energy (DOE) has a procedural protocol that it requires its contracted laboratories to use, it does not require adherence to the protocol by non-DOE contracted laboratories (US Department of Energy, 2001). Variance in test results has been noted between inter- and intra-laboratory reviews and can involve "concentrations of cells, media, or serum; the types of sample wells (i.e., flat-bottom vs. round-bottom); the number of replicate wells; length of incubation; blood

sample collection and shipping procedures; the stimulation index threshold that is used to define a positive result; and the statistical methods used to analyze data" (Donovan et al., 2007).

Additional concerns to the use of BeLPT as a routine screening tool has to do with the potential for BeS to develop into CBD. The BeLPT has been found to have only a 40–50% positive predictive value (US Department of Energy, 2001). Those who test positive may not even develop CBD; ranges of associations for BeS developing into CBD run from 14 to 100% (Newman et al., 2005), and such wide range offers no conclusive predictive values. Routinely screening for CBD before symptom development may be without justification for the emotional and financial costs as there is no cure and little success in slowing disease progression (Barna et al., 2003; Cullen, 2005; Borak et al., 2006; Donovan et al., 2007).

Chronic beryllium disease incidence has been estimated to run anywhere from 0.4 to 18% of exposed employees (Day et al., 2006; Mack et al., 2010). Similar to ABD, CBD manifests with respiratory symptoms typical to a reduction of pulmonary function: wheezing, coughing, shortness of breath, fatigue, and weight loss. Other signs of CBD are cough, chest pain, cor pulmonale, followed by cardiac failure, liver and spleen damage, and the development of kidney stones (ATSDR, 2002; Donovan et al., 2007). Histopathological manifestations of non-necrotizing granulomatous pulmonary lesions are characteristic in clinical CBD, but can also present as a "subclinical" CBD, i.e., in the absence of overt symptoms. Skin lesions may also develop.

Chronic beryllium disease is "practically indistinguishable" from sarcoidosis (Barnard et al., 1996). To this respect, BeLPT is considered "highly useful" in eliminating sarcoidosis as a differential diagnosis for CBD (Barna et al., 2003).

It is now "generally accepted" that the variances noted between Be exposures and manifestation of BeS and CBD are due to the genetic makeup of the exposed person and the nature of the exposure (Wambach and Laul, 2008; Van Dyke et al., 2011). Newman et al. (2005) speculated that BeS progresses into CBD in roughly 6–8% of cases per year after the diagnosis.

Although there is no definitive proof that BeS will inevitably lead to CBD, the development of CBD is of the same process as that of BeS. The immunological response of cytokine cascades from the activation of Be-antigen-specific CD4+ T-cells maintains the inflammatory process and subsequent cell damage as Be²⁺ stimulation continues (Wambach and Laul, 2008). The pulmonary granulomas are associated with a massive proliferation of T-cells. One feature of CBD is the continued disease progression even in the absence of continued beryllium exposure. Mack et al. (2010) speculated that the impairment of regulatory T-cells (T_{reg}) may prevent the control of the pro-inflammatory responses. Their study showed a correlation between the increase of T_{reg} cell dysfunction and a corresponding disease severity.

The condition is generally thought to be associated with low soluble compounds that remain in the lung tissues for an extended period of time. It has been associated with both high and low level exposures, but generally is seen with extended low level exposures (Wambach and Laul, 2008).

Beryllium has been classified as a *probable human carcinogen* by the EPA and a *known human carcinogen* by IARC and NTP (Bruce et al., 1998; NTP, 2011; IARC, 2012).

Infante et al. (1980) performed a study and found higher rates of lung cancer (and other respiratory diseases) among deceased white male beryllium workers based on the registration in the Beryllium Case Registry (BCR) at Massachusetts General Hospital. However, there are methodological flaws in their study. First, the population group itself is skewed by definition. Those workers exposed without any illness would not likely be registered. As Mass General is a major hospital, there is a greater likelihood that the more significantly ill would seek services there instead of a smaller general hospital. Second, there is only the word of the patient without corroboration as to the nature of the exposure in regards to concentrations, duration of each exposure, and most importantly, other potential exposures from occupational duties. Finally, they discounted the potential confound of smoking because it “seems unlikely that subjects entered into the BCR with the past diagnosis of acute respiratory illness would have had past smoking habits of sufficient magnitude to account for the excessive lung cancer risk in that subcohort.”

Mechanism of Action(s)

Beryllium works as both a chemical irritant and a cell-mediated hypersensitivity phenomenon. The chemical irritant mechanism of beryllium is generally straightforward and is akin to the nature of its group and the compounds it forms. Soluble forms will cause more invasive damage than insoluble forms, and the nature of the oxidative damage is contingent upon the type of compound. Sawyer et al. (2005) demonstrated via *in vitro* studies on mice macrophages that Be exposure initiates the formation of reactive oxygen species (ROS), which induces cell apoptosis.

The mechanism behind the development of the hypersensitivity reaction is not so clear-cut. What is known is that hypersensitivity is the result of the formation of an antigenic beryllium–hapten complex formed with a major histocompatibility class II molecule (MHCII) (Kreiss et al., 1993; Newman, 1993). CD4⁺ T-cells, in the presence of this complexed molecule, then trigger the production of pro-inflammatory cytokines TNF- α and TNF- γ . It is this cascade of inflammatory responses that is believed to be responsible for the formation of the non-caseating granulomas seen in beryllium-induced dermatitis and chronic disease. Regulatory T-cell dysfunction may also play a role in the perpetuation of the pro-inflammatory cytokine response (Mack et al., 2010).

What remains to be deduced is exactly why this hypersensitivity happens at all. Less than 1 in 6 exposed workers demonstrated any sensitization reaction, and there has been no establishment of a dose–response for the sensitization effect. Sawyer et al. (2005) speculated in their study on Be and ROS that “exogenous oxidative stress” increased the ROS formation in Be-exposed cell lines. They then speculated that the variances in the sensitizations of individuals may be due to “a pulmonary environment already under oxidative stress, for example, in the presence of pulmonary infection, smoking or other environmental stresses, could cause even greater levels of alveolar macrophage apoptosis.”

One presiding theory affixes the source of the sensitization to multiple genetic phenotypes in the exposed subject. One gene family of interest is the human leukocyte antigen (HLA) family, supported by the irregular proliferation of leukocytes and other immune response cytokines during exposure to beryllium. Currently, research supports a higher risk for workers with a non-*02-E69 HLA-DPB1 and HLA-DPB1 E69 homozygotic genotype (Van Dyke et al., 2011), although the population prevalence of HLA-DPB1 E69 is high, the “cross-sectional predictive value is relatively low” (McCanlies et al., 2003). Another area of interest may be the interleukin (IL) genes, which may play a part in the formation of the granulomatous lesions and fibrosis characteristic of CBD (McCanlies et al., 2010).

Chemical Pathology

Historically, bertrandite was considered as the source of beryllium toxicity. Beryl ore was once considered “nontoxic” and was even used in a study as a “negative control” (Wagner et al., 1969). Further irony in light of the origins of this text, beryllium poisoning was the reason for the initial meeting between Alice Hamilton and Harriet Hardy (Hardy, 1965).

The primary exposure route associated with adverse effects is through inhalation and dermal absorption, although ingestion is also possible. However, beryllium is typically not noted for adverse effects from ingestions in healthy individuals, as it tends to remain confined to the GI tract until excreted.

The solubility of Be particles is believed to play a significant role with the potential toxicity of the exposure, but the nature of that role appears dual-natured. Small particles (<10 μm) made from grinding or machining beryllium compounds are more soluble in acidic environments such as the internal environment of macrophages, to which Wambach and Laul (2008) associated their toxicity to macrophages and thus their longer retention and continued stimulation of the inflammatory processes. Wambach and Laul (2008) also pointed out that small particles are more likely to be deposited in the deepest part of the lung, where oxygen exchange takes place. On the other hand, Taiwo et al. (2010) suggested that more soluble compounds can be attributed to less toxic response, since the compound’s dissolution causes less actual contact

with the immune system. Accordingly, beryllium oxides calcined at temperatures lower than 500 °C are more associated with the onset of ABD than the development of CBD, which Wambach and Laul (2008) suggested is due to the smaller particles of the low temperature calcined oxide having a greater solubility than beryllium oxides calcined at higher temperatures (>1000 °C).

Solubility is also directly related to the duration of beryllium body load. Beryllium and its compounds are primarily excreted from the body through feces. The remaining is excreted in the urine, which can cause extended body burden until the conversion of insoluble forms into soluble forms is complete (Bruce et al., 1998).

SOURCES OF EXPOSURE

Occupational

Increases and improvements in engineering controls have reduced the nature and degree of employee occupational exposure. However, normal industrial operations coupled with accidental releases do allow for exposures of varying concentrations and types.

Occupational overexposure to beryllium occurs primarily via the inhalation route, although dermal exposure from particulate dust is also a consideration. Occupationally-related ingestion is rare with adequate engineering controls, although it can occur from respiratory clearance mechanisms allowing particulate-embedded mucus to be swallowed. Overexposure can occur during the processing of alloys and ceramics and from the generation of dusts, fumes, and other fine particulates during the manufacture of beryllium-containing materials.

Beryllium sensitization and CBD rates are clearly associated with the nature of the industry and the work process associated with the employee exposure. Newman et al. (2005) found that machinists were most likely to progress from BeS to CBD than other workers within the same industry. Stanton et al. (2006) found that BeS and CBD rates in the employees of beryllium-processing plants exceeded workers handling manufactured products, such as in a beryllium–copper alloy distribution center.

There is also substantial evidence that the form of beryllium exposure is directly related to its ability to induce sensitization; not all beryllium is equivalent and not all beryllium is capable of inducing disease. Deubner et al. (2001) examined 75 workers at a beryllium ore mining and milling facility in Utah. The workers involved in the mining operation were primarily exposed to beryl ore or bertrandite ore, and the milling operation workers were exposed to these ores and beryllium hydroxide. General area, breathing zone, and personal lapel samples were used to estimate the historical beryllium exposure. The

mean general area, breathing zones, and personal lapel samples ranges were 0.3–1.1, 1.1–8.1, and 0.05–6.9 µg/m³, respectively. No cases of BeS or CBD were found in workers who only worked in the mines, leading the study authors to suggest that the form of beryllium may influence the risk for developing BeS or CBD. Stefaniak et al. (2008) suggested that the difference in particle size between ore dusts and manufacturing dusts may account for a difference in bioavailability, subsequently affecting the alveolar particulate loads.

Aluminum production can be a cause of occupational beryllium exposure as beryllium is found in the bauxite ore mined for aluminum. Taiwo et al. (2010) found a prevalence of 0.47% of BeS in a composite study of nine aluminum-smelting plants located throughout four countries and speculated that the lower sensitization rate may be “related to work practices and the properties of the beryllium found in this work environment.”

Biomonitoring of beryllium exposures have been attempted through urine samples, but no correlation between ambient air concentration and urinary levels has yet been identified. Apostoli and Schaller (2001) in a study of metallurgical workers did indicate higher levels of beryllium in “exposed” workers versus controls. They stated, however, that their study had too limited a dataset to make exact correlations “without reservations.” To date, there are no biological exposure indices (BEI) for beryllium urinary levels.

Environmental

The average amount of beryllium permeating the earth’s crust is roughly 6 mg/kg—calculated from the beryllium ore content in soils as elemental beryllium is too reactive to occur naturally. Natural sources of beryllium in ambient air come from natural rock erosion, volcanic dusts, and combustion ash. Major manmade ambient air sources are manufacturing and processing of ores and from the combustion of coals as they are commonly combustion agents in power plants for the production of electricity. Be concentration in coal averages 2.3 parts per million (ppm) and can be released into the air as fly ash and other coal combustion products (Eskanazy, 2006). Urban and industrial population may experience slightly higher ambient beryllium exposures; Detroit, Michigan averaged ambient air concentrations of 0.02–0.2 ng/m³ from 1982 to 1992 while the yearly average concentration for the entire United States is below the detection limit of 0.03 ng/m³ (ATSDR, 2002).

Soil contamination is also a consideration in environmental exposures. Contaminated soils increase the potential for elevated ambient air levels from fine dust, and children are at increased risk as they are more likely to inhale or ingest contaminated soils by their propensity to play in dirt. By 2002 beryllium was identified as a contaminant in at least 535 of the 1,613 current or former National Priorities List (NPL)

sites; however, the beryllium form at these sites are “almost entirely” in insoluble forms and thus less likely to be exposure threats (ATSDR, 2002).

One of the primary concerns from environmental intrusion by beryllium is the potential for bioaccumulation. Ishikawa et al. (2004) found “abnormally high” levels of Be in samples of ascidian liver which they speculated may have been due to ascidian feeding on Be-enriched plankton. However, no study has found evidence of bioaccumulation moving up the food chain and ATSDR (2002) stated that Be “does not bioconcentrate in aquatic organisms.” Furthermore, a 2008 study of Floridian ospreys that “have frequently been used as indicator species for contamination” showed no significant elevation in trace beryllium. Samples were consistently below 1 µg/g dry feather weight (Lounsbury-Billie et al., 2008).

INDUSTRIAL HYGIENE

The generally accepted time-weighted occupational exposure limit of 2.0 µg/m³ has been utilized for various federal regulatory agencies since 1949 (Ward et al., 1992). Currently, Occupational Safety and Health Administration (OSHA) still sets the legally enforceable time-weighted average (TWA)—permissible exposure limit (PEL) as 2.0 µg/m³ with a ceiling of 5.0 µg/m³ and a 30 min peak level of 25 µg/m³. However, in light of some studies challenging the protectiveness of these limits, some agencies have modified their recommendations for occupational exposure limits. The NIOSH currently recommends a more conservative limit of 0.5 µg/m³, and in 2009, American Conference of Governmental Industrial Hygienists (ACGIH) significantly lowered their threshold limit value (TLV) to 0.05 µg/m³, a 40-fold reduction (ACGIH, 2009).

In their discussion of literature justifying reduction, ACGIH referenced reports by Kelleher et al., (2001); Madl et al., (2007); Schuler et al., (2005); Rosenman et al., (2005); and Stanton et al., (2006). However, Madl et al. (2007) pointed out that “(f)urthermore, no beryllium-sensitized and CBD workers were exposed to a median concentration >2 µg/m³, but approximately 50% of the beryllium-sensitized and CBD workers were exposed to a 95th percentile concentration greater than 2 µg/m³ when looking at supplemented data for only the highest exposed year.” They also noted that “(t)wenty-six of the 27 beryllium-sensitized and CBD workers had at least a 10% probability of being exposed to beryllium concentrations exceeding 0.2 µg/m³ during their career, and all cases had a greater than 5% probability of exceeding this level.”

Kelleher et al. (2001) noted problems in determining significant differences between cases and control and stated that “(m)achinist history remained the only significant variable,” which thus encompasses a potential for particulate size

as a variable. However, Kelleher et al. (2001) used lifetime exposure calculations to compare cases and controls, which might mask any particular exceedance of PELs. In their graphic representation, they noted that “the median cumulative exposure to total beryllium (based on the median exposure estimate) was 2.6 mg/m³-years in cases compared with 1.2 mg/m³-years in controls,” which implies a preponderance of PEL exceedance.

Borak (2006) in discussing a perceived need for lower regulatory limits admits that some studies that attribute BeS and CBD to exposure levels below 2.0 µg/m³ may actually have problems in Be contamination creating exposures exceeding 2.0 µg/m³. Stanton et al. (2006) noted study problems in small sampling sizes and poor historical exposure data. Schuler et al. (2005) also considered the possibilities that exposures may have actually exceeded 2.0 µg/m³. Despite the limitations in these studies, it is obvious that there is a growing concern as to the protectiveness of the current OSHA standard of 2.0 µg/m³, and that a revision of the standard to a lower PEL might reasonably be expected in the coming years.

No matter the exposure limit, good employee management and common sense dictate adherence to sound engineering and housekeeping controls. Proper personal protective equipment should be utilized when airborne exposures range near recommended exposure limits, and apparel should be protective against dermal exposures, especially in areas most prone to the presence of particulate matter or fumes. A 4-year program of instituting building design changes, restricted zone access, and required respirator wear in one facility resulted in a fourfold decrease in employee sensitization rates (Bailey et al., 2010). Therefore tracking areas of potential beryllium exposures in the workplace is imperative. Table 9.1 contains a list of the approved sampling protocols for quantification of beryllium in air or dust.

MEDICAL MANAGEMENT

The symptoms of acute or chronic beryllium-related disease may mimic other illnesses; for this reason, identification of beryllium exposure is critical in diagnosing the disease. A history of beryllium exposure, combined with weight loss, a nonproductive cough, eye irritation, irritation of the skin and respiratory tract, or pain in the sternum, suggests ABD. Chest X-rays can be useful in identifying pulmonary involvement, but have limited usefulness in diagnosis as the radiographic appearance is non-specific for beryllium disease (Stange et al., 1996). Thin-section computed tomography (TSCS) is a more sensitive technique than normal chest radiography, but it is only practical for confirmation of diagnosis rather than as a screening tool (Maier, 2002).

Chronic beryllium disease may be more difficult to diagnose than ABD because it generally requires months to years after the initial beryllium exposure and may manifest long after such exposure had stopped. Chronic beryllium disease may be precipitated by stress, such as surgery, combat, pregnancy, or another illness. Initially, CBD is characterized by shortness of breath on exertion, weight loss, chest pain, and cough. Reduced pulmonary function and reductions in vital capacity, forced expiratory volume, and maximal mid-expiratory flow are indicators of possible CBD. Abnormal BeLPT test results may be indicators of BeS (the precursor of CBD) and can differentiate between a differential diagnosis of sarcoidosis and CBD.

Beryllium can be measured in the urine or in various tissues. However, as is true with many other metals, beryllium levels may not correlate with the level or duration of exposure. Elevated levels of beryllium do indicate exposure sometime in the past, but the time since exposure cannot be estimated because of beryllium's long half-life.

Currently, the treatment protocol for beryllium disease is cessation of beryllium exposure and immunosuppression/anti-inflammatory treatment with corticosteroids (Sood, 2009). Palliative treatment with supplemental oxygen and respiratory therapy can be helpful, but as of this time there is no curative therapy for BeS or CBD.

BISMUTH AND RELATED COMPOUNDS

PAUL JONMAIRE

First aid: Since there are many bismuth compounds in commercial use there are no special first aid recommendations. General first aid recommendations are often appropriate. For dermal overexposure, remove contaminated clothing and wash with soap and water. For ocular overexposure, flush with water for 15 min.

Target organ(s): Include eye, respiratory tract, kidney, liver, and nervous system

Occupational exposure limits: Bismuth telluride undoped: 15 mg/m³ (OSHA TWA) 10 mg/m³ (ACGIH TWA) 10 mg/m³ total dust (NIOSH TWA); 5 mg/m³ respirable (OSHA TWA), and 5 mg/m³ respirable (NIOSH TWA)

BACKGROUND AND USES

Bismuth is a relatively rare metal found in the earth's crust at about the same level as silver. It is usually associated with copper, lead, tungsten, silver, and gold ores. Bismuth typically is a byproduct of copper and lead refining and smelting (USGS, 2013). About 8000 metric tons are produced worldwide annually. Production of bismuth in the United States ceased in 1997 (USGS, 2014a). In 2013 about 1700 tons of bismuth were imported into the United States, about half of which came from China (USGS, 2014b). In early times it was confused with tin and lead. In 1450, a German monk, Basil Valentine, first made reference to "wismut" or "white lead," which later would be Latinized to *bismutum*. Claude Geofory showed it to be distinct from lead in 1753 (WebElements Periodic Table of the Elements, 2012). A bronze knife from Machu Picchu with about 20% bismuth suggests that the Incas may have used it for metallurgical purposes (Palmierri, 1993). The most common bismuth minerals are bismite

(Bi₂O₃) and bismuthinite (Bi₂S₃) although it may occur in its metallic state (Bell, 2014). There are more than 100 bismuth-containing compounds on the U.S. EPA TSCA inventory (US EPA, 2013).

Bismuth is a very brittle metal rarely used by itself. The first widespread metallurgical uses for bismuth were in pewter alloys (Bell, 2014). Because of its low melting point, it is a component of "fusible alloys" found in fire sprinkler systems and low melting solders and other alloys of steel and aluminum (Palmierri, 1993). In the early 1990s research began on the evaluation of bismuth as a nontoxic replacement for lead in such uses as ceramic glazes, food processing equipment, free-machining brasses for plumbing applications, lubricating greases, and low toxicity fishing sinkers and shot for waterfowl hunting (USGS, 2014a; Lenntech, 2014). The Safe Drinking Water Act Amendments of 1996 have banned lead from all fixtures, fluxes, pipes, and solders used for installation or repair of facilities providing potable drinking water prompting a movement to replace lead with bismuth (Bell, 2014). In January 2010 both Vermont and California made the use of any product with greater than 0.25% lead unlawful. These regulations are part of a trend to use bismuth containing brass fittings and valves in water systems (AY McDonald, n.d.). As part of their "Design for the Environment" life-cycle assessment program, the Environmental Protection Agency (EPA) has promoted the use of bismuth in several lead-free solders (US EPA, 2005). Recently, new applications for bismuth include the use of bismuth zinc alloys to achieve thinner, more uniform galvanization (USGS, 2014b). Another developing application is the use of bismuth telluride-based compounds in the manufacture of semi-conductor devices. Bismuth telluride is both a mineral and manufactured compound and is used in both an

undoped and doped form. (“Doping” is depositing of a thin layer (often selenium) of a second metal on the semiconductor material of interest to modify its conductivity ACGIH, 2001; USGS, 2014b).

Bismuth is also used in cosmetics, flame retardants, and stabilizers in plastics, pigments, and pharmaceuticals. Bismuth trioxide is used in disinfectants, magnets, glass, ceramics, and rubber vulcanization. Bismuth phosphomolybdate is used as a catalyst in the production of acrylonitrile fiber (Digitalfire Hazards Database, 2008; Palmierri, 1993). Some inorganic bismuth compounds are used to treat abdominal problems such as diarrhea, abdominal pain, and ulcers. The most well-known bismuth compound, bismuth subsalicylate, is used to treat diarrhea, heartburn, and upset stomach. Bismuth subsalicylate, the principal ingredient of Pepto-Bismol and Kaopectate is consumed in large quantities around the globe (COT, 2008; East, 2009; NLM HSDB, 2013). Bismuth is used in surgical dressings (subnitrate and carbonate). Organic bismuth preparations such as bismuth tartarate were used more or less successfully until the 1940s to treat syphilis.

PHYSICAL AND CHEMICAL PROPERTIES

Elemental bismuth (Bi; CASRN 7440-69-9) is a soft, heavy, solid, brittle, pink-tinged white metal, insoluble in water. Its atomic number is 83 and atomic weight 209; density is 9.78 g/cc³. It may be flammable in powder form. Bismuth exists in trivalent and pentavalent states. The trivalent form is more stable and abundant. Like water, it expands upon solidification from the liquid state. It has a relatively low melting point of 271 °C (520 °F). It has the lowest thermal conductivity of all metals and is the most diamagnetic of all metals (i.e., repelled by both poles of a magnetic, therefore positioning itself at right angles to the magnetic lines of influence) (Bell, 2014; INCHEM, n.d.; Lenntech, 2014; WebElements Periodic Table of the Elements, 2012).

HEALTH EFFECTS

Bismuth salts are known for their low toxicity (Salvador et al., 2012). Bismuth and its various compounds are considered to be among the least toxic of heavy metals. Many bismuth compounds are water insoluble and minimally absorbed. Because of the typical low toxicity of bismuth and its compounds, pharmacological use is the primary source of information regarding the potential toxicity of bismuth and its compounds. Sano et al. (2005) performed oral administration studies with bismuth on rats. In one study, a single dose of bismuth of up to 2000 mg/kg produced no deaths or unusual findings in any of the tested animal groups. In a second study, rats received up to 1000 mg/kg/day for 28 days. Again there

were no unusual findings in any of the test groups. The authors concluded that the oral LD₅₀ of bismuth is greater than 2000 mg/kg and the no observed adverse effect level (NOAEL) was 1000 mg/kg. They also concluded that the adverse toxic effects of bismuth are low compared to lead, a material for which it is often considered a replacement.

Acute Effects

Although bismuth salts were being used for therapeutic purposes for many years, little attention was paid to their potential toxic effects (Beck, 1909). There have been reports as far back as 1786 of effects such as vomiting, twitching, and dizziness associated with ingestion of bismuth salts. Possible impurities such as arsenic or lead were most likely the actual source of these symptoms (Higgins, 1916). The acute toxicity depends upon the nature of the bismuth substance. Acute exposure to bismuth salts may cause contact sensitivity and epigastric discomfort, and substantial ingestion may cause nausea and vomiting. A gray blue color “bismuth gumline” can be associated with both acute and chronic exposures to bismuth compounds. Bismuth subsalicylate also has been linked to ringing in the ears (NLM, 2011). The clinical manifestations of acute bismuth intoxication are similar to those caused by lead and mercury, i.e., neurological abnormalities, especially encephalopathy and renal dysfunction, with nephrotic syndrome progressing to renal failure (INCHEM, n.d.). Numerous reports of eye and skin irritation have been associated with exposure to bismuth and its compound.

Chronic Effects

Use of bismuth compounds in medicine indicates that bismuth and its salts can cause various types of neurotoxicity, kidney and liver damage, usually mild. Symptoms of chronic toxicity include decreased appetite, weakness, rheumatic pain, diarrhea, fever, foul breath, gingivitis, and dermatitis. Chronic excessive ingestion also produces bismuth lines on the gums and can cause stomatitis, excess salivation, osteoarthropathy, and pathological fractures (COT, 2008; NLM HSDB, 2013). Bismuth salts react with sulfides produced by anaerobic bacteria in the gut to produce bismuth sulfides, which turn the stool black. With chronic ingestion bismuth can accumulate until nephrotoxicity and neurotoxicity develop. Neurotoxicity reports associated with chronic oral exposure to bismuth-containing pharmaceuticals describe a wide variety of symptoms. These include irritability, insomnia, difficulty sleeping, muscle twitching, hallucinations, confusion, myoclonus, ataxia, and progressive dementia (INCHEM, n.d.). With regard to bismuth encephalopathy, Slikkerveer and de Wolff (1992) proposed three distinct phases of toxicity. A prodromal initial stage lasting 2–6 weeks typically manifests itself with memory changes, incoordination, behavioral changes, and psychiatric symptoms. This is followed by fulminant

encephalopathy myoclonic jerks, confusion, and dysarthria. The third phase reflects recovery with no lasting effects, which is quite common when the offending bismuth compounds are withdrawn (INCHEM, n.d.).

Mutagenicity Bismuth subsalicylate was tested as part of the National Toxicological Program (NTP) mutagenicity testing program using the standard *Salmonella* testing protocol. The results did not suggest any mutagenic potential using this bioassay (Zeiger et al., 1987). Several bismuth compounds have been tested for their ability to cause chromosomal aberrations in lymphocytes. Bismuth citrate and bismuth glutathione showed no clastogenic potential; however, exposure to methylated bismuth did produce increased chromosomal aberrations and sister chromatid exchanges. Since bismuth ions are known to be methylated by intestinal flora, this finding is of potential interest (von Recklinghausen et al., 2008).

Carcinogenicity Bismuth and its compounds have not been identified as carcinogenic by the International Agency for Research on Cancer (IARC), the NTP, Occupational Safety and Health Administration (OSHA), the EPA through IRIS, or California's Prop 65. The American Conference of Governmental Industrial Hygienists (ACGIH) has assigned bismuth telluride an A4 carcinogenicity rating, "Not classifiable as a Human Carcinogen," based on a lack of response in chronic studies of dogs, rabbits, and rats. No data are available regarding the carcinogenicity of bismuth or its compounds in humans (National Library of Medicine, 2002).

Reproduction There are no data suggesting that bismuth presents a reproductive hazard. Bismuth levels in fetuses were reported to be the same as the parent following administration of bismuth salts to the mother (INCHEM, n.d.). There are two reports of women exposed to high levels of bismuth having normal pregnancies (NLM HSDB, 2013). In animal studies, bismuth citrate was given to pregnant rats and rabbits at 200 mg/kg and 1200 mg/kg body weight and no developmental anomalies were observed (Secker, 1993).

MODE OF ACTION

What is known about the biological activity bismuth and its compounds has been identified mostly from studies of their pharmacology. Bismuth is not an essential element for either man or animals (Fowler and Vouk, 1986). Almost all absorption of bismuth occurs from the gastrointestinal tract. Gastrointestinal absorption of bismuth compounds is primarily a function of their water solubility (INCHEM, n.d.). Absorbed bismuth is found primarily in the kidney with deposition occurring to a lesser extent in other organs such as liver, brain, lung, and spleen. Elimination occurs primarily via the

kidney (absorbed bismuth) and feces (unabsorbed) (Fowler and Vouk, 1986; Slikkerveer and de Wolff, 1992). The pharmacologically active bismuth compounds have been divided into four toxicological groups (Slikkerveer and de Wolff, 1989):

Group 1: Simple organic salts and subsalts that are insoluble in water are minimally absorbed from the gut and that cause virtually no toxicity (e.g., bismuth subcarbonate).

Group 2: Absorbable lipid-soluble organic compounds and complexes that elevate the blood level of bismuth and cause neurotoxicity and hepatotoxicity (e.g., bismuth subgallate).

Group 3: Absorbable water-soluble organic compounds and complexes that elevate the blood level of bismuth and cause nephrotoxicity (e.g., bismuth oxychloride).

Group 4: Water-soluble complexes that hydrolyze in the gastrointestinal tract, with some absorption of bismuth and the hydrolyzed radical, elevating the levels of bismuth and the complex radical (e.g., bismuth subsalicylate).

Most bismuth compounds are considered to be poorly to moderately absorbed following dermal application, inhalation, or ingestion. The mechanism of action of bismuth toxicity is not fully understood. Most cases of toxicity associated with nephrotoxicity are primarily associated with exposure to water soluble bismuth salts (INCHEM, n.d.).

Until the 1940s, bismuth compounds were given parenterally and orally to treat infections such as syphilis and gastrointestinal complaints. Bismuth compounds have bactericidal actions *in vitro* and cytoprotective effects *in vivo*. Bismuth compounds, the subcitrate and subsalicylate, increase mucous and bicarbonate secretion in the gut and accumulate preferentially in ulcers. These compounds have antibacterial effects on *Helicobacter pylori* and help prevent ulcer formation by binding mucous together and inhibiting pepsin activity (Bierer, 1990; East, 2009). Because of problems with acute and chronic bismuth poisoning, medical use of bismuth and bismuth compounds has been restricted in Europe, Canada, and Australia. In the United States doses of bismuth subsalicylate up to 4.8 g/day have been considered safe (Bierer, 1990).

OCCUPATIONAL EXPOSURE

Sources of Exposure

Although occupational exposure may occur in the manufacture of cosmetics, industrial chemicals, metal alloys, and pharmaceuticals, occupational overexposures are rare (Fowler and Vouk, 1986). Bismuth presents a low hazard for usual industrial handling.

Many occupations can present the possibility of overexposure to bismuth compounds because these compounds are used as coloring agents for ceramics, enamels, and paints; as corrosion inhibitors for water systems; as catalysts in the plastics and petroleum industry; and as flame retardants for resins. Bismuth is used in metallurgy for the manufacture of numerous alloys, some of which are used in welding and production of malleable irons. Bismuth telluride is used as a semi-conductor. Bismuth oxide, hydroxide, oxychloride, trichloride, and nitrate are used in cosmetics. Other salts such as succinate orthoxyquinolate, subnitrate, carbonate, and phosphate also have pharmaceutical applications (Nordberg, 2012). Workers can be exposed to insoluble bismuth material in the mining and processing of ore that contains lead or gold; when working with bismuth or its alloys; when formulating and using lubricants, catalysts, and as a base metal. Although the literature reports some symptoms from occupational overexposure to bismuth, it is uncommon. Overexposure to bismuth compounds in the workplace may cause some short-lived symptoms such as fatigue, joint pain, headaches, backaches, and other nonspecific symptoms (Fowler and Vouk, 1986). On the rare occasion when occupational overexposure to bismuth or its compounds are linked to human toxicity it is associated with other more toxic compounds. For example, in an article by Bachanek et al. (2000) numerous adverse health effects were reported over time in a worker in a glass factory in Poland. Findings included loss of hair, scars and ulcerations, trigeminal nerve damage, and impalpable lymph nodes. His teeth were extracted over a 13-month period because they showed unusual damage such as brittleness and dark brown color. Heavy metal levels of thallium, lead, cadmium, and bismuth were substantially elevated. Bismuth levels in tooth material were 180 times greater than the control group average. Ascribing the patient's medical problems to the various elevated metal levels was difficult although some of the observations could be linked directly to one of the other metals present. For example, hair loss is well known to be linked to thallium overexposure. Yet bismuth is included as one of the metals linked to the worker's illness.

Industrial Hygiene

The permissible exposure limit (PEL) values are established by the OSHA and the threshold limit values (TLV) are set by the ACGIH. The only PELs for bismuth compounds set by OSHA are for bismuth telluride undoped (15 mg/m^3 [total dust and 5 mg/m^3 respirable dust]) and selenium doped bismuth [5 mg/m^3] (OSHA, 2008). This limit is based on the observation that overexposure to these compounds may cause irritation of the eyes, nose, throat, and respiratory tract, as indicated by animal studies (NIOSH/OSHA, 1992). The TLVs set by ACGIH for these compounds are 10 and 5 mg/m^3 undoped and doped, respectively. These criteria were

established in 1973. The criterion set for bismuth telluride undoped is based on the compound being considered an "inert" material lacking any response other than physical irritation in an animal inhalation study. The criterion for "doped" bismuth telluride is based on the results of inhalation studies in several animal species, including dogs, rabbits, and rats, wherein granulomatous lesions were seen in all exposed species at 15 mg/m^3 for 1 year, 5 days per week. Since the lesions were considered mild and reversible, the lower criterion was recommended.

In any industrial operation, excessive exposure to hazardous materials should be avoided through use of appropriate administrative and engineering controls, such as local ventilation. If engineering controls are not feasible, a program requiring respirators and other personal protective equipment is needed. Impervious gloves, clothing, eye protection, and NIOSH-approved respiratory protection should be used to protect workers from overexposure to bismuth and bismuth compounds which may present a health hazard. If protective clothing is to be reused, laundering contaminated clothing should be controlled to avoid additional exposure-related hazards. For operations in which exposure to hazardous materials is possible, good personal hygiene habits are strongly recommended. These include no eating or smoking in the work area; washing hands and face after leaving the work area and before eating, smoking, or using toilet facilities; and removing contaminated clothing and showering at the end of the workday.

RISK ASSESSMENT

Although bismuth has not been the subject of any complete international review by WHO or other key organizations, e.g., US EPA, numerous organizations with a wide range of constituencies have opined on its hazard potential (COT, 2008). According to the Bismuth Institute Information Center, in a world where many elements and compounds present a multitude of hazards, bismuth metal is one of those rare elements that is considered safe because it is non-toxic and non-carcinogenic (Palmieri, 1993). Although the objectivity of a trade association group might be questioned, their conclusion is consistent with others such as Beliles (1979), who concludes that "except for strong acidic salts as bismuth trinitrate or violently reactive compounds such as bismuth tripentafluoride, bismuth compounds do not present a hazard by dermal application, inhalation or injection," the usual routes of occupational exposure. The International Labor Organization concludes that "there have been no reports of occupational (illness) during the production of metallic bismuth and the manufacture of pharmaceuticals, cosmetics and industrial chemicals. Because bismuth and its

compounds do not appear to have been responsible for poisoning associated with work, they are regarded as the least toxic of heavy metals currently used in industry" (Nordberg, 2012).

BORON

GIFFE T. JOHNSON

First aid:

Eye contact: Check for and remove any contact lenses. In case of contact, immediately flush eyes with plenty of water for at least 15 min. Get medical attention if irritation occurs.

Skin Contact: Wash with soap and water. Cover the irritated skin with an emollient. Get medical attention if irritation develops.

Inhalation: If inhaled, remove to fresh air. If not breathing, give artificial respiration. If breathing is difficult, give oxygen. Get medical attention.

Ingestion: Do not induce vomiting unless directed to do so by medical personnel. Never give anything by mouth to an unconscious person. If large quantities of this material are swallowed, call a physician immediately. Loosen tight clothing such as a collar, tie, belt or waistband.

Target organ(s): Skin, eyes, lungs, systemic toxicant

Occupational exposure limits: Boron oxide, total dust (8 h TWA): 15 mg/m³ (OSHA)

Boron trifluoride (ceiling): 3 mg/m³ (OSHA)

Reference values: Boron and boron compounds: RfC N/A (EPA); RfD 0.2 mg/kg/day (EPA); Inhalation MRL 0.3 mg/m³ (ATSDR); Oral MRL 0.2 mg/kg/day (ATSDR)

Risk/safety phrases: Skin irritant; eye irritant; corrosive

BACKGROUND AND USES

Boron occurs naturally as sodium borate ($\text{Na}_2\text{B}_4\text{O}_7$) and calcium borate. Borax ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$) has been used for

many purposes for years. The earth's crust contains approximately 0.0008% boron (Cotton et al., 1999; Jansen, 2003). Background levels of boron in U.S. soils have been reported to average 4.6–26 mg/kg. Boron is an essential nutrient for higher plants. Some studies indicate that it may also be an essential element for humans (Penland, 1994). Boracaptate is used in boron neutron capture therapy for treatment of malignant brain tumors. Approximately 225 compounds containing boron are listed on the Toxic Substances Control Act inventory.

Boron is used in high energy fuels, in nuclear reactors as a shielding material to absorb neutrons, for hardening steel alloys, as an abrasive, for fireproofing, and in the textile and glass industries. Commercial products that use boron include glass, fire retardants, leather finishing, laundry detergents, perborate bleaches, and pesticides. Boron as a trifluoride is used in the dry etching of semiconductors and as a hydride in the defense industry for rocket propellants. Boron compounds are used as catalysts in the production of polymers and in chemical synthesis. They also are used as biological growth control agents in water treatment algaecides, fertilizers, herbicides, and insecticides. Boric acid is used as a surface disinfectant and is a principal ingredient in several pesticides.

PHYSICAL AND CHEMICAL PROPERTIES

Boron (symbol B; CAS #7440-42-8) is a dark brown or black metalloid in the amorphous form. It has a molecular weight of 10.81 g/mole, a boiling point of 2550 °C (4622°F), and a melting point of 2300 °C (4172°F). It is insoluble in water but

soluble in nitric and sulfuric acids. It is insoluble in cold water, hot water, diethyl ether, and alcohol. If finely divided, it is soluble in most molten metals such as copper, iron, magnesium, aluminum, and calcium. Borates are relatively soluble in water.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Boron is never found as a free element in nature, and is commonly found attached to oxygen (Cotton et al., 1999). Atmospheric boron may be in the form of particulate matter or aerosols as borides, boron oxides, borates, boranes, organoboron compounds, trihalide boron compounds, or borazines. The half-life of airborne particles is usually on the order of days, depending on the size of the particle and atmospheric conditions (Nriagu, 1979). Many boron minerals are soluble in water, and it is unlikely that mineral equilibria will modulate the presence of boron in water (Rai et al., 1986). Boron has not been found to be significantly removed during conventional waste water treatment (Matthijs et al., 1999; Pahl et al., 2001; Waggott, 1969). Waterborne boron may be adsorbed by soils and sediments and adsorption-desorption reactions are likely to be the principal mechanism that determines the fate of boron in water (Rai et al., 1986). The extent of boron adsorption depends on the pH of the water and the chemical composition of the soil, with the greatest adsorption occurring at pH 7.5–9.0 (Keren and Mezuman, 1981; Keren et al., 1981; Waggott, 1969).

Although data is limited regarding the bioaccumulation of boron and boron-containing compounds, it is not expected to bioconcentrate or bioaccumulate (Tsui and McCart, 1981).

ECOTOXICOLOGY

Acute Effects

Although data are limited regarding the ecotoxicology of boron, evidence suggests that common environmental boron exposures resulting from both natural and anthropogenic sources do not have substantive acute effects on terrestrial and aquatic ecologies (Butterwick et al., 1989).

Chronic Effects

Although data are limited regarding the ecotoxicology of boron, evidence suggests that common environmental boron exposures resulting from both natural and anthropogenic sources do not have substantive chronic effects on terrestrial and aquatic ecologies (Butterwick et al., 1989).

MAMMALIAN TOXICOLOGY

Acute Effects

Boric acid has a relatively low toxicity in humans. In many cases of accidental or suicidal ingestion, the patient may be asymptomatic. If symptoms do occur, they may include abdominal pain, vomiting, diarrhea, headache, lethargy, and lightheadedness.

Workers exposed to borate dust are more likely to report symptoms such as nasal irritation than are nonworkers (Wegman et al., 1994). A decline in lung function was noted in borate workers over a 7-year period, but most of this (83%) was attributed to age and other factors. Decreases in lung function did not correlate with levels of exposure, but the probability of having symptoms did correlate with increasing levels of exposure.

Whorton et al. (1994) conducted an epidemiological study of male reproductive effects in a facility that produced inorganic borate. Using a standardized birth ratio method, they found that the birth rate among facility employees did not differ significantly from that of the general population.

Metaborates are highly alkaline and therefore may cause skin and eye damage. Boron trihalides have been shown to be respiratory irritants in animals and may have similar effects in humans. Borax and boric acid are absorbed from the gastrointestinal tract and damage skin. Borax is also a respiratory irritant. Air concentrations of 1.2–8.5 mg/m³ have been associated with respiratory irritation. A dry cough, sore throat, and shortness of breath have been reported. More than 1 g of borax or excessive percutaneous absorption may result in severe acute and sometimes fatal intoxication.

The gas diborane (B_2H_6) is a pulmonary irritant, which causes tightness in the chest, shortness of breath, cough, and nausea. Continuous exposure concentrations below, which pulmonary irritation occurs may produce headaches, dizziness, chills, and fatigue.

The vapor from pentaborane (B_5H_9), a liquid, affects the nervous system, causing hyperexcitability and narcosis. The onset of symptoms may be delayed for a couple of days. Exposure to higher concentrations may cause incoordination, tremors, and seizures.

Experiments with rats suggest that the testes are a primary target organ for boric acid toxicity (Ku et al., 1991). High doses of boric acid cause testicular lesions in adult rats. Mechanistic studies suggest a central nervous system-mediated effect rather than a direct hormonal one (Ku and Chapin, 1994).

Because boric acid has a half-life in humans of about 1 day, urine and blood levels do not increase over a work week (Culver et al., 1994; Moseman, 1994). Boron does not accumulate in the soft tissues of animals; however, in cases of boric acid poisoning, brain and liver concentrations may be very high (Moseman, 1994).

Chronic Effects

Boron trifluoride, a gas, is severely irritating to eyes, skin, and lungs. Workers exposed to concentrations of up to 32 ppm (90 mg/m³) for a decade or longer developed dryness of the nasal mucous membranes and epistaxis. Chronic exposure at low concentrations is not associated with adverse health effects.

Animal studies, including those conducted in rats and dogs exposed to high levels of boric acid or borax in the diet (Weir and Fisher, 1972) and mice exposed to boric acid in the diet (Dieter, 1994; NTP, 1987), have observed systemic effects such as hematological alterations (decreases in hemoglobin in rats and splenic hematopoiesis in mice), desquamation of footpad skin and bloody ocular discharge in rats, decreased body weight gain in rats and mice, lung hemorrhage in mice, and hepatic chronic inflammation and coagulative necrosis. In rats, systemic effects occurred from chronic exposure to 81 mg boron/kg/day (NOAEL of 24 mg boron/kg/day); in mice, at 79 mg boron/kg/day. Testicular atrophy was observed in rats exposed to 81 mg boron/kg/day as boric acid or borax (Weir and Fisher, 1972) and in mice exposed to 201 mg boron/kg/day as boric acid (Dieter, 1994; NTP, 1987).

Chemical Pathology

Boron is absorbed across pulmonary tissues into the blood. Workers exposed to borate dusts were found to have higher blood and urine boron concentrations at the end of a work shift compared to the beginning of the shift (Culver et al., 1994). Boron is almost completely absorbed in the gastrointestinal tract, with up to 95% of the ingested dose being recovered in the urine (Dourson et al., 1998).

Boron is distributed readily to all body tissues. Tissue levels from daily doses achieve steady state with plasma in neurological and reproductive tissues. Bone and adipose tissues have differential affinities for boron with bone having a higher affinity for boron and adipose tissue having a lower affinity for boron than other soft tissues (Ku et al., 1991).

Excretion of boron is accomplished mostly through renal elimination, with minor contributions from saliva, sweat, and feces (Jansen et al., 1984). In workers exposed to borax, the boron level in the urine at the end of a work shift is a more accurate indicator of exposure than is the blood level (Culver et al., 1994).

Mode of Action(s)

Borates may be corrosive and can irritate the skin and mucous membranes. Mechanisms related to potential neurological or reproductive toxicity have not been elucidated.

SOURCES OF EXPOSURE

Occupational

The NIOSH estimates that the number of workers potentially exposed to boron increased from 6500 in the early 1970s to 35,600 in the early 1980s (NOHS, 1989; NOES, 1989). Sittig (1985) reports that NIOSH estimated that the numbers of workers potentially exposed to borax, boron oxide, and boron trifluoride are 2,490,000; 21,000; and 50,000, respectively.

Workers in the industries of manufacture of glass wool, fiberglass and other glass products, cleaning and laundry products, fertilizers, pesticides, and cosmetics may be exposed to boron compounds (Jensen, 2009; Stokinger, 1981). Workers exposed to boron may absorb measurable quantities; end-of-shift boron concentrations in blood and urine of 0.11–0.26 µg/g and 3.16–10.72 µg/mg creatinine, respectively, have been reported in workers at a facility where borax is packaged and shipped (Culver et al., 1994). In occupational settings where higher exposures exist without exposure mitigation, boron exposure can be substantially higher. Workers from Kuandian City, China employed in boron mines or processing plants producing borax or boric acid had total daily boron measurements (in food, fluids, and personal air) averaging 41.2 mg/day for workers in the boron industry, 4.3 mg/day in the surrounding community, and 2.3 mg/day in a control group. Post-shift urine levels of boron measured in the boron industry workers was 499 mg/day, compared to 48.0 mg/day in the control group (Xing et al., 2008).

Large borax mining and refining plants may produce borax dusts in concentrations ranging from 1.1 to 14.6 mg/m³ for total particulate with a mean boric acid/boron oxide dust concentration of 4.1 mg/m³ for total particulate (Garabrant et al., 1984, 1985). In air samples from U.S. facilities where borax was packaged and shipped, mean dust concentrations have been observed in the range of 3.3–18 mg/m³ (Culver et al., 1994).

Environmental

Ingestion of boron from food and water is the most frequent route of environmental human exposure. Boron exposure may also occur from some consumer products, including cosmetics, medicines, and insecticides. Some areas of the western United States have natural boron-rich deposits in the soil may also have higher boron exposure.

Rainey et al. (2002) reported mean daily intakes of boron from food and beverage sources for male and female adults to be 1.28 and 1.00 mg, respectively. Daily dietary boron intakes were estimated at 0.75 mg for infants aged 0–6 months and 0.99 mg for infants aged 7–11 months. Daily boron intakes were estimated as 0.86 mg for children aged

1–3 years, 0.80 mg for children aged 4–8 years, 0.90 and 1.02 mg, respectively, for adolescent males aged 9–13 and 14–18 years, and 0.83 and 0.78 mg, respectively, for adolescent females aged 9–13 and 14–18 years.

Boron is fairly ubiquitous in surface water and groundwater; the average surface water boron concentration in the United States is about 0.1 mg/l (Butterwick et al., 1989; EPA, 1986), but concentrations vary greatly, depending on local geologic and anthropogenic sources of boron (Butterwick et al., 1989). Mean boron concentrations in soil in the United States are about 30 mg/kg, with concentrations ranging up to 300 mg/kg (Eckel and Langley, 1988).

In the United States, Canada, and England, concentrations of boron in tap water have been reported in a range of 0.007–0.2 mg/l (Choi and Chen, 1979; Davies, 1990; Waggett, 1969). Ambient air samples have reported boron concentrations from $<5 \times 10^{-7}$ to 8×10^{-5} mg/m³, with an average concentration of 2×10^{-5} mg/m³ (Howe, 1998). It has been estimated that approximately 11,600 tons of boron per year are released into the atmosphere as a component of fly ash produced by coal combustion (Bertine and Goldberg, 1971).

INDUSTRIAL HYGIENE

Borates, or oxygen and inorganic boron-containing compounds, are the most common form of boron found in commercial products. This group includes boric acid, boric oxide, and hydrides of boron (boranes). Elemental boron is rare in the workplace and is not regulated because it is inert and has minimal use. Dust is the most common form of

TABLE 11.1 Exposure Level Guidance and Regulatory Values

NIOSH REL (mg/m ³)	
Borax (10 h TWA)	5
Boron oxide (10 h TWA)	10
Boron tribromide (ceiling)	10
Boron trifluoride (ceiling)	3
Sodium tetraborate (10 h TWA)	1
Boron oxide	2000
Boron trifluoride	70
Sodium tetraborate	70
OSHA PEL (mg/m ³)	
Boron oxide, dust (8 h TWA)	15
Boron trifluoride (ceiling)	3
Boron tribromide (8 h TWA)	10
Boron trifluoride (ceiling)	3
OSHA Threshold Quantity (lbs)	
Boron trichloride	2500
Boron trifluoride	250

exposure and borate dusts should be kept below regulatory levels through appropriate control measures. The exposure limits and quantity threshold values for various boron compounds are listed in Table 11.1.

CADMIUM

FRANK D. STEPHEN

First aid: Report all exposures to medical personnel immediately. Eye: Wash eyes immediately with large amounts of water for 15 min. If irritation persists, seek medical attention. Skin: Wash the exposed area with soap and water for 15 min. Inhalation: Move the person to fresh air.

Target organ(s): Oral: Kidney and bone. Inhalation: Kidney and lung

Occupational exposure limits: OSHA-PEL $5 \mu\text{g}/\text{m}^3$ (8-h workday). NIOSH-REL $9 \text{ mg}/\text{m}^3$ (10 h TWA). ACGIH-TWA $0.01 \text{ mg}/\text{m}^3$

Reference values: MRL—short-term inhalation: $0.03 \mu\text{g Cd}/\text{m}^3$ (<14 day exposure). Chronic inhalation: $0.01 \mu\text{g Cd}/\text{m}^3$ (>1 year exposure). Chronic oral: $0.1 \mu\text{g/kg}/\text{day}$ (>1 year exposure). RfD: $5 \times 10^{-4} \text{ mg/kg}/\text{day}$ (water) and 1×10^{-3} (food). RfC: Not established

BACKGROUND AND USES

Cadmium (symbol Cd; CAS #744-43-9) is a naturally occurring element found in combination with zinc in the earth's crust. Most cadmium used in the United States is derived from zinc, copper, or lead extraction. Naturally, approximately 25,000 tons of cadmium are released into the environment mostly into water sources due to rock weathering and air due to forest fires and volcanoes. Industrial

manufacturing by humans is responsible for all other cadmium releases. Since cadmium can be extracted from zinc smelting, its ore is not mined for the metal. Approximately, 14 tons per year are produced worldwide with Canada being the main producer. Other major producers include the United States, Japan, Mexico, and Australia. It's used primarily in nickel cadmium batteries, coating and plating operations, and in pigments, plastics, and other synthetic products and alloys.

Overexposure to cadmium outside of the workplace is rare and mainly occurs through foodstuffs and smoking. Food sources containing cadmium include liver, mushrooms, cocoa powder, and shellfish. Consumption of these foods can increase the cadmium concentration in human bodies. An exposure to significantly higher cadmium levels occurs from smoking tobacco. Initially deposited in the lungs, cadmium is transported throughout the body by blood via the cardiovascular system, where it can enhance effects by potentiating cadmium that is already present from cadmium-rich food. Excessive environmental exposures have also been reported in some locations. Children living near a Mexican smelter were found to have cadmium exposure and body burdens above the acceptable levels set by the United States Environmental Protection Agency (EPA) (Diaz-Barrera et al., 1993). Nonoccupationally exposed Russians living near a metallurgical plant and storage battery factory also had an elevated body burden of cadmium (Bustueva et al., 1994).

TABLE 12.1 Physical and Chemical Properties of Cadmium

Molecular weight	112.41
Color	Silver-white
Physical state	Lustrous metal
Flash point	No data
Melting point	321 °C
Boiling point	765 °C
Density at 20°C	8.65 g/cm ³
Water solubility	Insoluble
Vapor pressure	7.5 × 10 ⁻³ mmHg

PHYSICAL AND CHEMICAL PROPERTIES

Cadmium is an odorless, silver-white lustrous metal with a bluish tinge, which is ductile and highly malleable with a melting point of 321 °C. The metal is soft enough to cut with a knife and will tarnish in air; as a powder, cadmium is flammable. Burning cadmium results in an odorless yellow-brown cadmium fume (cadmium monoxide or cadmium oxide fume) composed of finely divided particles dispersed in air. Both cadmium and cadmium oxide are insoluble in water and have a vapor pressure of approximately 0 mmHg. Cadmium is insoluble in water but can be solubilized in acid. Cadmium salts (e.g., cadmium sulfate and cadmium chloride) are soluble in water. Important physical and chemical properties are listed in Table 12.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Cadmium is found naturally as one of the core components in the earth's crust. Industrial emissions from combustion and leaching from contaminated waste sites are the most likely causes of cadmium release into the environment. Whether released into the air or soil, the cadmium finally gets accumulated mostly in the soil (Morrow, 2001; Wilber et al., 1992). When emitted into the air, it can condense onto respirable particulates and can be transported over distances up to a couple of miles and can persist in the atmosphere for up to 10 days (Steinnes and Friedland, 2006; Wilber et al., 1992; EPA, 1980). Cadmium particles can also settle due to gravity or attach to water droplets that get subsequently deposited terrestrially.

Unlike many other heavy metals, upon release into water sources, cadmium is very mobile. Cadmium in unpolluted fresh water can be found as its hydrated ion Cd(H₂O)₆²⁺ as opposed to polluted water sources where cadmium binds to humic substances leading to its transport and remobilization (EPA, 1979). The persistence of cadmium in water systems has been calculated to range from 4 to 10 years (Wester et al., 1992). Bacteria found in sediments have been found to aid in

the partitioning of cadmium from water to soil sediments (Burke and Pfister, 1988). Disturbance of cadmium adsorbed to clay sediment has been shown to release to water more easily than cadmium associated with carbonate materials (EPA, 1979). Due to its lack of volatility, cadmium does not partition from water back to the atmosphere (EPA, 1979). On land, once deposited in the soil, cadmium can entrain to water or air (EPA, 1985). Acidic conditions can cause cadmium to leach into water (Elinder, 1985), and a reaction with chloride can cause cadmium to poorly adsorb by clay (Roy et al., 1993).

Bioaccumulation through the food chain is of particular concern with regard to the final cadmium deposition in soil and sediments. Plants efficiently derive cadmium from the soil thereby introducing it into the food chain of animals and eventually humans. Acidic soil pH, which occurs due to acid rain, is of increasing concern because this condition makes it easier for plants to take up cadmium (Elinder, 1992). Bioaccumulation in terrestrial and aquatic organisms is well documented. Strikingly, cadmium levels in freshwater and marine animals have been found to be hundred to thousand times higher than that of surrounding water (EPA, 1979).

Bioaccumulation occurs at all levels of the food chain from grass to food crops leading to further accumulation in livestock. Factors influencing uptake by plants include root system, foliar uptake, and translocation rate within the plant as well as how deep cadmium deposition into the soil occurs (Nwosu et al., 1995). Cadmium has been found to accumulate in plant leaves, and when grown in the same soil, leafy vegetables will contain more cadmium than root vegetables or grains (He and Singh, 1994). Passage of cadmium from the soil to plant appears to happen via passive diffusion (Nwosu et al., 1995). Other factors that increase bioavailability and cadmium uptake include acidic as opposed to alkaline soils (Smith, 1994; He and Singh, 1994; Thornton, 1992), sandy soil as opposed to clay (He and Singh, 1994), and non-calcareous as opposed to calcareous (Thornton, 1992).

Although cadmium accumulates through the food chain, biomagnifications among livestock (animal-to-animal consumption) may not be significant primarily because cadmium is poorly absorbed in the intestine (Sprague, 1986) and is predominantly stored in the liver and kidney rather than skeletal muscle (Harrison and Klaverkamp; Sileo and Beyer, 1985; Vos et al., 1990). Rather, human accumulation of cadmium more likely results in consumption of beef and poultry raised in feed crops grown in cadmium-containing soils.

ECOTOXICOLOGY

Cadmium is found naturally in soils, sediments, rocks, and the earth's crust. As such, environmental exposures are always possible. Erosion of cadmium-containing soils into freshwater systems is possible through natural rainfall.

Further, cadmium can be released into the environment from the burning of municipal and industrial wastes, use of fossil fuels, and phosphate-based fertilizer application. Air entrainment of cadmium can result from natural events or human activity. Since cadmium is found in water and soil, it can be emitted into the air through forest fires, volcanoes, and wind-swept erosion of dry soils (EPA, 1985; Morrow, 2001) as well as aerosolizing of sea salt (Shevchenko et al., 2003). The main sources of cadmium introduction to air are from industrial activity such as smelting, coal boilers, municipal and sewage incinerators, and other urban and industrial emissions. Therefore, the risk of acute and chronic effects to ecosystems may exist. However, tolerance appears to play a role in various species exposed to cadmium from natural sources. Also, complicating the field studies is the inability to directly demonstrate that cadmium is the sole source of the effect observed. The following is a brief review of the laboratory studies where direct effects of cadmium were observed.

Acute Effects

Aquatic Species Laboratory exposures to cadmium produce various acute effects to aquatic organisms. Its toxicity in water is dependent upon a variety of natural factors such as water hardness, salinity and temperature, as well as chelating agents and organic matter. Embryonic and larval stage aquatic animals appear to be more sensitive than adult animals of the same species. Mortality studies found that 7-day exposure to 85.5 µg/l cadmium produced death in the snail *Physa integra* (Spehar et al., 1978). Cadmium LC₅₀s have been reported for crayfish (Mirenda, 1986), scallops (Pesch and Stewart, 1980), amphipods (Robinson et al., 1988), minnows (Pickering and Henderson, 1966), and various forms of amphibian (Westerman, 1977; Slooff and Baerselman, 1980; Canton and Slooff, 1982; Khangarot and Ray, 1987; Woodall et al., 1988).

Terrestrial Organisms Cadmium toxicity has been reported in several terrestrial species, including nematodes and snails. Cadmium LC₅₀s have been established for several nematode species while other researchers found decreases in fecundity, growth, and reproduction. Snails that were fed cadmium-enriched diets were found to have reduced food consumption, weight loss, shell growth, and reproductive activity. The toxicity to various juvenile avian species was also studied and cadmium LC₅₀s were reported for quail (Hill and Camardese, 1986; Hill et al., 1975), pheasant (Hill et al., 1975), mallard duck (Hill et al., 1975), and chickens (Pritzl et al., 1974).

Chronic Effects

Aquatic Organisms Laboratory studies have also investigated the potential for cadmium toxicity in animals due to

long-term exposure. Snails exposed to cadmium from the embryonic stage to adulthood were found to have delayed hatching times and reduced overall growth (Holcombe et al., 1984). Similar results were reported in minnows (Meteyer et al., 1988). Oysters exposed to cadmium concentrations of at least 5 µg/l for at least 35 weeks demonstrated slower growth than controls (Zaroogian and Morrison, 1981). Exposure to 3.5 µg/l cadmium produced retarded growth and death was observed to brook trout males during spawning (Benoit et al., 1976). Cadmium exposure during development of minnows and medaka produced malformed spinal vertebra (Bengtsson et al., 1975; Hiraoka and Okuda, 1984), and it was shown that calcium levels were decreased in fish with spinal malformations (Muramoto, 1981).

Terrestrial Organisms The toxicological potential of cadmium has also been studied experimentally in terrestrial species. Generally, in invertebrates there was reduced growth and reproduction observed after cadmium exposure otherwise cadmium had little to no effect. Male avians exposed to cadmium via intramuscular injection (pigeons) or diet (mallard ducks) had reduced testicular development and spermatogenesis while female mallards had reduced egg production (Lofts and Murton, 1967; White and Finley, 1978; White et al., 1978). Kidney damage was reported in various seabirds that had been contaminated in the wild and starlings exposed in the laboratory (Nicholson et al., 1983).

MAMMALIAN TOXICOLOGY

Acute Effects

Human health effects due to cadmium exposure are dependent on the route of exposure. The most common cadmium exposure route is inhalation. Deaths due to severe pulmonary edema and chemical pneumonitis, leading to death due to respiratory failure have been reported for accidental occupational exposure to cadmium (Beton et al. 1966; Patwardhan and Finckh, 1976; Lucas et al., 1980; Seidal et al., 1993). Nonlethal, immediate post-cadmium exposure effects due to acute cadmium inhalation primarily involve the respiratory tract, including, but not limited to, irritation, tight chest, cough, pain in chest on coughing, dyspnea, chills, sweating, and aching pain in back and limbs.

Chronic Effects

Human epidemiological studies have found that long-term cadmium inhalation exposure produces effects on the respiratory and renal systems also leading to cancer. Inhalation does not appear to have significant effects on the cardiovascular, gastrointestinal, hepatic, nervous, immune, or reproductive systems.

Respiratory In humans, inhalation exposure to high levels of cadmium oxide fumes or dust is intensely irritating to the respiratory tissue, but symptoms can be delayed. Occupationally exposed individuals have been reported to show signs of chronic rhinitis and impairment or loss of the sense of smell, progressive pulmonary fibrosis, severe dyspnea and wheezing, chest pain and precordial constriction, persistent cough, weakness and malaise, anorexia, nausea, diarrhea, nocturia, abdominal pain, hemoptysis, and prostration. Interestingly, Edling et al. (1986) did not find that cadmium exposure impaired the respiratory system function, and other studies have shown that cadmium-induced effects to the respiratory system can be partially reversible and even return to normal several years later (Bonnell, 1955; Chan et al., 1988).

Renal Kidney function is the primary target of chronic cadmium overexposure. Initial indications of impaired kidney function are proteinuria and decreased glomerular filtration rate (GFR). Occupational studies have shown that workers overexposed to cadmium had impaired nephron reabsorption of calcium, retinol-binding protein, beta 2-microglobulin, and transferrin. Cadmium-induced kidney impairment may continue to progress after exposure has stopped. A prospective study of 23 former cadmium workers reported that the GFR declined at a higher rate than normal (Järup et al., 1993). Further research indicated that glomerular damage correlated with blood cadmium levels (Järup et al., 1995). In this study, the authors found that every worker with cadmium blood levels over 75 nmol/l had glomerular damage compared with 33% of workers with blood concentrations between 50 and 75 nmol/l and only 3.4% of workers with concentrations below 50 nmol/l.

Recent studies have focused on identifying biomarkers of cadmium exposure. Increased urinary cadmium levels have been correlated with urinary human complex-forming glycoprotein (pHC) also called $\alpha 1$ microglobulin (Järup et al., 2000; Olsson et al., 2002; Nakadaira and Nishi, 2003; Teeyakasem et al., 2007).

Kidney stones may form in some groups as a result of disturbed calcium-phosphorus metabolism, specifically phosphaturia, low serum phosphorus, and low tubular reabsorption of calcium. Workers exposed to cadmium have been reported to have a higher prevalence of kidney stones (Järup and Elinder, 1993).

Cancer Epidemiological studies have been undertaken to research the possible effect cadmium has on carcinogenesis. There is little evidence to show that oral or dermal exposures to cadmium can be associated with increased human cancer rates. Several studies have suggested that there is an increase in mortality due to lung cancer in response to cadmium inhalation. The current data are conflicted regarding whether cadmium exposure causes prostate cancer. Based on the available epidemiological studies, the International Agency

for Research on Cancer (IARC) lists cadmium as a Group 1 carcinogen: carcinogenic to humans, whereas, the American Conference of Industrial Hygienists (ACGIH) has listed cadmium as an A2 carcinogen: suspected human carcinogen.

Sorahan and Lancashire (1997) reported a significant, exposure-related increase in lung cancer mortality among a cohort of cadmium workers. This increase in cancer incidence was also related to worker cadmium exposure in association with arsenic trioxide. Workers in nickel-cadmium battery facilities in England and Sweden were found to have increased lung cancer mortality (Sorahan, 1987; Järup et al., 1998). Similarly, increased respiratory tract and lung cancer mortality rates were observed amongst employees in cadmium recovery and processing facilities and/or smelter operations (Lemen et al., 1976; Thun et al., 1985; Ades and Kazantzis, 1988; Kazantzis et al., 1988; Stayner et al., 1992). The association between cadmium and lung cancer though is not completely clear. Many of the studies listed failed to reject other confounding factors such as smoking and exposure to other heavy metals.

Studies have also been conducted focusing on the relationship between cadmium exposure and prostate cancer. Early studies reported increases in prostate cancer after occupational exposure to cadmium (Kipling and Waterhouse, 1967; Kjellström et al., 1979; Lemen et al., 1976). However, subsequent investigations failed to find increases in prostate cancer rates among males occupationally exposed to cadmium (Elinder et al., 1985c; Kazantzis et al., 1988; Sorahan, 1987; Sorahan and Esmen, 2004; Thun et al., 1985; Kazantzis et al., 1992).

Skeletal Detailed clinical findings showing skeletal abnormalities in cadmium workers were reported by Gervais and Delpech (1963). Pathological fractures and bone changes were visible on X-rays. In Japan, the itai-itai disease occurred in people who worked in rice fields near a mine that produced zinc, lead, and cadmium (Kobayashi, 1971). Characterized by hypercalciuria, itai-itai causes inhibition of proximal tubular reabsorption leading to osteomalacia and painful fractures. Case studies indicate that calcium deficiency, osteoporosis, or osteomalacia can develop in some workers after long-term occupational exposure to high levels of cadmium (Adams et al., 1969; Blainey et al., 1980; Bonnell, 1955; Kazantzis, 1979; Scott et al., 1980). Effects on bone generally arise only after kidney damage has occurred and are likely to be secondary to resulting changes in calcium, phosphorus, and vitamin D metabolism (Blainey et al., 1980).

Chemical Pathology

Once deposited in the tissue, cadmium's main mechanism appears to be related to the original cadmium compound the subject was exposed to as well as the cadmium particle size.

Cadmium oxide (inhalation) and cadmium chloride (oral) are of greatest concern, and the smallest cadmium particles are considered the most dangerous as they seed deeper into the lung bronchial tree. It is generally thought that unbound cadmium ions, and not those bound to metallothionein or other proteins, produce the observed toxic effects (Goyer et al., 1989), including interfering with metal-dependent enzymes. Renal tubular membranes can be damaged by cadmium bound to metallothionein during cellular uptake (Suzuki and Cherian, 1987).

Mode of Action(s)

Toxicity Cadmium toxicity occurs in a variety of organs and tissues but the primary targets are the kidney, liver, and bone. Kidney deposition results in damage to the cells of the proximal convoluted tubule or interstitial fibrosis (Stowe et al., 1972). The resulting effects include increased urine concentration of low molecular weight proteins (e.g., β_2 -microglobulin), glucose, enzymes, and amino acids and increase in total urine output. Cadmium appears to interfere with the metabolism of iron, zinc, copper, and selenium (Petering et al., 1979; Jamall and Smith, 1985) and may deplete various enzymes (e.g., glutathione peroxidase and superoxide dismutase). Bone deposition causes decreased osteoblastic activity that results in decreased production of new osteoid and mineralization and osteoclastic bone resorption may be enhanced. Bone mineralization may also be affected indirectly by cadmium-induced blockage of hydroxylation of 25-hydroxy vitamin D to 1,25-dihydroxy vitamin D in the kidney.

Entrance and Metabolism Cadmium exposure in humans occurs either via oral or inhalation routes, whereas dermal exposure is of little consequence. Workers are typically exposed through inhalation, whereas the general public is more likely to be exposed orally through consumption of foodstuffs such as grains, cereal, and potatoes (Gartrell et al., 1986). Smoking significantly increases cadmium levels in both groups (Hovinga et al., 1993; Qu et al., 1993; Hertz-Pannier, Hu, 1994). It is estimated that 50% of cadmium from inhalation exposure is absorbed by the lung tissue. A greater percentage of cadmium is absorbed from inhalation rather than the oral route. The amount of cadmium absorption in the lung is dependent on the particle size. Smaller particles are of more danger in that they are delivered to the smallest respiratory bronchioles and alveoli. Subsequent absorption to the bloodstream results in delivery to the rest of the body. Larger particles are trapped in the ciliated mucosal cells of the upper respiratory system, cleared, and eventually enter into the gastrointestinal track. Data regarding cadmium deposition, retention, or absorption in the human lung are not available.

Gastrointestinal track absorption of calcium has been reported to be <10% of the intake (Flanagan et al., 1978;

McLellan et al., 1978; Newton et al., 1984; Rahola et al., 1973; Shaikh and Smith, 1980; Vanderpool and Reeves, 2001). The mechanism by which cadmium is absorbed is not completely understood, but evidence exists showing that divalent metal transporter I protein is involved (Park et al., 2002; Ryu et al., 2004; Kim et al., 2007). Absorbed cadmium is bound and transported via metallothionein, a low molecular weight compound (Cousins, 1979) and also has an affinity for sulfhydryl groups on albumin and metallothionein (Nordberg et al., 1985). The metal–protein complexes are deposited in the liver, from which they are slowly released, and subsequently deposited in the kidney. Cadmium does not appear to undergo any metabolic conversion to other molecular species. Once in the kidney, sufficient amounts can cause renal tubular damage. Animal studies have shown a retention halftime of 73 days in liver tissue and a lifetime in the kidney tissue (Shaikh, 1982). Cadmium concentrations reported to cause renal tubular toxicity have been estimated to be over 200 $\mu\text{g/g}$ wet weight in the cortex (Dudley et al., 1985). Lower levels of metallothionein-bound cadmium are considered nontoxic. The exact biochemical mechanism that determines this threshold is unknown (Goyer, 1989).

Excretion Cadmium is excreted from the body very slowly; its biological half-life in humans is 10–40 years. Urine cadmium concentration in occupationally exposed workers increases proportionally to the total cadmium body burden (Roels et al., 1981). Low level, long-term cadmium exposure results in urine cadmium excretion that reflects the total body burden and typically amounts to 1–2 $\mu\text{g/day}$ (Goyer, 1989). However, when the exposure is more intense, urine cadmium levels may be as high as 50 $\mu\text{g/g}$ of creatinine, and this value is reflective of the recent exposure rather than the body burden.

SOURCES OF EXPOSURE

Occupational

The greatest risk to cadmium exposure by industrial workers includes processes where cadmium-containing materials are heated, including coating and electroplating, smelting operations, nickel–cadmium battery production, and phosphate fertilizer production and application. Another major route of incidental exposure comes from the ingestion of foods and cigarettes introduced to the mouth by contaminated hands and inhalation of dust and fumes.

Environmental

Cadmium is a naturally occurring element in the earth's crust and thus, plants can accumulate large amounts of cadmium in their leaves. Smoking is a major source of environmental

cadmium because of the ability of tobacco leaves to accumulate high levels of cadmium. The major source of cadmium is from food intake. Dietary consumption of organ meats and shellfish, leafy vegetables, potatoes and grains, soybeans and sunflower seeds contributes to the total cadmium body burden. Cadmium exposure from drinking water is not a major concern because the EPA mandates control water cadmium concentrations to be <5 µg/l.

INDUSTRIAL HYGIENE

Exposure Limits

ACGIH The ACGIH has established a threshold limit value (TLV) (8-h time-weighted average (TWA)) of 0.01 mg/m³ for cadmium and 0.002 mg/m³ for cadmium compounds.

NIOSH The National Institute for Occupational Safety and Health (NIOSH) considers cadmium compounds to be potential occupational carcinogens as defined by the Occupational Safety and Health Administration (OSHA) carcinogen policy (29 CFR 1990). Based on human data, the NIOSH has established an Immediate Threat to Life and Health (IDLH) level 50 mg/m³ in dust (Barrett and Card, 1947; Bulmer et al., 1938; Reinl, 1961) and 9 mg/m³ in fumes (Beton et al., 1966) for cadmium compounds.

OSHA The OSHA has established a PEL (8-h TWA) of 5 µg/m³ for shipyard, construction, and general industry.

RISK ASSESSMENTS

Listings as Hazardous Waste

Cadmium has been classified as a hazardous waste and has been registered in various publications as such including:

Section 112 of the Clean Air Act lists cadmium compounds as one of the 189 chemicals inventoried as a hazardous air pollutant (EPA, 2007).

Title III of the Emergency Planning and Community Right-To-Know Act of 1986 (EPA, 2008c) requires annual reports of cadmium release to environmental release by any manufacture, import, process, or use.

Section 311 of the Clean Water Act requires that any discharge of cadmium and cadmium-containing compounds over a specified threshold level into navigable waters is subject to reporting requirements (EPA, 2008a).

The Resource Conservation and Recovery Act (RCRA) recognizes cadmium as a hazardous waste. Cadmium is also considered a priority persistent, bioaccumulative, and toxic (PBT) chemical under RCRA waste minimization chemical listing (EPA, 1998), thus, requiring groundwater monitoring at municipal solid waste landfills (EPA, 2008b).

IRIS The EPA's Integrated Risk Information System (IRIS) oral and carcinogenicity assessments for cadmium were last revised in 1994 and 1992, respectively. The critical clinical effect for cadmium is significant proteinuria at an oral reference dose (RfD) of 5×10^{-4} mg/kg/day (water) and 1×10^{-3} mg/kg/day (food). Based on the limited human evidence, the EPA has listed cadmium as a class B₁, probable human carcinogen, based on an inhalation unit risk of 1.8×10^{-3} per µg/m³. Carcinogenicity based on human exposures was described by Thun et al. (1985) showing that workplace exposures to cadmium could result in lung, trachea, or bronchus cancer.

WHO The World Health Organization (WHO) has set a drinking water guideline of 3 µg/l as well as an air guideline of 5 ng/m³ (annual average).

ATSDR The Agency for Toxic Substances and Disease Registry (ATSDR) has established Minimal Risk Levels (MRLs) for chronic and acute, oral and inhalation exposures to cadmium.

Inhalation The acute-duration MRL of 0.03 µg/m³ is based on a lowest-observed-adverse-effect level (LOAEL) of 0.088 mg/m³ in rats exposed to cadmium oxide for 6 h/day, 5 days/week for 2 weeks (NTP, 1995).

The chronic-duration MRL of 0.01 µg/m³ was derived using the 95% lower confidence limit of the urinary cadmium level associated with a 10% extra risk of low molecular weight proteinuria.

Oral The intermediate-duration MRL of 0.5 µg/kg/day is based on the skeletal effects in young female rats exposed to 0.05 mg/kg/day cadmium chloride in drinking water for up to 12 months (Brzóska and Moniuszko-Jakoniuk, 2005).

The chronic-duration oral MRL of 0.1 µg/kg/day is based on proteinuria estimated from a meta-analysis of environmental exposure data. Using pharmacokinetic models, the MRL was determined using a calculated intake of 0.33 µg/kg/day using the UCDL10 at age 55 and dividing by an uncertainty factor of 3 for human variability.

IARC The IARC's review of cadmium as a carcinogen was last revised in 2008. Based on the limited human studies, this review listed cadmium as a Group 1 carcinogen: carcinogenic to humans.

ACGIH The ACGIH has listed cadmium as an A2 carcinogen: suspected human carcinogen.

EPA Based on a chronic intake that would result in a kidney concentration of 200 µg/g, the EPA established a RfD of 5×10^{-4} mg/kg/day in water and 1×10^{-3} mg/kg/day in food (IRIS, 2008).

CalEPA The California Environmental Protection Agency (CalEPA) in October 1996 listed cadmium as a carcinogen under Proposition 65. The California Air Resources Board also identified cadmium as a toxic air contaminant.

FDA The United States Food and Drug Administration (FDA) limits cadmium levels in bottled drinking water at 0.005 mg/l (FDA, 2007).

CHROMIUM

KATHLEEN MACMAHON

Hexavalent Chromium Compounds Only

First aid: Seek medical assistance immediately as effects may be severe or life threatening. Oral exposure: Do not induce vomiting, seek medical assistance. Eye exposure: Remove from exposure, remove contact lenses, flush with water, see ophthalmologist. Inhalation exposure: Remove from exposure, ensure adequate ventilation, oxygen if symptomatic, seek medical assistance. Dermal exposure: Remove from exposure, flush with water, seek medical assistance.

Target organs: Inhalation exposure: Respiratory tract.
Dermal exposure: Skin, mucous membranes.

Occupational exposure limits (OELs): Specific Cr(VI) compounds may have distinct OELs.

OSHA: 5 µg/m³ 8 h time-weighted average (TWA).
NIOSH: 0.2 µg/m³ 8 h TWA.
ACGIH: 50 µg/m³ water-soluble 8 h TWA.
10 µg/m³ insoluble 8 h TWA.

Reference values:

RfC inhalation, chromic acid mists, Cr(VI) aerosols:	8 × 10 ⁻⁶ mg/m ³ .
RfC inhalation, Cr(VI) particulates:	1 × 10 ⁻⁴ mg/m ³ .
RfD Cr(VI) soluble salts:	3 × 10 ⁻³ mg/kg/day.
TDI oral:	3 × 10 ⁻³ mg/kg/day.
TDI inhalation:	3 × 10 ⁻⁵ mg/kg/day.
MRL inhalation, intermediate, Cr(VI) aerosols, mists:	5 × 10 ⁻⁶ mg/m ³ .
MRL inhalation, chronic, Cr(VI) aerosols, mists:	5 × 10 ⁻⁶ mg/m ³ .

MRL inhalation, intermediate, Cr(VI)

particulates: 3 × 10⁻⁴ mg/m³.

MRL oral, intermediate, Cr(VI)
compounds: 5 × 10⁻³ mg/kg/day.

MRL oral, chronic, Cr(VI)
compounds: 9 × 10⁻⁴ mg/kg/day.

Risk phrases: Specific Cr(VI) compounds may have distinct risk phrases.

R49: may cause cancer by inhalation.

R43: may cause sensitization by skin contact.

R50/53: very toxic to aquatic organisms; may cause long-term adverse effects in the aquatic environment.

Safety phrases: Specific Cr(VI) compounds may have distinct safety phrases.

S45: in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible).

S53: avoid exposure—obtain special instructions before use.

S60: this material and its container must be disposed of as hazardous waste.

S61: avoid release to the environment, refer to special instruction/safety data sheet.

BACKGROUND AND USES

Chromium occurs in several different oxidation states from chromium metal to hexavalent chromium (Cr(VI)) compounds. In the environment, chromium exists primarily in the trivalent (Cr(III)) and Cr(VI) oxidation states. In industry,

metallic or elemental chromium (Cr(0), Cr(III), and Cr(VI) are most common. Chromium-containing materials include chromite ore, chromium chemicals, ferroalloys, and metal. In the United States most chromite ore is converted into ferrochromium, which is used to produce stainless and heat-resisting steel (USGS, 2011). Trivalent chromium (Cr(III)) is an essential trace element involved in glucose metabolism. Hexavalent chromium compounds are a large group of chemicals with varying industrial uses. Hexavalent chromium-containing materials include chromate paint and primer pigments, graphic art supplies, fungicides, and corrosion inhibitors.

This chapter focuses on Cr(VI) compounds due to their industrial relevance and associated adverse health effects. Hexavalent chromium compounds are occupational carcinogens associated with an increased excess risk of lung cancer. Some industries with occupational exposure to Cr(VI) compounds include electroplating, welding, and chromate painting. Occupational and environmental exposure to Cr(VI) compounds has been extensively reviewed (ATSDR, 2012; EPA, 1998; IARC, 1990, 2012; 71 Fed. Reg. 10099 (2006); NIOSH, 2013; NTP, 2011).

PHYSICAL AND CHEMICAL PROPERTIES

Chromium occurs in oxidation states from Cr⁻² through Cr⁺⁶ but exists mainly in the Cr(III) and Cr(VI) states; Cr(III) is the most stable. Hexavalent chromium compounds have varying physical and chemical properties. Most Cr(VI) compounds are solids; chromyl chloride is a liquid. Their properties include corrosion-resistance, durability, and hardness. Sodium dichromate is the most common chromium chemical from which other Cr(VI) compounds are produced. Examples of other Cr(VI) compounds include sodium chromate, potassium dichromate, potassium chromate, ammonium dichromate, and chromic oxide.

The reduction of Cr(VI) to Cr(III) and the oxidation of Cr(III) to Cr(VI) are important sampling considerations when determining Cr(VI) levels in workplace air (Ashley et al., 2003). Factors that affect the reduction of Cr(VI) or oxidation of Cr(III) include the presence of other compounds in the sample (e.g., iron), the ratio of Cr(VI) to Cr(III) concentrations in the sample, and solution pH. The reduction of Cr(VI) is favored in acidic conditions while Cr(VI) is stabilized in basic conditions.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Chromium is distributed to the air, water, and soil from natural and anthropogenic sources. The environmental fate

of chromium is dependent on the oxidation state and solubility of the compound and the environmental conditions affecting reduction or oxidation, such as pH. Oxidizing conditions favor the formation of Cr(VI) compounds, particularly at higher temperatures, while reducing conditions favor the formation of Cr(III) compounds. Chemical manufacturing and natural gas, oil, and gas combustion are the primary sources of chromium in the atmosphere. Most of the chromium in air eventually ends up in water or soil. Electroplating, textile manufacturing, cooling water, and leather tanning are major sources of chromium in wastewater discharges to surface waters.

Chromium(III) is the predominant oxidation state of chromium in many soils. Cr(III) binds to soil and has low mobility. A lower soil pH favors the reduction of Cr(VI) to Cr(III). Runoff from soil and industrial processes may transport chromium to surface water. Cr(VI) compounds may leach into groundwater. The pH of the soil and aquatic environment is an important factor in chromium mobility, bioavailability, and toxicity. The chromate form predominates in most natural surface waters that are basic or neutral. The hydrochromate concentration increases in more acidic conditions. Most of the chromium released into surface water will be deposited in the sediment with the potential for accumulation in aquatic life (Velma et al. 2009). Chromium is not expected to biomagnify in the aquatic or terrestrial food chains (ATSDR, 2012).

ECOTOXICOLOGY

Acute Effects

Chromium(VI) is generally more toxic to aquatic life than Cr(III). Crustaceans and other freshwater invertebrates are more sensitive to the effects of Cr(VI) than fish. Of the species tested, the most sensitive freshwater organisms are more sensitive to Cr(VI) than the most sensitive marine organisms. The acute effects of chromium compounds in freshwater fish include cytotoxic, genotoxic, enzymatic, hematologic, and immunologic effects depending on the species and the dose (Velma et al., 2009). These effects are dependent on environmental factors, including pH, water hardness, salinity, and temperature.

Chronic Effects

Chronic effects of chromium in freshwater fish include cytotoxic, genotoxic, growth, and survival effects depending on the species and the dose (Velma et al., 2009). These effects are also dependent on other factors, including the organism age, exposure duration, and environmental conditions. Some fish species, such as rainbow trout, are more sensitive than other fish species to the effects of chromium, particularly Cr(VI).

MAMMALIAN TOXICOLOGY

Acute Effects

Acute inhalation exposure to Cr(VI) is associated with adverse respiratory effects, including nasal and respiratory irritation. Gibb et al. (2000a) reported diagnoses of irritated nasal septum, ulcerated nasal septum, and perforated eardrum in chromate production workers <1 month after employment. Ingestion of high doses of Cr(VI) may affect many organ systems and may be lethal.

Chronic Effects

Cr(VI) is a known human carcinogen by the inhalation route of exposure (NTP, 2011; IARC, 2012; EPA, 1998). Cr(VI) compounds are occupational carcinogens associated with an increased risk of lung cancer (71 Fed. Reg. 10099, 2006; NIOSH, 2013). The available evidence is inconclusive regarding the association of Cr(VI) compounds with nasal and nasal sinus cancers; there is little evidence of an association with stomach or other cancers (IARC, 2012). Non-malignant chronic respiratory effects include ulcerated or perforated nasal septa and respiratory sensitization.

Chronic dermal effects include skin ulcers and allergic contact dermatitis. Lindberg and Hedenstierna (1983) reported that exposures >2 µg/m³ chromic acid were associated with nasal septal ulceration and perforation. Gibb et al. (2000a) reported irritated or ulcerated skin, dermatitis, burn, conjunctivitis, and perforated nasal septum or eardrum in chromate production workers. Other chronic nonmalignant health effects include immunologic, hematologic, reproductive, and developmental effects (ATSDR, 2012).

Beaumont et al. (2008), in a reanalysis of Chinese data, reported an association between Cr(VI)-contaminated drinking water and stomach cancer. Chronic drinking water studies of sodium dichromate dihydrate (Cr(VI)) in rats resulted in an increased incidence of squamous cell epithelium tumors of the oral mucosa or tongue (NTP, 2008). Chronic drinking water studies in mice resulted in an increased incidence of small intestine tumors (NTP, 2008).

Chemical Pathology

Results of laboratory animal studies of the respiratory effects of Cr(VI) compounds vary with the Cr(VI) compound, dose, route of exposure, duration of study, and animal species. Intratracheal instillation of sodium dichromate or calcium chromate in rats resulted in lung tumors, including adenomas, adenocarcinomas, and squamous cell carcinomas (Steinhoff et al., 1986). Inhalation studies of sodium dichromate in rats also resulted in benign and malignant lung tumors (Glaser et al., 1986). Histopathologic respiratory effects included inflammatory, hyperplastic, and fibrotic changes.

Chronic drinking water studies of sodium dichromate dihydrate (Cr(VI)) in rats resulted in an increased incidence of squamous cell carcinoma or papilloma of the oral cavity (NTP, 2008). Similar chronic drinking water studies in mice resulted in an increased incidence of adenoma or carcinoma of the small intestine. Diffuse epithelial hyperplasia was reported in the small intestine of mice. Histiocytic cell infiltration was reported in the duodenum, mesenteric lymph node, and other locations in rats and mice (NTP, 2008).

Mode of Action

Several mechanisms may be involved in Cr(VI) carcinogenesis, including DNA damage, oxidative stress, aneuploidy, and cell transformation (IARC, 2012). Cr(VI) carcinogenicity may result from damage mediated by the bioreactive products of intracellular Cr(VI) reduction, including the Cr(VI) intermediates (Cr(V) and Cr(IV)), and reactive oxygen species (ROS) (O'Brien et al., 2003). These intermediates and ROS may result in DNA damage, including interstrand cross-links, DNA–protein cross-linking, and double-strand breaks. These genotoxic effects are consistent with the mechanistic events associated with carcinogenesis.

SOURCES OF EXPOSURE

Occupational

Workers may be exposed to airborne Cr(VI) when Cr(VI) compounds are manufactured from other forms of chromium (e.g., production of chromates from chromite ore); when using Cr(VI)-containing materials to manufacture other products (e.g., chromate-containing paints, electroplating); or when Cr(VI) is produced as a by-product of a process (e.g., welding). Primary industries with the majority of occupational exposures to airborne Cr(VI) compounds include welding, painting, electroplating, steel mills, iron and steel foundries, wood preserving, paint and coatings production, chromium catalyst production, plastic colorant producers and users, production of chromates and related chemicals from chromite ore, plating mixture production, printing ink producers, chromium metal production, chromate pigment production, and chromated copper arsenate producers (71 Fed. Reg. 10099, 2006).

Welders are the largest group of workers potentially exposed to Cr(VI) compounds (71 Fed. Reg. 10099, 2006). Cr(VI) exposures to welders are dependent on several process factors, including the welding process and shield-gas type, and the Cr content of both the consumable material and the base metal (Keane et al., 2009; Meeker et al., 2010). Other industrial sectors with substantial numbers of workers exposed include painting, electroplating, steel mills, and iron and steel foundries (71 Fed. Reg. 10099, 2006).

Blade et al. (2007) conducted a series of field surveys of workplaces where there was a potential for Cr(VI) exposure. The authors reported that controlling airborne Cr(VI) exposures was moderately difficult in those operations that involved joining or cutting metals with a relatively high chromium content. Airborne Cr(VI) exposures were reported most difficult to control in those operations involving the application of coatings or finishes.

Dermal exposure to Cr(VI)-containing substances may occur with any task where there is a potential for splashing, spilling, or other skin contact. If not adequately protected, workers' skin may be directly exposed to liquid forms of Cr(VI) (e.g., electroplating baths) or solid forms (e.g., Portland cement). A variety of construction materials contain Portland cement, including cement, mortar, stucco, and terrazzo (OSHA, 2008). Dermal exposure may also occur because of contamination of workplace surfaces or equipment.

Environmental

Chromium(VI) compounds are released to the air, water, and soil from natural and industrial sources. Cr(VI) levels are usually low in U.S. ambient air, <30 ng/m³ (ATSDR, 2012). Chromium in the air is eventually deposited on to the soil and water. Environmental conditions in the soil and water, (e.g., pH), affect the state of chromium, potential exposures, and toxicity. Cr(VI) compounds may be present in surface waters or groundwater. Potential exposures to Cr(VI) may occur from the ingestion of drinking water or the inhalation of water droplets when showering (OEHHA, 2009).

INDUSTRIAL HYGIENE (PPE)

U.S. Occupational Exposure Limits for Cr(VI) Compounds*			
Agency	OEL	Cr(VI) Compound(s)	TWA, µg/m ³
NIOSH	REL	All	0.2
OSHA	PEL	All	5
ACGIH	TLV	Water soluble	50
		Insoluble	10

Sources: NIOSH (2005), ACGIH (2011).

* Specific Cr(VI) compounds may have distinct OELs.

The control measures for Cr(VI) compounds, consistent with the hierarchy of controls, include: elimination, substitution, engineering controls, administrative controls and appropriate work practices, and the use of protective clothing and equipment (NIOSH, 2013). Employers should provide gloves, chemical protective clothing (CPC), and eye protective equipment for workers with potential skin or eye contact with Cr(VI) compounds. Selection of CPC should be based on permeation properties and other factors, including size, dexterity, cut and tear resistance, and other chemicals being used. Dermal and mucous membrane contact should be

prevented by full-body protective clothing, including head, neck, and face protection; coveralls or similar protective body clothing; impermeable gloves with gauntlets; and shoes and apron. When respiratory protection is needed to control workplace exposures, the employer should establish a comprehensive respiratory protection program as described in the OSHA respiratory protection standard (CFR, 2006 29 CFR 1910.134).

RISK ASSESSMENTS

Studies of chromate manufacturing workers in Baltimore, Maryland, and Painesville, Ohio provided exposure-response data for assessing the excess risk of lung cancer associated with occupational exposure to Cr(VI). These cohorts provided the basis for robust quantitative assessments of occupational risk of Cr(VI) exposure due to the quality and quantity of the exposure and worker data, extent of exposure, and years of follow-up.

Park et al. (2004) calculated excess lifetime risk of lung cancer death resulting from occupational exposure to chromium-containing mists and dusts using the data of Gibb et al. (2000b), the Baltimore cohort of chromate chemical production workers. This cohort had extensive historical exposure assessment and smoking information, strong statistical power, and a relative lack of potentially confounding exposures. A linear relative rate model was selected to estimate the exposure response that was the basis for the risk assessment. The excess lifetime risk of lung cancer death was approximately 6 per 1000 workers from a 45-year working lifetime exposure to 1 µg/m³ soluble hexavalent chromium.

Crump et al. (2003) calculated estimates of excess lifetime risk of lung cancer death using the data of Luippold et al. (2003), the Painesville cohort of chromate chemical production workers. This cohort had an extensive exposure assessment (Proctor et al., 2003). The estimate of excess lifetime risk of lung cancer death was approximately 2 per 1000 workers from a 45-year working lifetime exposure to 1 µg/m³ hexavalent chromium.

The findings and conclusions in this report are those of the author and do not necessarily represent the views of the National Institute for Occupational Safety and Health.

COBALT

DAVINDERJIT SINGH AND RAYMOND D. HARBISON

First aid (metal dust and fume): Eye: Irrigate immediately; skin: soap wash immediately; breathing: respiratory support; swallow: medical attention immediately.

Target organ(s): Respiratory tract, skin, heart, blood, thyroid gland, ear, eye

Occupational exposure limits: NIOSH REL: 0.05 mg/m³; OSHA PEL: 0.1 mg/m³; American Conference of Governmental Industrial Hygienists (ACGIH) TLV: Time-weighted average (TWA) 0.02 mg/m³; Cal/OSHA PEL: 0.02 mg/m³

Reference values: No reference dose or reference concentration set by EPA. Agency for Toxic Substances and Disease Registry (ATSDR) MRL: 0.0001 mg/m³ (inhalational), 0.01 mg/kg/day (ingestion); ATSDR MRL: 0.00003 mg/m³ (mice); CalEPA REL: 0.000005 mg/m³ (mice); NIOSH ILDH: 20 mg Co/m³

Risk phrases: 22-42/43

Harmful if swallowed

May cause sensitization by inhalation and skin contact

Safety phrases: 22-24-37

Do not breathe dust. Avoid contact with skin. Wear suitable gloves

BACKGROUND AND USES

Cobalt (Co; CASRN 7440-48-4) is a silvery-gray brittle but hard metal, which is distributed widely in nature, including rocks, soil, plants, and animals. It is a metal with no odor and no vapor pressure at room temperature and is insoluble in water, except for ultrafine cobalt powder, which is water

soluble. It is stable in air but chemically reactive with dilute acids and is a nonvolatile metal. Required in small amounts, cobalt is important for the sustenance of life. It is the only metal found in vitamins, most importantly as a part of vitamin B12 and is necessary in the formation of blood. Cobalt is a component of many naturally occurring minerals like sulfides, hydrates, and oxides. Cobalt compounds can occur in various oxidation states (0, +1, +2, +3, and +4) but the most common oxidation states are +2 and +3. Cobalt has one naturally occurring isotope, cobalt-59 and 26 radioactive isotopes. Common ores of cobalt are cobaltite, erythrite [Co₃(AsO₄)₂·8H₂O], chlorathite, and linnealite (Co₃S₄). Cobalt is used extensively in industries, and more than a million workers are exposed to various industrial processes involving cobalt and its compounds. In occupational settings, inhalational and dermal contact are the two most common routes of exposure.

Cobalt and its compounds are used as an important catalyst in various industrial processes. Cobalt catalysts are used in various processes such as a desulfurization catalyst for gas and oil and for polyesters, pottery, plastic, and detergent production. Cobalt is usually recovered as a byproduct of mining and refining of various minerals like copper and iron. It has the unique ability to be ductile as well as a malleable metal. This property allows it to be transformed into both thin wires and thin sheets. Cobalt is used in the production of various household products like paints, hair dyes, glass, ceramics, enamel, pottery, jewelry, and consumer batteries. It is an important component of porcelain, cement, rubber, and chemical industries. It is used in the production of super alloys to retain physical and chemical properties at extreme temperatures. This property is used in the production of drills, cutting tools, and as parts in rocket, gas turbine,

and aircraft engines (Harper et al., 2012). Major uses of cobalt worldwide are in the production of super alloys and other alloys (30%), as hard metals (13%), and as catalysts (10%). In the United States, more than 50% of cobalt used is as a super alloy for the production of aircraft gas turbine engines. Cobalt-60 is the radioactive isotope of cobalt and is used in cancer therapy.

PHYSICAL AND CHEMICAL PROPERTIES

Cobalt is a hard magnetic metal, like iron and nickel. It has the properties of both ductility as well as malleability. Due to this property, it can be molded into wires and compressed into sheets. Cobalt occurs in two allotropic forms, hexagonal and cubic. The hexagonal form is more stable than the cubic form at room temperature. The boiling point of cobalt is about 2927°C (5301°F) and the melting point is about 1490°C (2723°F). Cobalt as a metal is mildly reactive with oxygen and will burn only in powder form. It is soluble in dilute acids but is water soluble only in ultrafine powder form (Kyono et al., 1992).

MAMMALIAN TOXICOLOGY

Acute Effects

Animal Acute Toxicity Cobalt causes both acute and chronic health effects, although chronic effects are more common. Acute effects of cobalt have been studied in experimental animals extensively. The oral LD₅₀ ranges from 42.4 to 317 mg/kg body weight for cobalt compounds for laboratory animals (FDRL, 1984a, 1984b, 1984c; Singh and Junnarkar, 1991). Rats exposed to varied concentrations were observed to have cardiac damage, elevated heart rate, degenerative heart lesions, reduction in heart enzyme activity, and lesions of respiratory tract and kidney damage (Morvai et al., 1993; Grice et al., 1969; Domingo et al., 1984; Holly, 1955; Murdock, 1959). Rats administered with fine cobalt particles showed signs of lung abnormalities like focal hypertrophy of lung epithelium, macrophage abnormalities, and type 2 alveolar epithelium proliferations (Kyono et al., 1992). Necrosis and inflammation were noted in rats when doses of cobalt were administered for 16 days. Thymus necrosis and testicular atrophy were also observed (Bucher et al., 1990). Injection of cobalt in rats at doses of 15 mg/kg led to the breakage of red blood cells and oxidation of hemoglobin iron and methemoglobinuria (Horiguchi et al., 2004).

Human Acute Toxicity

Dermal All forms of cobalt metal, cobalt alloys, and cobalt salts can result in skin manifestations. Cobalt along with

nickel and chromium are considered the more common causes of occupational skin diseases such as irritant eczemas and occupational dermatitis (Kanerva et al., 1988; Kiec-Swierczynska and Szymczk, 1995). In a study over an 11-year period in the United Kingdom, cobalt was associated with 4% of all cases of occupational contact dermatitis (Athavale et al., 2007). Allergic contact dermatitis was also observed in hard metal workers exposed to cobalt (Dooms-Goossens et al., 1986; Julander et al., 2009). Urticarial reactions have also been observed when exposed to cobalt and its salts. Combined dermal exposure to cobalt nanoparticles and UV-B can result in the activation and accumulation of skin fibroblasts and thickening of the epidermis layer of the skin (Murray et al., 2009). The mechanism by which cobalt and its compounds cause skin toxicity is not clear, but studies have highlighted the role of reactive oxygen species (Gault et al., 2010).

Cobalt has skin sensitization properties, which have been shown in both human and animal studies. Another study demonstrated that permeation through damaged skin was significantly higher for metals like cobalt (Filon et al., 2009). Oxidation of metallic cobalt into ions has been proposed as the mechanism by which cobalt can permeate through the skin. Cobalt sensitization can also result in chromium cross-sensitization in construction workers exposed to chromium dust (Bock et al., 2003).

Respiratory Respiratory effects of cobalt and its compounds have been studied extensively, more so in association with other hard metals especially tungsten carbide. A study of male workers exposed to a cobalt dust mixture for at least 2 years reported significantly higher levels (0.4 µmol/g) of cobalt in the urine than nonexposed workers (0.019 µmol/g); cobalt exposure was reported below 41.5 ppm (Gennart et al., 1993). A study conducted in a tungsten carbide processing industry reported varied respiratory abnormalities (Coates and Watson, 1973). Exposed workers presented with interstitial pulmonary fibrosis, deposition of collagen and elastic tissue in the septal areas, and alteration of type 1 pneumocytes. Hard metal industries have been a common source of cobalt exposure. Hard metal alloy exposure was shown to be associated with abnormal pulmonary function tests and abnormal radiographic findings in workers (Bech et al., 1962). Common symptoms included excessive cough, chest tightness, and shortness of breath.

Early human exposure was ascribed to cobalt when respiratory conditions like interstitial fibrosis and emphysema were noticed in 12 workers exposed to dust containing tungsten and cobalt (Bech, 1974). Workers exposed to 0.005 mg cobalt/m³ in industries processing tungsten carbide alloy developed asthma, pneumonia, and wheezing. When exposed to 0.007 mg cobalt/m³ at work, hypersensitivity to cobalt resulted in asthma and skin rashes. An isolated case of fibrosing alveolitis was observed in a hard metal worker

employed in a cobalt grinding process (Zanelli et al., 1994). Association between cobalt and occupational asthma has been observed in a retrospective cohort study done in Japan. Workers exposed to cobalt were followed for signs of respiratory disease. 5.6% of workers (18 cases) developed occupational asthma when exposed to air having a concentration ranging from 3 to 1292 µg cobalt/m³ of air (Kusaka et al., 1986). Hypersensitivity to cobalt has been suggested to be the cause of respiratory signs and symptoms. Sensitization to cobalt is linked with the occurrence of bronchial asthma when exposed to both cobalt as well as hard metal dust (Linna et al., 2004). In addition, studies have shown an association of giant cell interstitial pneumonia with hard metal lung disease (Dai et al., 2009; Sakai et al., 2010). In one study that compared 100 cases of hard metal lung disease, giant cell interstitial pneumonia was observed in 59 of the cases though cobalt exposure was found in only six workers (Naqvi et al., 2008). Individually, one case of giant cell interstitial pneumonitis was observed in a worker exposed to cobalt dust (Sundaram et al., 2001).

In recent years, cobalt has become a major component of nanotube industries. Nanotubes containing cobalt metal are used as a high strength material in the production of electronics and medical equipment (Martin and Kohli, 2003). Nanotubes deposit in the lungs and accumulate because of high biopersistence and cause fibrotic reactions as a result of the inflammatory response (Muller et al., 2005). Studies also found that the presence of cobalt containing nanotubes resulted in the formation of granulomas. Such granulomas were also observed in studies conducted on experimental animals (Warheit et al., 2004). Cobalt exposure is associated with dental technicians who manufacture and handle dental prosthesis. Pneumoconiosis and pulmonary fibrosis were observed in technicians exposed to cobalt dust (Sherson et al., 1990; Selden et al., 1996). Prolonged cough and increased phlegm were also noticed in dental technicians exposed to cobalt compounds (Radi et al., 2002).

Cardiac Lower left ventricular fraction was observed in workers who were exposed to high levels of cobalt and its compounds (Horowitz et al., 1988; D'Adda et al., 1994). Hypertension along with reversible electrocardiogram (ECG) changes (Alexandersson et al., 1980) and elevated heart rate (Raffn et al., 1988) were observed when workers were exposed to 0.01 mg/m³ and 0.8 mg/m³ of cobalt hard metal, respectively. Altered left ventricular diastolic function increased myocardial stiffness but no ECG changes were observed in the study conducted on exposed workers in Finland (Linna et al., 2004).

Chronic Effects

Animal Chronic Effects Cobalt may induce developmental (stunted growth, lower body weight in new born,

decreased survival) and reproductive toxicity (lower sperm count, decreased epididymis weight) in animals when exposed. Hamsters developed emphysema when exposed to cobalt compounds for prolonged periods of time. When laboratory rats were administered an intramuscular injection of cobalt powder, sarcoma, especially rhabdomyosarcoma, was observed at the injection site after 122 weeks (Heath, 1954, 1956). Similarly, sarcomas were observed after 6 years in rabbits when metallic cobalt was implanted in the femoral artery (Schinz and Uehlinger, 1942).

Human Chronic Effects Cobalt was shown to be associated with beer drinkers and cardiomyopathy due to its chronic consumption. Beer drinker cardiomyopathy syndrome was observed when cobalt salts were added as a stabilizer. According to reports, it could result in pericardial effusion and congestive heart failure (Barborik and Dusek, 1972; Kennedy et al., 1981; Smith and Carson, 1981) though the review conducted by Seghizzi could not find any evidence of cardiomyopathy associated with cobalt exposure in beer drinkers (Seghizzi et al., 1994). Cobalt is no longer added to beer as a foam stabilizer. Various studies have proposed an association of cobalt and cardiomyopathy in exposed subjects. Cardiomyopathy has been reported in cases of exposure to cobalt and cobalt dust (Kennedy et al., 1981; Jarvis et al., 1992).

Cobalt and its compounds have also been shown to be genotoxic. Cobalt sulfide is associated with breaks in DNA strands in Chinese hamster ovary cells (Costa et al., 1982). DNA base damage was also noticed in human lymphocytes during cobalt compounds exposure in the presence of hydrogen peroxide (Nackerdien et al., 1991; Kawanishi et al., 1994; Lloyd et al., 1997; De Boeck et al., 1998). Cobalt-tungsten combination has been shown to convert osteoblast-like cells to cells with carcinogenic phenotype and damage DNA to impart chromosomal abnormalities (Miller et al., 2001). Studies have also shown the synergistic carcinogenic potential of hard metal dust of tungsten and cobalt carbide (Sheppard et al., 2006). Such synergistic potential has been associated with an increased risk of lung carcinoma (Moulin et al., 1998). Some studies have also highlighted the role of cobalt in substituting essential divalent metal ions, including iron or copper that can alter important cellular functions. No epidemiological study has been able to identify cobalt as a carcinogenic agent though the combination of cobalt with other metals (tungsten) has been shown to have carcinogenic potential (Lasfargues et al., 1994; Moulin et al., 1998; Wild et al., 2000). In the Lasfargues study, the cohort exposed to cobalt had a significantly higher risk of lung cancer (SMR = 2.13). Moulin calculated an odds ratio of 1.93 among workers exposed to tungsten carbide–cobalt. Wild et al. (2000) calculated a higher standardized mortality ratio (SMR) of twofold in workers who were twice as exposed to cobalt compounds. These studies are of uncertain relevance

due to the small size of cohorts and confounders like the presence of multiple metals to which the workers were exposed.

Cobalt and cobalt compounds along with soluble cobalt salts are labeled as Group 2B carcinogens (possibly carcinogenic to humans), and cobalt metal with tungsten chloride has been labeled as 2A (probably carcinogenic to humans) by the International Agency for Research on Cancer (IARC, 2006). The European Commission classified cobalt sulfate and cobalt dichloride in the category 1B (presumed to be carcinogenic to humans, classification largely based on animal evidence). The National Institute of Environmental Health Sciences has labeled cobalt sulfate and cobalt-tungsten carbide as “reasonably anticipated to be a human carcinogen.” ACGIH has labeled cobalt in the carcinogenic category of A3 (confirmed animal carcinogen with unknown relevance to humans) (ACGIH, 2007).

Mode of Action

The mechanism by which cobalt exposure results in toxic effects is not fully understood. Exposure to cobalt chloride causes a rapid increase of the intracellular levels of hypoxia-inducible factor-1 α (Torii et al., 2011). Hypoxic state induced by cobalt is implicated as one of the precursors to lung effects. In another study, exposure to cobalt and its compounds activated phosphatidylinositol-3-kinase pathway and production of reactive oxygen species (Chachami et al., 2004). Studies have suggested the role of reactive oxygen species (Nemery et al., 1994; Sarkar, 1995; Salnikow et al., 2000; Lison et al., 2001). Similarly, exposure of a variety of cell lines to soluble cobalt salts in lungs, neuronal tissue, and liver resulted in an increased reactive oxygen species production (Salnikow et al., 2000; BelAiba et al., 2004). This resulted in an accelerated accumulation of oxidative stress products, release of cytokines, cell damage, and death. In another study, cobalt potentiated the reactivity of neutrophil-derived oxidants resulting in protease and oxidant-mediated tissue injury (Ramafi et al., 2004).

Chemical Pathology

Cobalt exposure is associated with skin pathology, including sensitization, epidermal thickening, and contact dermatitis (Asano et al., 2009). Exposure has also been associated with lung pathology, including interstitial pneumonia and fibrosis (Davison et al., 1983), fibrosing alveolitis (Van Den Eeckhout et al., 1989), and possible lung carcinoma (Wild et al., 2009). Cobalt is soluble in various body fluids, including lung airway lining, gastrointestinal tract, and skin sweat glands and can be absorbed from exposure pathways like inhalation, ingestion, or dermal contact. Absorption of cobalt depends upon the route of exposure with 30% absorption possible via inhalational route, 3–50% via ingestion, and

0.024 and 3.6% via intact and abraded skin, respectively (Stefaniak et al., 2011). Ultrafine cobalt particles have a size of 20 nm; these particles can cause pulmonary inflammation when exposed for prolonged periods of time. (Kyono et al., 1992; Zhang et al., 1998). The effects of cobalt are affected in the presence of other chemicals. Mutual exposure to nickel and cobalt chloride led to a synergistic effect in cell culture and lowered cell viability than when exposed individually (Cross et al., 2001).

SOURCES OF EXPOSURE

Occupational

Occupational exposure to cobalt occurs from diverse industries and occupations such as mining, heavy metal superalloy production, and tungsten carbide processing. In addition, workers are also exposed when cobalt or its compounds are involved in the refining of cobalt and processing of various alloys and its salts (Swennen et al., 1993). Cobalt air levels have been associated with corresponding incidence of occupational asthma and hard metal disease in the hard metal industry. Suspected asthma incidence was highest in powder plant maintenance, in areas of chemical testing, metal pressing, and sintering. Also, cases suspected of hard metal disease were observed in metal pressing, sintering, and grinding. Along with the respiratory route of occupational exposure, dermal exposure is also common. Exposure to cobalt is particularly common in workplaces that involve the use of cutting or grinding tools, refining or processing cobalt metal or ores, and ceramics. Exposure is also prevalent in industries using cobalt to color glass and producing drier for enamel and paint. For most of the cases, except in the processing of cobalt powder, the exposure is not only to cobalt but also to other metals and compounds like tungsten carbide, chromium, iron, etc. A combination of cobalt with these metals may alter the chemical reactivity of cobalt.

Environmental

Cobalt is found throughout the environment in low concentrations in air, food, and water. The amount of cobalt in air is <2 ng/m³, which is less than the cobalt exposure from food and water. In drinking water, cobalt concentration is <1–2 parts per billion(ppb). An average person consumes about 11 µg of cobalt in the diet in the form of vitamin B₁₂. The concentration in food and water may be many times more in areas that are in the vicinity and/or in the areas of mining, smelting, or hard metal industries. Environmental exposure may occur from surgical procedures such as hip implants (Sunderman et al., 1989) and dental prosthesis (Kettelarij et al., 2014). Elevated blood cobalt levels were observed due to metal hip implants in the absence of other

etiologies in patients undergoing total hip replacement (Pizon et al., 2013).

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration (OSHA) has assigned an 8-h permissible exposure limit (PEL) of 0.1 mg/m³, and the National Institute for Occupational Safety and Health (NIOSH) recommends an 8-h TWA of 0.05 mg/m³ (NIOSH, 2007). ACGIH has recommended an 8-h TWA of 0.02 mg/m³. No reference concentration (RfC) or reference dose (RfD) has been associated with cobalt and its compounds though ATSDR has recommended minimal risk levels (MRL) of 0.0001 mg/m³ via inhalational route and 0.01 mg/kg/day via ingestion (ATSDR, 2004).

MEDICAL MANAGEMENT

Diagnosis

The diagnosis of respiratory illness associated with cobalt is by the worker complaints, work history and signs detected from X-ray abnormalities, pulmonary function tests, Bronchoalveolar lavage and lung biopsy, to high resolution tomography scanning (Dunlop et al., 2005; Gotway et al., 2002). Signs may include dyspnea, shortness of breath, and expectoration; physical examination may reveal crackles. Chest X-ray generally presents with a reticulo-nodular pattern predominantly in the lower zones. Pulmonary function tests may show lowered diffusion capacity with restrictive pattern. Bronchial lavage can reveal multinucleate giant cells and elevation in eosinophil count and T-lymphocytes. Lung biopsy may show giant cell interstitial pneumonitis, fibrosing alveolitis, or inflammatory infiltrates. In another study, high resolution tomography scanning indicated large cystic spaces in mid and upper lungs, upper lobe reticulation, and traction bronchiectasis (Gotway et al., 2002).

Biomonitoring can be undertaken to assess exposure and determine the efficacy of health and safety procedure. Concentrations of cobalt and its compounds in blood and urine show a positively linear association with air concentration levels (Ichikawa et al., 1985). Workers exposed to cobalt may have higher IgA levels and lowered IgE levels (Bencko et al., 1986). In one study human leukocyte antigen residue was monitored to distinguish workers exposed to cobalt and those predisposed to develop hard metal disease (Potolicchio et al., 1997).

Treatment

Early diagnosis and treatment is important in the management of cases exposed to cobalt and cobalt compounds. Removal of the worker from the exposure to cobalt and

its compounds is an important initial step in the treatment protocol. In a study, cobalt-exposed workers with the symptoms of cough and eczema showed recovery when the exposure was withdrawn. One worker who remained on the job developed lung nodules 2.5 years later. In another study, proper diagnosis of three patients and removal from cobalt exposure resulted in complete recovery for two; the third had some mild lingering effects (Anttila et al., 1986). A fourth patient in the same report was not diagnosed efficiently and developed lingering, severe respiratory effects. Treatment of chronic effects should be symptomatic. Studies have shown the improvement in symptoms in hard metal disease patients with the administration of steroids (Nureki et al., 2013), but no clinical trials have been performed to confirm the effectiveness of such agents.

15

COPPER

MARIE M. BOURGEOIS

First aid: Inhalation: Remove to fresh air. Provide respiratory support. Ingestion: Induce vomiting immediately as directed by medical personnel. Skin: Immediately flush skin with plenty of soap and water for at least 15 min. Remove contaminated clothing and shoes. Eye contact: Immediately flush eyes with plenty of water for at least 15 min. Get medical attention immediately.

Target organ(s): Eyes, skin, respiratory system, liver, kidneys (increased risk with Wilson's disease)

Occupational exposure limits: NIOSH REL: TWA 1 mg/m³, OSHA PEL: TWA 1 mg/m³ and ACGIH TLV: TWA 1 mg/m³ [REL, PEL, and TLV also apply to other copper compounds (as Cu) except copper fume], TLV 0.2 mg/m³ (fume), NIOSH IDHL: 100 mg/m³

Reference values: MRL: 0.01 mg/kg/day (oral)

Risk phrases: 11-36/37

Flammable: Irritating to eyes and respiratory system

Safety phrases: 26-60

In case of contact with eyes, rinse immediately with plenty of water and seek medical advice. This material and/or its container must be disposed of as hazardous waste.

BACKGROUND AND USES

Copper (symbol Cu; CAS #7440-50-8) is distributed widely in nature; it is the twenty-sixth most abundant element in the earth's crust and is an essential element for many life forms. Copper is an abundant reddish, odorless metal that takes on a greenish-blue patina when exposed to the elements. It was the first metal worked by humans, and copper salts were among

the first materials regularly used for therapeutic and cosmetic purposes.

Most animals require copper for certain biological processes. A deficiency of copper, as well as an excess, can have adverse health effects. The daily intake of copper in the United States ranges from 2 to 5 mg, almost all of which is excreted in the feces. Shellfish, seeds, nuts, and grains are rich sources of dietary copper. Minute amounts of cupric ion are absorbed and stored, mainly in the liver, blood, and brain. Copper is an essential cofactor in several enzyme systems (Shaligram and Campbell, 2012). Cuproenzymes catalyze important biochemical reactions, including iron absorption and heme biosynthesis (Colotti et al., 2013). Copper deficiency may lead to anemia and neutropenia, and eventually to bone lesions resembling scurvy and to pathological fractures without hemorrhage (Kumar et al., 2005; Halldanarson et al., 2008). Copper is also found in some intrauterine devices for the prevention of pregnancy (IPCS, 1998; Szymanski et al., 2012).

Extracting copper from ores involves crushing, roasting, and smelting to produce "matte," a mixture of varying proportions of copper and iron sulfides, which is further refined electrolytically to remove the sulfur and iron. Once separated from its ore, copper is used in a variety of products, including electrical machinery and wiring, roof sheeting and water pipes, and chemical and heating applications. Its malleability and luster have made it a valuable metal since humans began working metal. American coins are all copper alloys (ATSDR, 2004). The biocidal properties of copper salts such as copper sulfate and copper naphthenate make it a common ingredient in fungicides and disinfectants (Reigart and Roberts, 1999). Copper also has important industrial properties, including efficient thermal and electrical conductivity and resistance to corrosion. It

is used for electroplating because it increases hardness in its alloys, principally brass (with zinc) and bronze (with tin), and in special mixtures with other metals such as nickel, beryllium, and cobalt (HSDB, 2007a and HSDB, 2007b).

PHYSICAL AND CHEMICAL PROPERTIES

Copper is a group IB transition element on the periodic table and exists in four oxidation states: Cu⁰ Cu¹⁺ (cuprous ion), Cu²⁺ (cupric ion), and Cu³⁺. In a natural state, copper is likely to be found in a variety of solid salts and compounds, but it can be found in the elemental form as well. Copper compounds generally are blue or green. The common green color of copper on exposure to air is a basic carbonate compound. The more important industrial compounds are copper sulfate and copper chloride; these and others are listed, with their common uses, in Table 15.1.

Copper is insoluble in water but readily dissolves in hot sulfuric and nitric acids. The vapor pressure is negligible at low temperatures, but in an industrial setting, in which very high temperatures are used to smelt copper ore, some potentially harmful copper fumes may be emitted. Although it is not combustible in bulk, powdered copper may ignite. Fires and explosions may result from contact with oxidizing agents, strong mineral acids, alkali metals, and halogens (NIOSH, 2010). Selected chemical and physical properties of copper are presented in Table 15.2.

TABLE 15.1 Common Uses of Copper and Copper Compounds

Substance (CAS Number)	Uses
Copper (Cu) (#7440-50-8)	Electrical conductor, electronics, alloys (bronze, brass, bell, and gun metal)
Copper sulfate (CuSO ₄) (#7758-98-7)	Parasiticide, fungicide, algicide, herbicide, dye mordant, wood preservative, tanning, electroplating, pigment (ink, photography)
Copper cyanide [Cu (CN) ₂] (#14763-77-0)	Electroplating, antifouling paint, fungicide, insecticide
Cupric acetoarsenite (Cu ₄ AS ₆ C ₄ H ₈ O ₄) (#12002-03-8)	Marine pigment, insecticide
Cupric acetate (CuC ₄ HsO ₄) (#142-71-2)	Fungicide pigments, dyes
Copper chloride (CuCl ₂) (#7447-39-4)	Electroplating, wood preservative, petroleum desulfurizing, catalyst, mordant, pigments
Copper oxide (Cu ₂ O) (#1317-39-1)	Pigment, antifouling paint, fungicide, catalyst
Copper nitrate [Cu (NO ₃) ₂] (#3251-23-8)	Herbicide, fungicide, wood preservative, colorant, mordant, photocopying, catalyst

TABLE 15.2 Chemical and Physical Properties of Copper

Characteristic	Information
Chemical name	Copper
Synonyms/trade names	Copper metal dusts, copper metal fumes
Chemical formula	Cu
CASRN	7440-50-8
Molecular weight	63.546 g/mol
Melting point	1083 °C (decomposes)
Boiling point	2595 °C (decomposes)
Vapor pressure	0 mmHg at 20 °C
Density/specific gravity	8.94 g/cm ³ at 20 °C
Flashpoint	Not available
Water solubility at 25 °C	Insolubility
Explosion limits	Not available
Octanol/water partition coefficient (log K _{ow})	-0.57
Henry's law constant	0.0245 atm m ³ /mol
Odor threshold	Odorless
Conversion factors	Not available

ENVIRONMENTAL FATE AND BIOACCUMULATION

Elemental copper is stable in the environment. There is little danger of volatilization so copper can be expected to adsorb to sediments and suspended solids in water. This copper is primarily Cu²⁺ and is of limited bioavailability when bound to organic matter. Other forms of copper are slightly more bioavailable; these can produce adverse effects in the right conditions (e.g., low pH). Water-soluble forms of copper may enter groundwater supplies. No evidence of bioaccumulation has been found, and there is little evidence of biomagnification (ATSDR, 2004).

There is variation in the bioconcentration factors of some species of fish (10–667) and mollusks (up to 30,000) (Perwak et al., 1980; Georgopoulos et al., 2006). The higher value in mollusks is likely due to the fact that they are filter feeders. However, it is thought that long-term exposure in aquatic and terrestrial environments can lead to the release of the constituent copper compounds in more bioavailable forms. These more bioavailable forms have the potential to yield toxic effects under specific chemical conditions. Mobilization is not usually seen without prolonged exposure to a pH value of 3 or less (HSDB, 2007a and HSDB, 2007b). There are no data on the log K_{ow} of copper, so it is difficult to make determinations about soil mobility.

ECOTOXICOLOGY

Environmental copper has anthropogenic and natural origins (sea spray, hazardous waste dumps, wastewater processing,

and industry). Industrial processes accounted for approximately 1.4 billion pounds of environmental copper in 2000 alone. Copper and cupric compounds have been found in more than a third of the proposed Environmental Protection Agency(EPA) National Priorities List sites (HSDB, 2007a and HSDB, 2007b). Airborne copper concentrations in rural and urban areas range from 5 to 200 ng/m³.

Concentrations in fresh and salt water bodies range from 4 to 10 parts per billion (ppb). Copper concentrations in soil vary considerably according to land use, soil composition, pH, depth, and moisture. Copper binds strongly to organic materials in soils. Naturally occurring copper concentrations average 50 ppm with substantially higher concentrations present near agricultural or industrial sites (Davies and Bennett, 1985).

MAMMALIAN TOXICOLOGY

Acute Effects

Although acute toxicity is uncommon, it is more likely to occur with exposure to copper than chronic toxicity (Box 15.1). Dust and fumes, as well as the green carbonate, are irritating to the eyes, skin, and respiratory tract. The National Institute of Occupational Safety and Health (NIOSH) notes that there is little evidence copper dusts and mists (not fume) present a serious occupational risk. Ingestion of copper-contaminated

water may result in gastrointestinal upset, most often nausea and vomiting. Irritation of nasal mucous membranes may occur after inhalation of copper salts. Metal fume fever may result from acute exposure to copper fume; however, the incidence is relatively low due to the high temperatures required to volatilize copper. It is characterized by fever, arthralgia, nausea, cough, and lassitude (NIOSH, 2010). Several renal failure patients have developed acute hemolytic anemia subsequent to copper intoxication when the dialysis tubing and filters contained copper (USEPA, 1985).

Animal studies of acute copper toxicity have demonstrated effects similar to those seen in humans (Fieten et al., 2012). The more severe responses to copper overexposure occurred with concentrations greater than what would be expected in the workplace or through nonoccupational exposure. Romeu-Moreno et al. (1994) exposed rats to high inhalation concentrations of CuSO₄ and found high concentrations of accumulated copper in the liver and plasma.

Individuals susceptible to copper-induced toxicity include those suffering from a hereditary metabolic disorder called Wilson's disease, in which the pathway for excretion and storage of copper does not function properly and copper accumulates more rapidly (Muller et al., 1998; Wijmenga and Klomp, 2004). Other deficiencies may result in infantile cirrhosis in children from overexposure to copper.

Chronic Effects

Chronic illnesses are not reported with copper overexposure, and if they are present in copper-generating facilities, they are linked to the presence of other harmful metals and, in some cases, to exposure to radon (Wu et al., 1992). There is some indication that increased levels of hepatic copper are associated with cellular injury (Johncilla and Mitchell, 2011). Chen et al. (1993) described a higher than expected number of deaths from lung cancer in copper miners but attributed these deaths to general exposure to dust, not specifically to copper dust. Copper has not been found to have any carcinogenic, teratogenic, or mutagenic properties (HSDB, 2007a and HSDB, 2007b). Ostiguy et al. (1995) did not find any significant respiratory dysfunctions in a population of workers exposed to low levels of metal dust and fumes. Some instances of a greenish discoloration of the skin and hair from prolonged exposure to copper were reported in the past, but this effect was not associated with any noticeable ill effects. There is no evidence of carcinogenicity from chronic copper exposure (Lightfoot et al., 2010).

Gleason (1968) reported general malaise and "head stuffiness" in a worker polishing copper plates. After local exhaust measures were improved, the workers' complaints disappeared. Some reports exist of ulcerated lesions of the nose resulting from inhalation of copper dust. Fine fragments of copper that penetrate the eye during certain industrial operations can cause severe ocular damage. Ingestion of

BOX 15.1 TOXICITY OF COPPER

Copper in plasma

About 7% loosely bound to albumin (cytotoxic)

About 93% tightly bound to ceruloplasmin (nontoxic)

Copper in tissue

Most tightly bound to ceruloplasmin (nontoxic) and metallothionein (less toxic)

Unbound or free (toxic)

The cellular and tissue damage caused by copper is related to free or loosely bound and exchangeable copper ions. Toxicity results when ingested copper salts exceed the binding capacity of ceruloplasmin and metallothionein or when the individual has a genetically determined deficiency in binding protein capacity (e.g., Wilson's disease, Menkes' syndrome).

copper dust has been linked to a variety of health problems, including a metallic taste in the mouth, nausea, vomiting, epigastric burning, and diarrhea (Suciu et al., 1981).

Skin eruptions may be accompanied by swelling and itching in workers exposed to “cement copper,” which is precipitated from solution by metallic ion (Hostynék and Maibach, 2003). Hypersensitivity reactions to copper in a welder were described by Forstrom et al. (1977); Dhir et al. (1977) described such reactions in furniture polishers using a commercial spirit colored blue with CuSO₄ (Dhir et al., 1977; Forstrom et al., 1977).

Pimentel and Menezes (1977) described “vineyard sprayer’s lung” in rural workers in Portugal who applied sprays of Bordeaux mixture (CuSO₄ and CaOH involving precipitation of CuOH and several basic sulfates of copper) (Pimentel and Menezes, 1977). These workers had interstitial pulmonary lesions consisting of copper-containing histolytic granulomas and nodular fibrohyaline scars, which were regressing, remaining stationary, or progressing to diffuse pulmonary fibrosis and lung cancer. Lesions containing copper also were found in the nasal mucosa, liver, kidneys, spleen, and lymph nodes. Copper-related liver lesions included sarcoid-like granulomas, fibrosis, cirrhosis, and angiosarcomas, along with idiopathic portal hypertension.

Chemical Pathology

No published data are available regarding the health effects of copper on humans exposed orally or by inhalation for chronic

durations. Additionally, data from chronic animal studies for oral and inhalation exposures to copper are inadequate. There are chronic animal studies for oral exposures to copper compounds such as copper cyanide.

Mode of Action(s)

Because of copper’s low toxicity, few studies of copper-mediated toxicity have been reported, and therefore the mechanism of toxicity is unclear. Most data are from *in vitro* assays or animal studies, neither of which are conclusive in occupational medicine. Copper retained by the liver is bound to metal-binding proteins, specifically metallothionein (-Figure 15.1); this prevents free ions from continually circulating in the body (Boveris et al., 2012). The bound copper is excreted primarily through the bile. Excessive copper may produce liver oxidative damage. The generation of hydroxyl radicals from unbound copper is a possible mechanism for copper toxicity. Sagripanti et al. (1991) found that Cu(II) bound itself to certain sites in the deoxyribonucleic acid and suggested this as a possible mechanism for copper toxicity (Sagripanti et al., 1991). Variations in some tissue pathology as a result of exposure to copper were found *in vitro* to be related to inhibition of the Na⁺/K⁽⁺⁾ pump and calcium homeostasis (Benders et al., 1994).

Increases in urinary and plasma copper levels, detectable by atomic absorption or inductively coupled plasma-atomic emission spectroscopy, can be indicative of occupational overexposure to copper.

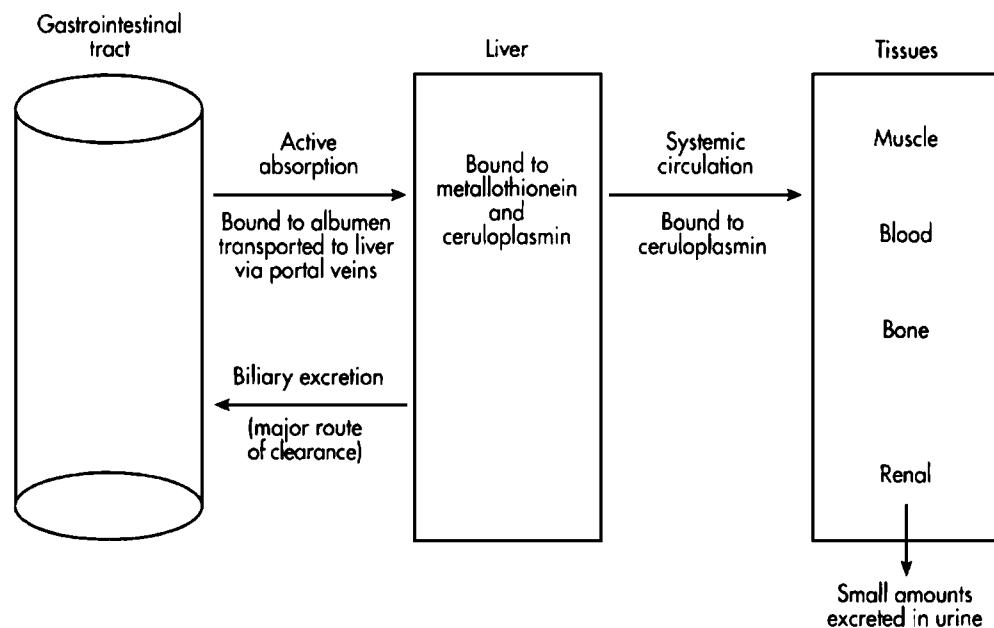

FIGURE 15.1 Mammalian copper.

SOURCES OF EXPOSURE

Exposure to copper in humans can occur through inhalation, ingestion, and eye or skin contact (IPCS, 1998; HSDB, 2007b).

Occupational

Copper exposure is common in occupations, including asphalt makers, electroplaters, wallpaper makers and embossers, solderers, especially miners and smelters of copper ore (ATSDR, 2004). The major industrial route of exposure to copper is inhalation of dust and fumes. Dermal contact and ingestion are less likely to cause adverse effects in an occupational setting (Weir, 1979). The salts of copper generally are considered more toxic than copper dust and fumes, which are relatively nontoxic. The vaporization point of copper is high (about 2350 °C [4262 °F]), and it is rare to encounter these fumes in industry.

Another hazard in copper mining is concurrent exposure to more hazardous metals and compounds. Exposure to arsenic, selenium, lead, and cadmium is associated with copper mining. Industrial hygiene measures are more appropriately tailored to these more hazardous materials than to the copper present. Respiratory protection with face masks and adequate ventilation is recommended in mining operations to protect against exposure to dust and fumes. Protective clothing should be worn, and the skin should be washed after a work shift to reduce dermal contact.

Environmental

Copper is environmentally ubiquitous. The general population may be exposed to copper through the ingestion of drinking water and foods, contact with copper-containing soil, and inhalation of air tainted with copper (HSDB, 2007). Copper concentrations in drinking water range from 20 to 75 ppb and drinking water is the greatest potential exposure source. They may be substantially higher in homes with copper piping/fixtures or lower pH water. Soils, sediments, and dusts commonly contain copper and copper compounds. Many foods, particularly organ meats and mollusks, also contain significant amounts of copper.

INDUSTRIAL HYGIENE

The current Occupational Health and Safety Administration (OSHA) recommended exposure limit(PEL), NIOSH recommended exposure limit(REL), and American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value(TLV) for copper are 1 mg/m³ as an 8-h time-weighted average (TWA) concentration. This applies to other copper compounds except copper fume. The OSHA PEL and NIOSH REL for copper fume are 0.1 mg/m³ as an 8-h (TWA) concentration, and the ACGIH TLV is 0.2 mg/m³. Recommendations by NIOSH on respiratory protection for workers exposed to copper are listed in Table 15.3.

TABLE 15.3 Recommended Respiratory Protection for Workers

Condition/Airborne Concentration of Copper	Minimum Respiratory Protection
Up to 5 mg/m ³	(APF=5) Any quarter-mask respirator
Up to 10 mg/m ³	(APF=10) Any particulate respirator equipped with an N95, R95, or P95 filter (including N95, R95, and P95 filtering facepieces) except quarter-mask respirators. The following filters may also be used: N99, R99, P99, N100, R100, P100
Up to 25 mg/m ³	(APF=10) Any supplied-air respirator
Up to 50 mg/m ³	(APF=25) Any supplied-air respirator operated in a continuous-flow mode (APF=25) Any powered, air-purifying respirator with a high efficiency particulate filter (APF=50) Any air-purifying, full facepiece respirator with an N100, R100, or P100 filter (APF=50) Any powered, air-purifying respirator with a tight-fitting facepiece and a high efficiency particulate filter (APF=50) Any self-contained breathing apparatus with a full facepiece
Up to 100 mg/m ³	(APF=50) Any supplied-air respirator with a full facepiece (APF=2000) Any supplied-air respirator that has a full facepiece and is operated in a pressure-demand or other positive-pressure mode
Emergency or planned entry into unknown concentrations or IDLH conditions	(APF=10,000) Any self-contained breathing apparatus that has a full facepiece and is operated in a pressure-demand or other positive-pressure mode (APF=10,000) Any supplied-air respirator that has a full facepiece and is operated in a pressure-demand or other positive-pressure mode in combination with an auxiliary self-contained positive-pressure breathing apparatus
Escape	(APF=50) Any air-purifying, full facepiece respirator with an N100, R100, or P100 filter Any appropriate escape-type, self-contained breathing apparatus

RISK ASSESSMENTS

No chronic reference dose (RfD) or reference concentration (RfC) for copper is currently available on EPA's Integrated Risk Information System (IRIS) or in the Drinking Water Standards and Health Advisories. There are no human carcinogenicity data and inadequate animal data from assays of copper compounds.

²ACGIH, 2009. Threshold limit values (TLVs) for chemical substances and physical agents and Biological Exposure Indices (BEIs). Cincinnati, OH.

BACKGROUND AND USES

Gallium (symbol Ga; CAS# 7440-55-3) and indium (symbol In; CAS# 7440-74-6) are considered together because they are both widely used in the electronics industry, their radioisotopes are used for diagnostic imaging in medicine, and they are both group III elements (Browning, 1969; Ferm and Carpenter, 1970; Abrams and Murrer, 1993). Both elements typically for compounds with an oxidation state of 3⁺. Though neither element is essential for human nutrition, both are widely distributed in low concentrations in the environment (Smith et al., 1978). Gallium is found in concentrations of 0.01–0.7% in bauxite and germanite ores, and also found in zinc-rich ores.

Radioisotopes of gallium are useful for localizing bone and inflammatory lesions and tumor-associated lymphomas (van Amsterdam et al., 1996). Nonradioactive gallium nitrate (CAS# 13494-90-1) is a potent inhibitor of bone resorption that has been used to treat malignancy-associated hypercalcemia. Radioisotopes of indium have been used to label phagocytes and lymphocytes to localize inflammatory lesions (Dudley and Marrer, 1952; Abrams and Murrer, 1993). Despite early optimism, neither element has found wide use as a treatment for malignancies.

Alloys and compounds containing each element have been used as commercial semiconductors. For example, gallium arsenide (symbol GaAs; CAS# 1303-00-0), indium

phosphide (symbol InP; CAS# 22398-80-7), and indium–tin oxide (symbol $\text{In}_2\text{O}_3\text{SnO}_2$; CAS# 50926-11-9) are among the most widely used intermetallic semiconductor components (Harrison, 1986; McIntyr and Sherin, 1989). Gallium arsenide is also incorporated into light-emitting diodes and photovoltaic cells, while gallium alloys are used for dental amalgam as a low toxicity replacement for mercury. Indium compounds are gaining increasing use for soldering, flat-panel electronic components, and photovoltaic cells. A substance made by combining indium (24%) and gallium (76%) is liquid at room temperature and is used as a wetting agent for sealing glass to metal or glass to glass when high temperatures cannot be used.

PHYSICAL AND CHEMICAL PROPERTIES

Gallium is a silvery liquid at 29.75°C (85.55°F), which boils at 2204°C (3999.2°F) and has the largest liquid range of any metal. Despite the liquid state, the vapor pressure of elemental gallium is negligible. Indium is a silvery-white, malleable metal that melts at 156°C (312.8°F) and boils at 2072°C (3761.6°F). Oxides of both elements are amphoteric. Both gallium and indium form arsenides, halides, hydroxides, oxides, and phosphides, some of which may be degraded by acids and fire to produce highly toxic gases such as arsine and stibine. Reaction of indium oxide with water produces an insoluble indium hydroxide [In(OH)_3], which limits mobilization in solution. Gallium salt solubility increases with increasing ionic strength.

MAMMALIAN TOXICOLOGY

Acute Effects

The oral median lethal dosage (LD_{50}) for gallium arsenide and indium arsenide is $>15\text{ g/kg}$ in rodents with an inhalation exposure threshold for acute effects of 152.5 mg/m^3 for gallium arsenide and 139 mg/m^3 for indium arsenide (Wald and Becker, 1986). Indium hydroxide [In(OH)_3] and gallium hydroxide [Ga(OH)_3] are quickly lethal, teratogenic, and embryocidal in animal models via intravenous administration (Ferm and Carpenter, 1970), despite relative insolubility of the hydroxide salts. Parenterally administered indium chloride has been shown to cause acute tubular necrosis.

Ivanoff et al. (2011) reported the acute symptoms of a human case exposed to aqueous gallium chloride as erythema, nausea, contact dermatitis, and difficulty in breathing, which progressed to cardiomyopathy and neuropathy.

Chronic Effects

Gallium can cause neuromuscular toxicity, including loss of vision and paralysis, as well as constitutional symptoms such

as pruritus and anorexia (Browning, 1969). Chronic exposure to gallium oxide (Ga_2O_3) and gallium arsenide (GaAs ; $\geq 0.1\text{ mg/m}^3$) particles resulted in alveolar proteinosis and pulmonary fibrosis over several weeks or months of exposure in rats with additional incidence of benign respiratory lesions.

Subchronic exposure to indium phosphide ($\geq 1.0\text{ mg/m}^3$) dusts in rats resulted in pulmonary alveolar proteinosis and fibrosis with an increased incidence of non-neoplastic hepatic lesions and mononuclear cell leukemia (NTP, 2001).

Epidemiological data suggest increased incidence of pulmonary alveolar proteinosis, interstitial pneumonia, and fibrosis with chronic exposure to indium phosphide dust (Homma et al., 2003; Cummings et al., 2010; Nakano et al., 2009; Tanaka et al., 2010). Progressive dyspnea has been used to signal the onset of pulmonary alveolar proteinosis. Observed lesions are consistent with animal models though a decisive correlation between the exposure and disease is lacking.

Based on the toxicological evidence, the International Agency for Research on Cancer (IARC) has listed gallium arsenide and indium phosphate as Group 1 and Group 2A human carcinogens, respectively. The American Conference of Governmental Industrial (ACGIH) has classified gallium arsenide as A3 (ACGIH, 2009). Neither chemical has been classified as a carcinogen in its elemental form (IARC, 2006a).

Mechanisms of Action

Absorption of gallium and indium compounds from the gastrointestinal tract is generally below 2% of oral intake in humans (Castronovo and Wagner, 1971; Blazka, 1998). Absorbed gallium exhibits a biphasic half-life in blood with an initial half-life phase estimated at 1 h and the second phase ranges from 1 to 5 days (NTP, 2000). Indium is predominantly absorbed across the lung epithelia and, when absorbed, retained within the pulmonary interstitium and sequestered by serum transferrin (Zhang et al., 2004; Nakano et al., 2009; Hoet et al., 2012). Release from biological reservoirs may lead to prolonged secondary exposure.

Indium accumulates in reticuloendothelial and hepatic phagocytes that were found to be less responsive to mitogens and less able to synthesize immunoglobulin (Silberstein et al., 1985). Gottschling et al. (2001) suggests the role of indium in oxidative stress-mediated pulmonary inflammation progressing to neoplastic growth in rats though the exact mechanism for pulmonary indium toxicity has not been completely elucidated. Absorbed gallium arsenide dissociates in the biological fluid whereby gallium becomes rapidly bound and excreted from the body. The anionic partner, i.e., inorganic arsenic, may mobilize after dissociation and induce toxicity.

Animal models have suggested gallium-induced inhibition of δ -aminolevulinic acid dehydratase (ALAD) in the kidney, liver, and erythrocytes (Goering and Rehm, 1990;

Flora et al., 2009). *In vitro* models using GaCl₃ produced cytostatic effects on peripheral blood mononuclear cells (Chang et al., 2003).

Chemical Pathology

Acute gallium poisoning from gallium chloride has been characterized by one case study. This case exhibited erythema, nausea, contact dermatitis, and difficulty in breathing, which eventually progressed to tachycardia and arrhythmia with peripheral neuropathy (leg tremors). Blood tests revealed electrolyte imbalance with decreased serum phosphate levels (Ivanoff et al., 2011).

Chronic exposure to indium compounds has been associated with interstitial pneumonia and pulmonary alveolar proteinosis as assessed by high resolution computed topography (HRCT) scans though definitive causation has not been implied. HRCT scans of patients have revealed typical pathophysiology such as glass opacities, pneumothorax, and intra-/interlobular septal thickening while lung biopsies have confirmed eosinophilic alveolar intrusion and cholesterol clefts. Bronchoalveolar lavage fluid of patients has also confirmed the presence of eosinophilic infiltrate and foamy macrophages (Homma et al., 2003; Cummings et al., 2010; Nakano et al., 2009). The analysis of metal has confirmed the presence of indium within the interstitial tissue.

Workers observed during continued indium exposure bore stable elevated indium plasma levels, which cleared slowly after removal from exposure; levels of the exposed remained higher than the unexposed controls even after several years. Epidemiological studies have associated KL-6 surfactant protein expression and indium exposure, especially to indium–tin oxide, and may act as a biomarker of secondary pulmonary alveolar proteinosis; however, the link (Homma et al., 2005; Hamaguchi et al., 2008; Hoet et al., 2012).

SOURCES OF EXPOSURE

Occupational

Occupational gallium and indium exposure occurs primarily from respirable dusts produced from sawing, grinding, and cleaning of ingots, wafer fabrication, and workroom cleaning operations. Elevated plasma and urine levels were found in an exposed cohort working in a Belgian indium ingot fabrication plant with an ambient air concentration averaging 190 µg/m³ (range: 10–1030 µg/m³) compared to an unexposed cohort. Both plasma and urine levels fell below the limits of detection for the unexposed. Health assessments were not performed to analyze the risk of exposure (Hoet et al., 2012).

In cases of improper handling and storage, exposure by means of smoke and fumes from chemical reactivity or electrical fires may cause human illness. For example,

gallium arsenide and indium arsenide may release arsine gas under certain conditions (Harrison, 1986; Wald and Becker, 1986; McIntyr and Sherin, 1989; Scott et al., 1989).

Environmental

Environmental exposure to indium compounds has been measured in ambient air as 43 ng/m³ and in rainwater as 0.59 µg/l. Exposure via the environment is considered negligible (IARC, 2006b).

INDUSTRIAL HYGENE

When working with inorganic compounds and elemental forms of gallium and indium, proper skin and eye/face protection is suggested to avoid direct contact. In grinding and cleaning operations, proper personal respiration equipment should be utilized to avoid inhalation.

No exposure limits have been set for elemental gallium. However, Occupational Safety and Health Administration (OSHA) and ACGIH have set an 8-h time-weighted average (TWA) at 0.01 mg/m³ and 0.0003 mg/m³, respectively, for gallium arsenide, while NIOSH recommends a ceiling exposure value of 0.002 mg/m³.

The ACGIH and NIOSH have set TWA exposure limits for inorganic indium (As In) at 0.1 mg/m³. Currently, permissible exposure limit (PEL) and reference values have not been established for either elemental indium or indium compounds (CDC, 2013).

MEDICAL MANAGEMENT

There is no specific therapy for gallium or indium poisoning though oxalic acid has been suggested for chelating gallium after acute exposures (Ivanoff et al., 2011). Removal to fresh air with respiratory support is suggested after acute inhalation exposure. Ocular exposure should be irrigated immediately for a minimum of 15 min.

In cases of pulmonary alveolar proteinosis from chronic indium and indium compound exposure, whole lung lavage has been shown to attenuate decreased pulmonary function (Trapnell et al., 2003).

GERMANIUM

MAREK BANASIK

First aid: Eyes: Irrigate thoroughly with water if discomfort persists, obtain medical attention; skin: wash off thoroughly with soap and water; inhalation: remove from exposure, seek medical advice; ingestion: wash out mouth thoroughly with water—in severe cases, obtain medical attention.

Occupational exposure limit(s): None

Reference value(s): None

Hazard statement(s): None

Precautionary statements(s): None

Risk phrase(s): None

Safety phrase(s): None

BACKGROUND AND USES

Germanium [symbol Ge; Chemical Abstracts Service Registry Number (CASRN): 7440-56-4] is never found in a pure state in the environment. In the refined state, it is a gray-white metalloid. Like its counterparts in group 14 of the periodic table (carbon, silicon, tin, and lead), germanium has both metallic and nonmetallic properties. It has a valence of +2 or +4; the atom usually is quadrivalent.

Germanium is a true semiconductor, is highly transparent to infrared light, and has a high index of refraction. Germanium and its compounds or alloys have found wide use in the optical and electronics industries. In electronic applications, it often is alloyed with antimony, gallium, indium, or arsenic.

Germanium is a low production volume chemical. In the United States (US), the national production volume in 2012, including manufacturing and importing, was 61,890 pounds

(*ca.* 28,073 kg) (EPA, 2012). In the same year, the national production volume for germanium dioxide (GeO_2 , CASRN: 1310-53-8), including manufacturing and importing, was 32,536 pounds (*ca.* 14,758 kg) (EPA, 2012). No registration or production volume data are available for germanium or GeO_2 in the European Union (ECHA, 2014).

No formal regulatory risk assessments have been performed on germanium or germanium compounds. The repeated dose toxicology of GeO_2 has primarily been evaluated in exploratory animal studies to evaluate the adverse effects reported in humans, who consumed germanium-containing products for its alleged health protective effects.

PHYSICAL AND CHEMICAL PROPERTIES

Germanium is a grayish-white, lustrous, brittle metalloid. When crystalline, it exists in a diamond-cubic structure. It has a very low vapor pressure and is insoluble in water. A summary of germanium's physicochemical properties is provided in Table 17.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Metals are recalcitrant to degradation; therefore, no biodegradation studies have been performed on germanium compounds. Naturally occurring germanium exists in mineral ores; therefore, the levels of free germanium are expected to be low and of low concern for bioaccumulation in aquatic and terrestrial species, due to negligible exposures.

TABLE 17.1 Physical and Chemical Properties of Germanium

Characteristic	Information
Name	Germanium
Atomic symbol	Ge
CASRN	7440-56-4
Molecular weight	72.59 g/mol
Physical state	Grayish-white, lustrous, brittle metalloid
Melting point	937.2 °C
Vapor pressure	0 mmHg at 25 °C
Density	5.323 g/cm ³ at 25 °C
Water solubility	Insoluble

ECOTOXICOLOGY

No aquatic toxicology data were identified for germanium or germanium compounds.

MAMMALIAN TOXICOLOGY

Some germanium compounds have been claimed to have bone marrow- and immune-modulating properties (St. Georgiev, 1988). These compounds were incorporated into health food supplements and herbal teas but were subsequently banned by many countries due to numerous cases of adverse effects in humans (reviewed by Tao and Bolger, 1997). In addition to case study findings, several acute and repeated dose toxicity studies have been performed on experimental animals, which generally show the same types of toxicity occurring in humans. A summary of these studies is provided below.

Acute Studies

The acute oral toxicity of GeO₂ is low (reviewed by Tao and Bolger, 1997). In rats and male mice, median lethal dose (LD₅₀) values of 3.7 and 6.3 g/kg body weight (bw) have been reported, respectively. In male and female rats and mice, correspondingly low LD₅₀ values (\geq 6.3 g/kg bw) were reported for bis-carboxyethyl germanium sesquioxide (i.e., germanium-132 or Ge-132).

Lin et al. (1999) evaluated the kinetics and tissue distribution of GeO₂ in male Wistar rats after single and repeated exposures, respectively. In the single dose studies, six rats were administered 100 mg/kg bw by gavage. A maximum serum concentration of $15.5 \pm 0.7 \mu\text{g}/\text{ml}$ (mean \pm S.E.M.) was reported. The absorption- and elimination-half lives were

$0.7 \pm 0.1 \text{ h}$ and $2.3 \pm 0.5 \text{ h}$, respectively. In the repeated dose studies, 15 rats were administered daily doses of GeO₂ at 100 mg/kg bw/day by gavage for 4 weeks. Statistically significant concentrations of GeO₂ were reported in the following tissues, compared to the controls (all tissues $<1 \mu\text{g}/\text{g}$): sciatic nerve ($5.5 \pm 0.2 \mu\text{g}/\text{g}$), kidney ($4.9 \pm 0.2 \mu\text{g}/\text{g}$), liver ($3.5 \pm 0.1 \mu\text{g}/\text{g}$), serum ($3.2 \pm 0.2 \mu\text{g}/\text{g}$), heart ($3.1 \pm 0.1 \mu\text{g}/\text{g}$), lungs ($1.9 \pm 0.1 \mu\text{g}/\text{g}$), gastrocnemius muscle ($1.7 \pm 0.1 \mu\text{g}/\text{g}$), and brain ($1.5 \pm 0.1 \mu\text{g}/\text{g}$).

As discussed in the following sections, the tissue distribution data reflect some of the target organs identified from repeated dose studies in experimental animals and in human case study reports.

Repeated Dose Studies

Tao and Bolger (1997) reviewed the available repeated dose toxicity studies in animals administered with germanium compounds. As summarized in Table 17.2, the toxicity of inorganic germanium (i.e., GeO₂) was shown to be greater than organic germanium (i.e., Ge-132). The target organs included the kidney, liver, peripheral nerves, and skeletal muscle. Adverse renal effects were reported even after cessation of treatment, up to 24 weeks in one study.

In humans who consumed germanium compounds as a supplement or tonic, the toxicity of germanium reveals similar target organs as reported in experimental animal studies. It should be noted, however, that no reports were identified for systemic toxicity occurring through occupational exposures. As shown in Table 17.3, renal dysfunction and anemia were reported in 100% of patients treated for germanium toxicity. In some cases, renal function was still impaired for 10–31 months after the patients stopped taking germanium products.

SOURCES OF EXPOSURE

Occupational

Elemental germanium may ignite spontaneously and explode when suspended in air as a fine powder (HSDB, 2002). Germanium dioxide dust can form germanic acid, an irritant, if it contacts the eye (HSDB, 2000). Occupational exposures to dusts and fumes may occur during activities that involve separation and purification of the ore concentrate.

Environmental

The major source of germanium exposures in the general population occurs through the consumption of foodstuffs. Daily consumption estimates have been reported between 0.367 and 1.5 mg/day (reviewed by Tao and Bolger, 1997).

TABLE 17.2 Repeated Dose Toxicity Studies in Rats Treated with Germanium Dioxide or Germanium-132

Study Type	Test Substance; Dose	Exposure Regimen	Effect
13-week dietary study	GeO ₂ ; calculated intake: 150 mg/kg bw/day	Daily	<ul style="list-style-type: none"> • ↑ Serum creatinine, BUN^a, and serum phosphate • ↓ Creatinine clearance • ↑ Kidney weight • ↑ GOT^b and GPT^c • ↓ Total protein and albumin
4- and 24-week dietary studies	Ge-132; calculated intake: 1 mg/kg bw/day	Daily	<ul style="list-style-type: none"> • No toxic symptoms or behavior • Slight ↓ in bw in male rats at 6 months • Small ↓ in erythropoiesis and ↑ in cellular metabolism after 28 days • Moderate ↓ in renal efficiency at 6 months

INDUSTRIAL HYGIENE

The primary routes for potential exposure are through inhalation of dust and contact with skin/eyes. Engineering controls and personal protective equipment are required or recommended. A respirator and polyvinyl alcohol protective gloves are required. If chipping or dust formation is possible, safety goggles or safety glasses with side shields are also required.

BACKGROUND AND USES

“There are strange things done ‘neath the midnight sun by the men who moil for gold.”

So begins *The Cremation of Sam McGee* by British-Canadian poet Robert William Service. Metallic gold [symbol Au; Chemical Abstracts Service Registry Number (CASRN): 7440-57-5] is virtually insoluble, except in aqua regia. Gold exists in three primary forms, elemental, Au (I), and Au (III). As a precious metal, it is resistant to ionization and generally considered biologically benign in its elemental state. Occupational hazards in gold mining and refining arise from mechanical, environmental, and chemical factors and processes involved in the extraction of the precious metal, not from the metal itself. Gold salts, on the other hand, can be irritating and sensitizing and can

cause systemic toxicity (Ainsworth et al., 1981; Barelli et al., 1987; Brown and Hill, 1994; Cohen, 1988; Gleichman et al., 1991; Gortenutti et al., 1985; Hall et al., 1987).

Rheumatoid arthritis is the only medical indication for chrysotherapy (i.e., gold therapy), and for some of these long-suffering patients, gold can give impressive, long-lasting relief. Most therapeutic forms are gold salts containing Au (I). Gold has a long biological half-life and can be detected in the blood for as long as 10 months after administration has stopped (Cohen, 1988). Its mode of action is unknown.

In the United States (US) in 2012, the national production volume, including manufacturing and importing, was withheld by the two listed companies. One company classified the manufacturing and importing data, as well as past production volume data, as confidential business information. The same company listed an on-site production volume of 8,228 pounds (*ca.* 3,732 kg) (EPA, 2012). The second company reported a manufacturing production volume of 26,252 pounds (*ca.* 11,908 kg) with a past production volume of 38,884 pounds (*ca.* 17,637 kg); no importing data were reported, and the volume used on-site was listed as 0 pounds (EPA, 2012). In the European Union, gold was not registered (ECHA, 2014).

The potential risks from gold relate primarily to adverse effects that may occur from the various gold compounds that are used therapeutically. A summary of these data is provided below.

PHYSICAL AND CHEMICAL PROPERTIES

A summary of elemental gold’s physicochemical properties is provided in Table 18.1.

TABLE 18.1 Physical and Chemical Properties of Gold

Characteristic	Information
Name	Gold
Atomic symbol	Au
CASRN	7440-57-5
Molecular weight	196.97 g/mol
Physical state	Soft yellow metal
Melting point	1,064.76 °C
Boiling point	2,700 °C
Density	19.3 g/cm ³
Water solubility	Insoluble

Source: HSDB (2004).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Metals are recalcitrant to degradation; therefore, no bio-degradation studies have been performed on gold or its compounds. Naturally occurring gold exists in mineral ores; therefore, the levels of free gold are expected to be low and of low concern for bioaccumulation in aquatic and terrestrial species, due to negligible exposures.

ECOTOXICOLOGY

No aquatic toxicology data were identified for gold or its compounds.

MAMMALIAN TOXICOLOGY

Gold poisoning is most likely to be seen in association with medical uses of gold salts (Jackson et al., 1986; Rollins and Craig, 1991; Stuve and Galle, 1970; Voil et al., 1977). Gold salts are poorly absorbed, and until recently gold therapy for rheumatoid arthritis meant an intramuscular injection of gold sodium thiomalate (CASRN: 12244-57-4) in aqueous solution or gold thioglucose (CASRN: 12192-57-3) in oil. In the past decade an organic gold compound, auranofin, had been developed for oral administration. About 25% of the gold in the compound was absorbed by the gastrointestinal tract (Brent and Parra, 2005).

Episodes of vasodilation with facial flushing, hypotension, nausea, and light-headedness, the so-called nitritoid reaction, occur within minutes after injection of gold sodium thiomalate. Concomitant use of an angiotensin-converting enzyme inhibitor may increase the likelihood of this side effect (Healey and Backes, 1989).

The gold ion is a protoplasmic poison with an affinity for mitochondria. It forms complexes with a variety of proteins and thus can become part of a hapten or an immune complex (Gleichman et al., 1991). Gold salts show a wide range of

clinical toxicity such as stomatitis and skin rashes with an element of photosensitivity, glomerulitis with proteinuria and hematuria, bone marrow suppression with thrombocytopenia and neutropenia, inflammatory enterocolitis, and pulmonary infiltrates with dyspnea and restrictive changes on spirometry.

Lymphadenopathy and eosinophilia often accompany gold salt toxicity, suggesting immunological sensitization as a pathogenetic factor. Gold salts interact with other drugs, such as nonsteroidal anti-inflammatory agents, which enhance gold-related renal and pulmonary toxicity (Martin et al., 1981; McFadden et al., 1989).

SOURCES OF EXPOSURE

Occupational

In South Africa, extraordinarily deep gold deposits subject miners to intense heat and pressure changes. In Brazil, liquid mercury is used to separate gold from the earth and sediments. When the gold–mercury amalgam is heated, the mercury vaporizes and is allowed to discharge into the environment, contaminating waterways and posing risks to wildlife and humans. Halogens, especially fluorine, are used in gold refining. Electroplating of jewelry and electronic applications requires gold potassium cyanide salts, which are irritants and systemic toxicants. Because metallic gold is biologically inert, no standards have been recommended by the US Occupational Safety and Health Administration, the US National Institute for Occupational Safety and Health, or the American Conference of Governmental Industrial Hygienists.

Environmental

Environmental exposures to gold are expected to be low. Background levels of $\leq 0.1 \mu\text{g}/\text{ml}$ and $< 0.0005 \mu\text{g}/\text{ml}$ in whole blood and serum, respectively, have been reported (Brent and Parra, 2005).

INDUSTRIAL HYGIENE

Workplace engineering controls (e.g., local exhaust) are recommended when cutting, grinding, or melting gold or other operations that may generate dusts or fumes. Personal protective equipment include safety glasses and protective gloves. Respiratory protection is not normally required, except in operations where dust or fumes are created.

IRON

STEVE MORRIS AND JAYME P. COYLE

Target organ(s) iron (elemental) ^a	No established target organs
Occupational exposure limits iron (elemental)	No established exposure limits
Reference values iron (elemental)	No established reference values
Risk/safety phrases iron (elemental)	No established risk/safety phrases

^aFor values for iron compounds, refer to Table 19.1.

BACKGROUND AND USES

Iron (symbol Fe; CASRN 7439-89-6) is the fourth most abundant element in the earth's crust (5%). It is a transition metal and is placed within the d-block of the periodic table and naturally occurs coordinated with other elements. It is mainly extracted from hematite (Fe_2O_3) and limonite ($\text{Fe}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$), although other ores, such as magnetite (Fe_3O_4), siderite (FeCO_3), and taconite (an iron silicate), are also the key sources. Iron is used principally for structural materials, primarily steel, an iron carbon alloy. It is also used in magnets, dyes, pigments, abrasives, and polishing compounds (e.g., jeweler's rouge).

Apart from being an essential nutrient for erythropoiesis, iron is also important for the proper functioning of myoglobin, heme enzymes, and metalloflavoprotein enzymes (Hardman and Limbird, 1996). Iron oxide (CAS #1309-37-1) is a ubiquitous oxidized form of iron found. Iron chloride (CAS #7705-08-0) and other iron salts are widely used in industrial and chemical synthesis processes. Iron

pentacarbonyl (iron carbonyl; CAS #13463-40-6) is used in organic synthesis as an anti-knock fuel additive and as high frequency coils in electronics (O'Neil, 2001).

PHYSICAL AND CHEMICAL PROPERTIES

Iron has a melting point and boiling point of 1538 °C [2800 °F] and 2862 °C [5182 °F], respectively. Iron compounds are generally solid at room temperature.

Iron oxide (Fe_2O_3) is a reddish brown solid that decomposes at 1566 °C and is insoluble in water. Rust is a non-protective superficial oxidized product, which corrodes and mobilizes over time.

Iron pentacarbonyl ($\text{Fe}(\text{CO})_5^{5+}$) is a colorless to dark red, oily water-insoluble liquid with a density of 1.49 g/cm³ and boiling point of 103 °C. The vapor pressure and flash point of iron carbonyl are 40 mmHg at 30.3 °C (86.5 °F) and -15 °C (5.0 °F), respectively; the latter qualifies it as a class IB flammable liquid. Both air and light can decompose the compound to inorganic iron and gaseous carbon monoxide (NIOSH, 2005).

MAMMALIAN TOXICOLOGY

Acute Effects

Overexposure to therapeutic iron salts by means of ingestion may cause vomiting and intestinal bleeding. In severe cases, acidosis may occur with accompanying damage to the liver, kidneys, and cardiovascular system.

Chronic Effects

Chau et al. (1993) studied the mortality of French iron miners. These researchers reported no excess of lung cancer in nonsmokers, moderate smokers, or miners who had worked above or below the ground for <20 years. However, they found a significant excess of lung cancer in moderate smokers who had worked underground for 20–29 years (standardized mortality ratio [SMR] = 349) and in moderate and heavy smokers who had worked underground for over 30 years (SMR = 588 and 478, respectively). The authors attributed the higher risk of lung cancer to diesel engine emissions, dust, and explosions.

Sitas et al. (1989) investigated the mortality patterns in a cohort of iron workers. They found a higher mortality rate from cancer of the trachea, bronchus, and lungs in workers over the age of 65 (1.71 proportional mortality ratio). Workers under the age of 65 had an increased risk of nonmalignant respiratory disease (1.58 proportional mortality ratio). These findings were supported by Adzersen et al. (2003) from a large cohort of German iron foundry workers with an increased standardized mortality rate (151.7) for the same respiratory neoplasms; however, this cohort was not analyzed for either smoking habits or alcohol consumption.

Andjelkovich et al. (1995) studied the mortality of iron foundry workers exposed to formaldehyde. They found an association between lung cancer and exposure to silica but no association between exposure to formaldehyde and any type of mortality from respiratory system disorders. Westberg et al. (2013) studied cancer morbidity from quartz exposure in a Swedish cohort and reported significantly increased incidence of lung and pleural neoplasms (1.58 standardized incidence ratio), particularly with a latency period of 20 years or more. The cohort was incompletely assessed for smoking history, confounding exposures to solvents and respirable dusts, and a discernible dose-response trend could not be determined.

Studies addressing the effects of exposure to organic chemicals, such as isocyanates, in the iron industry are being increasingly researched (Westberg et al., 2005; Liljelind et al., 2010). One study conducted by Andersson et al. (2009) reported an 8-h TWA of 0.98 mg/m³ respirable dust within a selection of Swedish iron foundries. These studies may offer insight into associations drawn between iron foundry workers and the observed morbidity and mortality figures obtained by the aforementioned studies.

A well-studied series of workers with siderosis showed no increase in morbidity or mortality from respiratory disease (Stanescu et al., 1967; Kleinfeld et al., 1969). Albu and Popescu (1973) found no impairment in pulmonary blood flow in 12 iron oxide pigment workers with radiographic nodular opacities. Morgan (1978) reported a case of pneumoconiosis in a worker exposed for 9 years to extremely dusty atmospheres in a mill that pulverized magnetite with a negligible silica content.

The primary complaints were cough and sputum. Although the chest X-ray showed several rounded opacities throughout both the lung fields, pulmonary function tests were normal. Severe cases of siderosis may be complicated with secondary fibrosis to result in dyspnea.

Mechanisms of Action

Considerable iron oxide dust may be caught in the respiratory tract defenses and expectorated in sputum, a process well known to exposed workers because of the rust color of phlegm. The remaining iron oxide accumulates in the lymphoid tissue along the bronchi, especially at the bifurcation.

Experiments on low level lung exposure to ferric oxide particles in human subjects demonstrated insignificant effects on pulmonary epithelial cells and pulmonary function with iron homeostasis abnormalities. Decreases in transferrin accompanied increases in ferritin and lactoferritin levels, which resolved by day 4 postexposure (Ghio et al., 1998; Lay et al., 2001). When inhaled, iron compounds can accumulate in alveolar macrophages, which may be inactivated if overly burdened.

Unbound iron (Fe^{2+}) in serum is a redox active metal, which readily undergoes Fenton reactions with endogenous oxygen species.

Chemical Pathology

The chest X-ray changes with this benign pneumoconiosis are easily confused with those of silicosis, hemosiderosis, and a number of diseases that produce bilateral densities. Typically, a confirmation of bilateral opacities related to iron particulate or fume exposure does not progress to a significant disability or clinical pathology and remains a rare outcome of exposure.

In a case series of 15 welders, CT scans revealed alveolar septal thickening suggestive of fibrosis. The histopathology confirmed the presence of hemosiderin via Prussian blue-positive lung sections and increased iron-containing alveolar macrophages. Energy dispersive X-ray analysis (EDX) confirmed iron, with an additional few peaks corresponding to low level aluminum and silicon deposition (Buerke et al., 2002).

SOURCES OF EXPOSURE

Occupational

Occupational siderosis is caused by exposure to iron oxide, for example, in paint pigments and jeweler's rouge. Other jobs that can give rise to siderosis are the manufacture of iron oxide and iron shot, the sieving and bagging of powder from emery rock, and grinding with an emery wheel.

TABLE 19.1 Exposure Limits and Threshold Limit Values for Iron Compounds

Iron Compound	CAS Number	PEL (mg/m ³)	REL (mg/m ³)	TLV (mg/m ³)
Iron oxide dust and fumes	1309-37-1	10	5	5
Iron pentacarbonyl	13463-40-6	None	0.23; 0.45 ^a	0.23; 0.45*
Iron salts	Varied	None	1	1

Sources: American Conference of Governmental Industrial Hygienists (ACGIH) (2010) and National Institute for Occupational Safety and Health (NIOSH) (2005).

^aShort-term exposure limit of 15 min.

PEL: permissible exposure limit, set by the Occupational Safety and Health Administration; REL: recommended exposure limit, set by the National Institute for Occupational Safety and Health; TLV: threshold limit value, set by the American Conference of Governmental Industrial Hygienists.

Workers using electric arc or oxyacetylene equipment in welding, cutting, grinding, or polishing are at risk, especially when working in closed spaces such as boilers or tanks or below the decks in ships. The high temperatures of welding operations produce an iron oxide fume that is readily inhaled in the absence of respiratory protection. Because of the heat and physical effort required in this work, it is often impossible for a worker to wear a useful mask except for very short periods.

Workers may be exposed to vapors of iron pentacarbonyl, as it is used in organic synthesis, electronics, and in motor fuels as an additive. Similarly, accidental spills of iron salts in manufacturing and chemical synthesis industry may allow for exposure.

Environmental

Old, unlined lead drinking water distribution pipes release iron compounds, such as hematite and iron hydroxide, over years of use, especially within areas supplying chlorinated water. Water laden with iron compounds gives the characteristic “red water” (iron may be found in drinking water supplied by old pipes lined with iron (Sarin et al., 2004).

INDUSTRIAL HYGIENE

The exposure limits and threshold limit values for iron compounds are listed in Table 19.1. No established occupational limits have been established for elemental iron.

Iron workers may be at a risk of hearing loss because of their noisy work environment (Burton and Burr, 1993), and impaired hearing may result in poor balance thereby increasing the risk of accidents (Kilburn et al., 1992). For controlling particulates and fume, proper ventilation and, when necessary, respirator use is recommended.

MEDICAL MANAGEMENT

Evacuation from the area is recommended after heavy exposure to iron particulates and fume. Administration of oxygen

is recommended if respiratory problems are observed (Currence et al., 2005).

In cases of acute iron salt exposure with associated high serum iron levels, chelation therapy with deferoxamine is recommended. Deferiprone and Exjade are also available as oral chelating agents for iron clearance. Thereafter, titration should be reduced gradually. Avoid chelation therapy for more than 24 hours due to the increased risk of injury.

LEAD

FRANK D. STEPHEN

Target organs: Central/peripheral nervous system, cardiovascular system, kidney, and blood

OSHA PEL: 50 µg/m³ (TWA) (lead); 0.075 mg/m³ general industry (tetraethyl lead), 0.1 mg/m³ construction (tetraethyl lead)

ACGIH BEI: 30 µg/100 ml

ATSDR: 10 µg/dl blood lead action level in children

FDA: 0.005 mg/l bottled drinking water limit; 0.5–3.0 µg/ml action level (ceramic ware); 0.5–7.0 µg/ml action level (silver-plated hollowware)

BACKGROUND AND USES

Lead has had a multitude of practical uses for over 8000 years and reports of poisoning exist in all ancient civilizations, including Greece, Rome, and China. By the second century in Greece, lead was known to cause colic when swallowed, and lead intoxication also produced paralysis. Piping was made of lead as early as the Roman Empire, and even during Ceasar's reign it was noted that water from earthenware pipes tasted better than that delivered in pipes of lead (Pioreschi, 1998). Lead poisoning outbreaks were common in the Middle Ages due to the fortification of wine with lead-containing additives to improve the taste of poorly vented wines. The Devonshire colic of 1767 was attributed to the storage of cider in earthenware that had been painted with glaze, which contained lead. Colonial America did not escape the ravishes of lead poisoning. Rum distilled in vessels containing lead produced colic and in 1723 prompted the Massachusetts legislature to outlaw the distillation of rum and other hard liquors in lead pipes. French physician Luis Tanquerel des Planches, in 1839, examined 1217 cases of lead poisoning and observed a causative relationship between

exposure to lead dust and central nervous system and renal toxicity. Even Beethoven may have been a victim of lead poisoning due to his abusive consumption of wine (Mai, 2006).

Currently, much of the lead used in the United States is found in vehicle batteries. Historically, in addition to pipes and batteries, metallic lead (or lead as an alloy) has been used industrially to produce ammunition, cable covers, weights, radiation shields, and solder. Compounds that include lead have been used in paints, glazes for ceramics, dyes, caulks, glass, and semiconductors, but ironically lead was never used in "lead" pencils. In the United States, tetraethyl- and tetramethyl lead were used as gasoline additives to boost octane ratings and reduce engine "knock" until banned in 1996. Publicly, there is a great amount of public awareness with regard to the poisoning of children who have been exposed to old paint, putty, or soils contaminated with lead.

The presence of lead in the human body is considered to be a sign of environmental pollution since lead is not known to have any biological use to humans. Industrial lead intoxication in the United States and elsewhere still occurs. Although acute lead poisoning is almost nonexistent today, low level exposure in some areas of the world is still persistent. Blood lead levels are significantly higher than during preindustrial history, and our understanding of the significance of subclinical blood lead levels is greater. Today, there is no threshold of blood lead levels that is considered safe (Sanborn et al., 2002).

PHYSICAL AND CHEMICAL PROPERTIES

Occurring naturally in the earth's crust, lead (symbol Pb; CAS #7439-92-1) is a heavy bluish-gray metal that is

TABLE 20.1 Physical and Chemical Properties of Lead

Molecular weight	207.2
Color	Bluish gray
Physical state	Solid
Flash point	No data
Melting point	327.46 °C
Boiling point	1740 °C
Density at 20 °C	11.34 g/cm ³
Water solubility	Insoluble
Vapor pressure	1.77 mmHg at 1000 °C

lustrous when freshly cut. It is rarely found as a pure metal but rather is complexed with other elements to form lead compounds. Found in ore with copper, zinc, and silver, lead is found in mineral form as galena (PbS), anglesite ($PbSO_4$), and cerussite ($PbCO_3$). It is easily malleable, smelted, and can be added to other metals to form alloys. Resistant to air and water corrosion, it does not mix easily with many solvents but will react with hot acids such as nitric and sulfuric. It has 4 naturally occurring isotopes as well as 17 that have been produced experimentally. Burning with a bluish-white flame, powdered lead displays pyrophoricity and releases toxic fumes when burned. Important physical and chemical properties are listed in Table 20.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Lead is found naturally in the earth's crust and can be dispersed throughout the environment as a result of anthropogenic activities, volcanic eruptions, and wind and soil erosion. Anthropogenic activities include mining and smelting operations. Once entrained in the air, lead can be removed by gravitational settling and precipitation. Eventually deposited in the soil, lead adsorbs tightly and rarely leaches to the subsoil or groundwater. In the environment, lead compounds can be converted to other forms of lead compounds. It is constantly cycled through all phases of the environment by such processes as wind spread of dust, stream and river flow, precipitation, and subsequent runoff and weathering.

Air In the air, lead exists naturally as $PbSO_4$ and $PbCO_3$. Lead particles in air can also be emitted from anthropogenic sources such as smelting industries and mining (in the form of inorganic salts such as $PbSO_4$ and PbS) and vehicle/automobiles exhaust (in the form of halides such as $PbBrCl$ and $2PbBrCl\ NH_4Cl$) (EPA, 1986).

Water Since lead is found in multiple chemical forms, its chemistry in water can be complex. Preferentially, lead will combine with the anions found in water to form compounds that have low solubility. In freshwater, the divalent form

(Pb^{2+}) of lead is the most stable ionic species; however, $PbCO_3$ forms under alkaline conditions. It can be removed from freshwater through natural settling into sediment or through absorption to polar particulates. In saltwater, lead chloride and carbonate are the predominant species. Lead will form stable complexes with organic matter in water. Species of organic lead (e.g., tetraethyl lead) can degrade from tetraalkyl forms to trialkyl, dialkyl, and finally inorganic lead oxides. Volatilization or photolysis also occurs.

Soil Lead naturally occurs in the soil as a constituent of the earth's crust with additional human contribution coming from lead-containing products (e.g., paint). From natural sources the accumulation of soil lead is dependent on the atmospheric deposition. Once adsorbed to soil particles, lead's soil presence is rather stable but can be affected by chemical exchange with other minerals. Its stability prevents lead from leaching beyond upper levels. It can also form stable organic compounds, which chelate with organic matter.

Atmospheric lead most often enters the soil as lead sulfur compounds (e.g., $PbSO_4$ or PbS). Soil conditions/composition will dictate what types of reactions lead will undergo. Almost all lead released to the atmosphere from human activity will be reactive and after transformation will be adsorbed to soil. The amount of soluble lead in soil is dependent on the pH and the availability of carbonates and phosphates. Organic lead compounds will remain in soil after deposition but can be converted microbially to water-soluble forms, which may in turn leach.

MAMMALIAN TOXICOLOGY

Acute Effects

Symptoms of acute lead poisoning can be found in many different body systems. The encephalopathic effects of central nervous system lead intoxication have been known for hundreds of years. Acute neurological symptoms in adults generally result from inhalation of lead dust or fumes while effects in children occur after ingestion.

Neurobehaviorally, exposed individuals exhibit headaches, hallucinations, poor attention spans, dizziness, irritability, forgetfulness, fatigue, lethargy and general weakness, impotence, decreased libido, paresthesia, and tremors in peripheral muscles due to poor nerve conduction. Similar symptoms have been reported in children exposed to lead containing paint chips, putty, and contaminated soils.

Children absorb lead much faster than adults, thus, the end points of exposure to children are of greater concern. A review conducted in the early 1970s by the National Academy of Sciences (NAS) (NAS, 1972) found that children suffered neurological symptoms such as convulsions, stupor,

ataxia, and in some cases even coma and death. Further, children who suffer from lead intoxication were found to have permanent neurological and cognitive impairments. Encephalopathies in children were found to correlate with blood lead levels in excess of 80 µg/dl (Bradley et al., 1956; Bradley and Baumgartner 1958; Rummo et al., 1979; Smith et al., 1983).

Chronic Effects

Almost all human physiological systems have been shown to suffer from negative chronic effects due to long-term lead exposure.

Neurological Lead exposures have been associated with behavioral effects for centuries (Whitfield et al., 1972). Exposure in the workplace produces chronic, long-term negative neuropsychological outcomes such as conflict in interpersonal relationships; poor performance on neurobehavioral tests; disturbances in mood; decreases in memory, IQ test, and cognitive performance; nervousness; ability to cope; reaction time; visual motor performance; and hand dexterity. Kumar et al. (1987) reported that these conditions can then worsen resulting in delirium, convulsions, coma, and death. Traditionally, blood lead levels ranging from 50 to 300 µg/dl were thought to be indicative of acute poisoning (Smith et al., 1938), but blood lead levels as low as 10 µg/dl have been associated with decreased IQ scores and increased aggression (Guidotti and Ragain, 2007).

Neuropsychological effects have been observed in many lead industry workers with blood lead levels between 40 and 80 µg/dl. One difficulty when trying to determine a consensus as to the neurobehavior of adults in response to lead exposure was in the varied methodology employed in these studies. A review of various studies shows that blood lead levels of approximately 60 µg/dl were correlated with decreased reaction time (NIOSH, 1974; Stollery et al., 1989, 1991). High blood and bone lead levels were also positively associated with long-term decreases in cognitive function. In a study of 427 Canadian lead workers, Lindgren et al. (1996) found that visuomotor skills were decreased in those highly exposed. Lead-exposed workers were more likely to get into interpersonal conflicts with fellow coworkers (Parkinson et al., 1986).

A meta-analysis performed by Meyer-Baron and Seeber (2000) found that blood lead concentrations ranging from 30 to 50 µg/dl decreased scores on various behavioral tests and that these decreases were equal to that of people who had aged, without lead exposure, 20 years. Schwartz et al. (2005) followed a cohort of 576 lead workers for 5 years investigating the relationship between blood and tibia lead levels and scores on neurobehavioral tests. They found decreases in lead-exposed individuals at the start of the study and a continued decrease over the course of the study as compared

to the nonexposed control group with respect to decision making and manual dexterity.

Renal With over 40 reviews of occupational studies examined, a relationship between lead exposure and renal function has been well established. Lead nephropathy is an irreversible renal disease that develops over long periods of excessive exposure (Landrigan, 1990). Characterized by a progressive destruction of proximal tubular cells and ensuing interstitial fibrosis, typical lead-induced renal disease results in suppressed glomerular filtration rate, proteinuria/enzymuria, and impaired glucose absorption.

Glomerular filtration rate decreases, as measured by increased serum creatinine concentration, have been used as a barometer of renal dysfunction as related to lead exposure. Payton et al. (1994) reviewed data from 744 subjects and found a decrease in creatinine clearance of 10.4 ml/min (11% from the group mean). Kim et al. (1996) showed an association between blood lead and serum creatinine concentrations in 459 middle-aged men. Increased serum creatinine concentrations were found in subjects with blood lead level concentrations as low as 10 µg/dl (Kim et al., 1996; Muntner et al., 2003). Finally, in a longitudinal study conducted by Tsaih et al. (2004), a 4–8-year follow-up of 448 individuals (mean age 66 years old) found a positive association between blood lead levels and serum creatinine concentrations.

Cardiovascular The available literature is replete with epidemiological studies examining the relationship between blood pressure and body lead burdens. A complete review would be beyond the reach of this chapter. These types of studies pose difficulty for the researcher. The need to control for many confounders and covariates, genetic predisposition, other lifestyle factors and the choice of body lead repository as well as one time blood pressure measurement makes ardent conclusions from the data difficult.

Several meta-analyses were performed, and the results showed that a direct relationship between systolic pressure and increased lead burden exists. This effect is seen more in persons of middle age rather than the young. Pressure increases are about 1 and 0.6 mmHg, for systolic and diastolic, respectively, for every doubling of blood lead concentration (Nawrot et al., 2002; Staessen et al., 1994). A third study found a 1.25 mmHg systolic increase (Schwartz, 1995). However, a study conducted by Staessen using multiple blood pressure measurements did not find this association (Staessen et al., 1996).

Longitudinal studies have examined the relationship of the source of body lead burden and hypertension with slightly differing results. Blood lead levels were found to increase diastolic pressure (Batuman et al., 1983; dos Santos et al., 1994). Weiss et al. (1986, 1988) found that blood lead levels above 30 µg/dl were predictive of an increase in systolic blood pressure in Boston police officers. However, a study of

70 workers at a battery manufacturing plant found no significant correlation between blood lead levels and blood pressure during a 6- to 10-year follow-up period (Navah et al., 1996).

In a study of 590 individuals, Hu et al. (1996) found that average patellar blood lead levels were significantly higher in hypertensive individuals. Similar results were observed in the Nurses Health Study (Korrick et al., 1999). In contrast, Cheng et al. (2001) found a positive association between tibial lead levels and increased blood pressure but no such association was found in blood or patellar lead levels. Finally, Nash et al. (2003) found a positive association between high blood lead levels and hypertension risk in middle-aged women.

A study of 496 workers at an organic lead-manufacturing plant found a positive association between blood and tibial lead levels and systolic blood pressure (Glenn et al., 2003).

Hematological Anemia may result from decreased hemoglobin content in red blood cells as well as hemolysis (resulting in hematuria). Lead alters the function of three different enzymes, δ -aminolevulinic acid dehydratase (ALAD), δ -aminolevulinic synthetase (ALAS), and ferrochelatase, which interrupt the normal production of heme. The activity of ALAD is also a sensitive indicator of lead exposure. Finally, renal damage may also cause lead-induced anemia due to a decrease in erythropoietin production, which results in poor maturation of erythroid progenitor cells (Osterode et al., 1999).

Musculoskeletal Lead workers with blood lead levels higher than 40 $\mu\text{g}/\text{dl}$ reported muscle soreness, weakness, cramps, and pain (Rosenman et al., 2003; Holness and Nethercott, 1988; Marino et al., 1989; Matte et al., 1989; Pagliuca et al., 1990). Bone is the largest repository of lead in the body accounting for up to 75–95% of the body burden (Barry, 1975). Surprisingly, bone mineral density was increased in a cohort of a highly lead exposed boys in New York City (Campbell et al., 2004) leading to the speculation that lead accelerates bone maturation. Increased blood lead levels are also associated with dental cavities in children (Moss et al., 1999; Campbell et al., 2000; Gemmel et al., 2002). A review of over 10,000 people enrolled in the NHANES III study found that increasing blood lead levels were positively associated with increased periodontal bone loss (Dye et al., 2002).

Gastrointestinal As described earlier in this chapter, lead ingestion causes colic and abdominal distress. Other gastrointestinal signs and symptoms include decreased appetite (and resultant weight loss), abdominal pain, constipation, diarrhea, nausea, vomiting. Shock may result if there is a loss of water from the gastrointestinal tract.

Immunological While no conclusive data exist to demonstrate a clinical significance of lead exposure to the immune

system, a small bank of research shows that specific end points are affected by lead exposure. Cellular immune parameters such as cellular subpopulations, mitogenic response have all been shown to be altered in lead-exposed workers. Workers exposed to lead had decreased CD4+ T lymphocyte subpopulations (Fischbein et al., 1993; Ündeger et al., 1996; Basaran and Ündeger, 2000) and had decreased response to concanavalin A or phytohemagglutinin-induced mitogenesis (Alomran and Shleamoon, 1988; Fischbein et al., 1993; Mishra et al., 2003).

Reproductive The reproductive health of men and women as relating to lead exposure for men and women has been evaluated. An inverse relationship between exposure and spermatogenesis exists at blood lead levels exceeding 40 $\mu\text{g}/\text{dl}$. Data also exist demonstrating a relationship between moderately high blood lead levels and spontaneous abortion and preterm delivery. Although associated with adverse reproductive outcomes, there are not data suggesting that lead is a human teratogen (Winder, 1993).

Sallmén et al. (2000) found an inverse relationship between blood lead levels and sperm production in 2111 Finnish lead workers leading to a delay in conception but not decreasing success. Decreased sperm production was also related to those who had been exposed longer occupationally (Gennart et al., 1992). Alterations in sperm number, chromatin quality and physical abnormalities, as well as decreased levels of serum testosterone were found (Alexander et al., 1998). Some of these observed effects might be due to a direct mechanism of action on the testis. Ng et al. (1991) studied 122 lead battery workers in Singapore and found increased serum luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels—indicative of Leydig and Sertoli cell damage—while no decrease in testosterone level was found.

Nordstrom et al. (1979) reported that women working in a smelter plant in Sweden had a higher incidence of spontaneous abortions than women who became pregnant before being employed or lived further than 10 km away. Further, abortion rates were higher for women who worked in the most contaminated areas of the plant. Borja-Aburto et al. (1999) studied 668 women in Mexico City and found that there was an increased risk of spontaneous abortion related to blood lead levels.

Chemical Pathology

Responsible for a myriad of health effects, lead has no known biochemical or physiological role in the human body. Entrance into the body is dependent on the form of lead. Inorganic forms of lead only enter the body through inhalation and ingestion whereas tetraethyl lead penetrates the skin and can be inhaled. Less than 20% of ingested inorganic lead gets absorbed in adults, but pregnant women and children

may absorb as much as 50%. Inhalation results in about 40% of lead being deposited in the lungs and almost all of that lead enters into the bloodstream.

Once having entered the body, lead preferentially partitions to blood, soft tissue, and bone. Deposition time can be measured in days (for blood) to years (for bone). In fact, lead deposited into bone, teeth, nails, and hair is considered safe since that lead is not readily available to other tissues. However, lead can be reintroduced into the blood long after original exposures if released during bone remodeling. While not a concern to adults, this is of particular concern in children whose bones are constantly remodeling during their adolescent years. Lead is also stored very well in liver, kidney, and neural tissue.

Mode of Action(s)

Neurological An enormous number of studies have been published reporting the effects of lead neurotoxicity. Attempting to adequately review all of those studies would be well beyond the intended scope of this chapter and might require the dedication of an entire text to the subject. The following section will discuss the effects of lead on enzyme and neurotransmitter systems.

Enzymatic activation by lead is accomplished by mimicking the action of calcium. Calmodulin is an enzyme that requires a calcium-induced conformational change to become active. Lead mimics calcium by binding to and inappropriately activating calmodulin resulting in altered cAMP second messenger systems and increased protein phosphorylation.

Protein kinase C (PKC) is a family of calcium-dependent enzymes that phosphorylates serine and threonine residues in proteins. In neurons involved in spatial learning and memory processing, lead can mimic calcium by binding to and activating PKC- γ . Potentially, the activation of this enzyme during development could lead to a disruption in the formation of the blood-brain barrier.

Similar to lead's ability to activate calmodulin and PKC, lead also has the ability to mimic zinc. Sp1 is a zinc finger transcriptional regulator that when bound to lead will alter the expression of certain genes such as the β -amyloid precursor protein (APP) gene. Interestingly, the lead-induced expression of APP was only observed during neonatal rat brain development while induction was unaltered in older rats.

It is well documented that lead can affect almost all neurotransmitter systems in the brain. Cholinergic, glutamatergic, and dopaminergic systems all play a role in memory formation and each can be affected by lead exposure.

While results from several studies are inconsistent, lead has been found to suppress acetylcholine release thereby decreasing cholinergic function. Acetylcholine release at the neuromuscular junction is dependent on the calcium influx into the synaptic termini. Lead not only blocks action

potential-induced calcium influx into the termini but also blocks the binding of acetylcholine to nicotinic receptors.

Lead exposure decreased hippocampal neuron function by blocking glutamate release without affecting subsequent binding to *N*-methyl-D-aspartate (NMDA) receptors (in fact, the number of receptors may be increased in an attempt to compensate for decreased glutamate release). These effects were observed to be greater when exposure occurred during development than after weaning but continued into adulthood even after lead was absent. This suggests a role for lead interfering with normal synaptogenesis.

Dopaminergic systems also have a role in memory and have been shown to be sensitive to lead exposure. Pre-synaptically, lead appears to decrease dopamine synthesis and release. A compensatory increase on postsynaptic neurons has been observed. Lead may also affect brain reward centers by decreasing dopamine release in the mesolimbic pathway of the frontal cortex and nucleus accumbens.

Hypertension Lead's mechanism of action appears to be dependent on the tissue in which it accumulates. As discussed previously in this chapter, lead may induce hypertension in exposed workers. Vaziri et al. (1997) and Gonick et al. (1997) demonstrated in rats that lead-depleted nitric oxide levels contributed to a decrease in both the peripheral (vasodilation) and central (anti-sympathetic) control of blood pressure regulation. Reactive oxygen species are speculated as being the causative agent in decreasing nitric oxide levels. Lead may also interfere with the ability of nitric oxide to cause vasodilation. Decreased vascular β -adrenergic receptor density and elevated levels of norepinephrine may also contribute to the sympathetic nervous system control of hypertension.

Renal Several studies have indicated that lead preferentially forms inclusion bodies in the nucleus of proximal renal tubule cells as it partitions from the cytoplasmic to nuclear fractions (Choie and Richter, 1972; Goyer et al., 1970a, 1970b). Putnam (1986) has described how the development of intranuclear inclusion bodies in the cells of the proximal renal tubules is used as a marker for lead nephrotoxicity.

Decreased capsular blood flow and glomerular filtration rate have been observed in rats exposed to lead but the mechanisms are not known (Aviv et al., 1980; Khalil-Manesh et al., 1992a, 1992b). Urinary *N*-acetyl-beta-D-glucosaminidase (NAG), another proposed marker for early lead detection, results from lead-induced oxidative stress possibly related to the depletion of nitric oxide. Finally, mitochondria in the cells of proximal renal tubules accumulate lead resulting in decreased pyruvate/malate- or succinate-mediated respiration (Fowler et al., 1980; Oskarsson and Fowler, 1985).

Hematological As described earlier in this chapter, the inhibition of three enzymes, ALAS, ALAD, and ferrochelatase,

leads to decreased heme synthesis. This results in microcytic anemia due to low hemoglobin levels. During the production of heme, lead is able to bind to ALAS and decrease the production of aminolevulinic acid. Further, much like mercury, lead is able to bind sulphydryl groups on proteins. Lead binds to vicinal sulphydryls in the active site of ALAD. As zinc is needed for ALAD activity, it only binds to one sulphydryl. Lead, on the other hand, cross-bridges the sulphydryls thereby decreasing the production of porphobilinogen. Finally, lead is also able to bind vicinal sulphydryl groups on the mitochondrial enzyme ferrochelatase resulting in a decrease in the amount of heme produced.

SOURCES OF EXPOSURE

Due to strict regulations, the use of many of the anthropogenic sources of lead has been significantly decreased or eliminated altogether. Lead is an elemental metal and as such cannot degrade; discarded sources of lead leave a footprint indicative of use resulting in higher than expected levels of lead.

Occupational

Occupational exposure to lead may occur during the manufacture, storage, and recycling of batteries; the preparation and use of lead-based ceramic glaze and paint; the addition of lead to gasoline (now banned in the United States); printing operations; the production of capacitors, resistors, and semiconductors; and smelting processes.

Exposure may also occur, during the construction of tank linings, piping, and other equipment used to carry corrosive gases and liquids, when protective clothing is worn to shield against radiographic rays and atomic radiation and in the working of steel and other metals (Budavari et al., 1989).

Construction activities such as residential lead remediation, dismantling of steel structures, and painting/sanding of structures containing lead are also sources of potential lead exposure (Grimsley and Adams-Mount, 1994; Rabin et al., 1994). Other potential occupational exposures to lead include: firearms instructors and students, automobile/radiator repair workers.

Environmental

The primary source of non-soil exposure for many individuals has been human emission into the environment, most notably due to leaded gasoline. As late as 1984 vehicle emissions accounted for over 90% of all environmental anthropogenic lead. The use of lead as an additive in gasoline was banned in the United States as of December 31, 1995.

The general population is exposed to lead in food, soil, ambient air, and drinking water. Due to the presence of lead

in soil, children are at a greater risk from this source of exposure as are individuals living in urban areas, near former mining operations, smelting plants, and sites of production and/or disposal. Non-occupationally, people can still be exposed to lead in some paints, ammunition, solder, and pesticides. Other potential sources of lead exposure include environmental tobacco smoke, renovation/remodeling of older homes with lead-based paint and/or putty, consumption of produce from contaminated gardens, recreational use of shooting ranges, pica, and secondary occupational exposure.

INDUSTRIAL HYGIENE

Exposure Limits

ACGIH The American Conference of Industrial Hygienists (ACGIH) has established a threshold limit value (TLV) of 0.05 mg/m³ for inorganic lead (ACGIH, 2004).

NIOSH The National Institute for Occupational Safety and Health (NIOSH) has established a recommended exposure limit (REL) (10-h time-weighted average (TWA) based on a 40-h workweek) for lead of 0.05 mg/m³ and an Immediately Dangerous to Health or Life (IDHL) value of 100 mg/m³ (NIOSH, 2005).

OSHA The Occupational Safety and Health Administration (OSHA) has established a permissible exposure limit (PEL) (8-h TWA) of 50 µg/m³ (0.006 ppm) for lead (OSHA, 2005d), 0.075 mg/m³ for the general industry use of tetraethyl lead (OSHA, 2005c), and 0.1 mg/m³ for construction and all other uses of tetraethyl lead (OSHA, 2005a and b). Supplemental control of lead exposure, provided in the form of respirators, must be instituted when lead exposure levels cannot be maintained at ≤50 µg/m³.

RISK ASSESSMENTS

Listings as Hazardous Waste

Lead has been classified as a hazardous waste and has been registered in various publications as such including:

Section 112 of The Clean Air Act lists mercury compounds as one of the 188 chemicals inventoried as a hazardous air pollutant.

Section 313 of Superfund Amendments and Reauthorization Act (SARA) designate lead and lead compounds as hazardous substances.

Lead and lead compounds, including tetraethyl lead, are subject to the Emergency Planning and Community Right-to-Know-Act (EPCRA)

Section 307 of The Clean Water Act lists lead as a "priority pollutant."

Lead acetate (U144) and lead phosphate (U145) and tetraethyl lead (P110) are listed as a hazardous waste under Resource Conservation and Recovery Act (RCRA).

IRIS The Environmental Protection Agency's (EPA) Integrated Risk Information System (IRIS) oral and carcinogenicity assessments for lead were revised in 2005. Based on the human evidence, the EPA has assigned lead a weight-of-evidence carcinogen classification of B2, probable human carcinogen, based on the inadequate information in humans and sufficient data in animals (IRIS, 2005). The EPA has not developed a lead reference concentration (RfC) and decided that since some health effects attributed to lead exposure occur at blood lead levels as low as to be essentially without a threshold the EPA has not developed a reference dose (RfD) for inorganic lead (IRIS, 2005).

ATSDR The EPA determined that some health effects attributed to lead exposure occur at blood lead levels "as low as to be essentially without a threshold." Thus, the EPA did not develop a RfD or derive a RfC for lead and lead-containing compounds. Likewise, the Agency for Toxic Substances and Disease Registry (ATSDR) did not derive a Minimal Risk Level (MRL) for lead (IRIS, 2005). However, ATSDR has established a blood lead action level in children of 10 µg/dl (ATSDR, 1997).

IARC The International Agency for Research on Cancer (IARC) review of lead as a carcinogen was last revised in 2004. Based on limited human studies, this review listed organic lead as a Group 3 carcinogen: not classifiable as to their carcinogenicity to humans whereas inorganic lead compounds are listed as Group 2A carcinogens: probably carcinogenic to humans (IARC, 2004).

ACGIH The ACGIH has listed lead as an A3 carcinogen: confirmed animal carcinogen with unknown relevance to humans (ACGIH, 2004). The biological exposure index (BEI) for blood lead has been established at 30 µg/100 ml.

NTP The National Toxicology Program (NTP) has listed lead as reasonably anticipated to be a human carcinogen (NTP, 2005).

EPA The EPA has not established a RfD or RfC for lead. Lead has been listed as a B2 carcinogen: probable human carcinogen (IRIS, 2005). Finally, the EPA has established a safe drinking water standard Maximum Contaminant Level (MCL) of zero and a Maximum Contaminant Level Goal (MCLG) action level of 0.015 mg/l for lead (EPA, 2002).

CalEPA The California Environmental Protection Agency (CalEPA) in October 1992 listed lead and lead-containing compounds as a human carcinogen under Proposition 65.

FDA The United States Food and Drug Administration (FDA) limits lead levels in bottled drinking water at 0.005 mg/l (FDA, 2004). The FDA has set action levels for lead in ceramic ware (0.5–3.0 µg/ml) and silver-plated hollowware (0.5–7.0 µg/ml) (FDA, 2004).

LITHIUM

USHANG DESAI

Target organ(s)	Inhalation: Respiratory system, eye, and skin Ingestion: Nervous system, gastrointestinal system, cardiovascular system, kidney
Occupational exposure limits	OSHA PEL ¹ : 0.025 mg/m ³ as lithium hydride (LiH) ACGIH TLV ² : 0.025 mg/m ³ as LiH NIOSH REL ³ : 0.025 mg/m ³ as LiH
Reference values	NIOSH Immediately Dangerous to Life or Health Concentration (IDLH): 55 mg/m ³ as LiH Lithium (CASRN 7439-93-2) Provisional chronic oral RfD: 20 µg/kg/day
Risk/safety phrases	For Lithium Hydride (CASRN 7580-67-8): Risk phrases: R 14/15 reacts violently with water liberating extremely flammable gases R25 Toxic if swallowed R35 Causes severe burns Safety phrases: S25 avoid contact with eyes S36/37/39 wear suitable protective clothing, gloves, and eye/face protection S 45 in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible) S7/8 keep container tightly closed and dry For lithium nitride (CASRN 26134-62-3) 1. Risk phrases: R14/15 reacts violently with water, liberating extremely flammable gases R29 contact with water liberates toxic gas R34 causes burns 2. Safety phrases: S16 keep away from sources of ignition—no smoking. S22 do not breathe dust. S26 in case of contact with eyes, rinse immediately with plenty of water and seek medical advice. S27 take off immediately all contaminated clothing. S36/37/39 wear suitable protective clothing, gloves, and eye/face protection. S45 in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible).

¹ OSHA PELs (permissible exposure limits) are 8 h TWA (time-weighted average) concentrations

² ACGIH TLVs (time limit threshold values) are 8 h TWA concentrations established by American Conference of Governmental Industrial Hygienists

³ NIOSH RELs (recommended exposure limits) are 10 h TWA concentrations established by National Institute for Occupational Safety and Health

BACKGROUND AND USES

Lithium is the 27th most abundant naturally found element on the earth. It's present in the earth's crust to the extent of about 0.006 wt% (Habashi, 1997). Lithium has several uses but one of the most important uses is for making high energy rechargeable lithium-ion batteries. These rechargeable batteries are much lighter than lead and sulfuric acid batteries and cut use of toxic lead and cadmium. Lithium commonly used in the manufacturing of polyester fibers, as a catalyst, the manufacturing of lubricants and greases, in the production of synthetic rubber, in glass, and aluminum production. Lithium is also used to make alloys with aluminum and magnesium; these alloys are very light, but very strong and used to make armor plates and in aerospace applications. Lithium hydride (LiH, CASRN 7580-67-8) is an important industrial source for hydrogen, as a drying agent, and as a reducing agent in organic synthesis particularly in the form of its derivatives lithium aluminum hydride and lithium borohydride (Buchner et al., 1989). Lithium carbonate (CASRN 554-13-2) is also used as an important pharmaceutical for the treatment of bipolar mood disorders (Amdisen, 1988) and neutropenia caused by chemotherapy and hypersplenism (Herbert et al., 1988).

PHYSICAL AND CHEMICAL PROPERTIES

Lithium is an odorless, soft silver-white solid metal with a melting point of 180.54 °C, boiling point of 1342 °C, and auto ignition temperature of 179 °C (Weast, 1976–1977). Melting point of Li is twice as high as sodium but is considerably lower than the melting temperature of most common metals and is one of the reasons why Li may be used efficiently as a reactor coolant and heat transport medium (Table 21.1). It is an alkali metal similar to magnesium and sodium in chemical and physical properties (Birch, 1988; Arena, 1986). Lithium is stable at room temperature under normal argon or mineral oil storage condition but can react intensively when exposed to water (Messer, 1966; Cowles and Pasternak, 1969). Lithium is the only alkali metal that will react with nitrogen gas to form a lithium nitride (Addison and Davies, 1969). Most common Li compounds formed because of lithium

reactions are lithium hydride (LiH), lithium oxide (Li₂O), lithium nitride (Li₃N), and lithium hydroxide (LiOH). All these compounds are stable but extremely reactive and corrosive.

Lithium hydroxide (LiOH): Corrosive; no metal or refractory material can handle molten LiOH in higher concentrations. Lithium oxide (Li₂O): Extremely reactive with water, carbon dioxide, refractory compounds. Lithium nitride (Li₃N): Highly reactive; no metal or ceramic has been found resistant to molten nitride. Lithium hydride (LiH): Reduces oxides, chlorides, sulfides readily; reacts with metals and ceramic at high temperatures (Cowles and Pasternak, 1969; Weast, 1976–1977; Landolt and Sittig, 1961; Perry, 1973).

MAMMALIAN TOXICOLOGY

Animals were exposed to 5–55 mg LiH/m³ (4–48 mg Li/m³) at 50% relative humidity for 4–7 h to assess the toxicology of LiH. All exposure levels of LiH-induced respiratory effects, such as sneezing and coughing. Lithium hydride concentrations of approximately 10 mg/m³ corroded patches of body fur and skin. Occasionally severe inflammation and irritation of the eyes were observed and in a few animals the external nasal septum was destroyed. This toxicity was because of the alkalinity of the hydrolysis product, lithium hydroxide (Spiegl et al., 1956). Following exposure of approximately 5 mg LiH/m³ for 5 days (average exposure is 4 h/day), ulceration of nose and forepaws, inflammation of eyes, partial sloughing of mucosal epithelium of trachea, and emphysema was also observed. No histopathological changes were noticed in the lungs after 2–5 months following exposure (Spiegl et al., 1956).

Chmielnicka and Nasiadek's study group found that oral administration of lithium carbonate-induced renal toxicity in rats and the resulting lithium concentration in serum and urine was determined to be dose dependent. They observed higher activity of *N*-acetyl-β-glucoaminidase (NAG) and a significant increase of copper and protein in the urine of exposed rats compared to the control group. They also found diuretic and proteinuric effects after lithium intoxication. The urinary excretion of lithium affects several factors, including water and sodium balance in the body. The most important in lithium toxicity is dehydration, which will produce sodium and water imbalance in the body (Chmielnicka and Nasiadek, 2003).

Teratogenicity Teratogenicity is the ability of the drugs/chemical substances to cause defects in developing fetus in the mammals. It is a potential side effect of many drugs such as thalidomide. A multicenter study on pregnant women was conducted in the United States and Canada to evaluate teratogenic effects of lithium during the first trimester of the pregnancy. This prospective study on pregnant women

TABLE 21.1 Physical and Chemical Properties of Lithium Compounds

Formula	LiOH	Li ₂ O	Li ₃ N	LiH
Molecular weight	23.95	29.88	34.82	7.95
Density (g/cm ³) at 15–20 °C	2.54	2.01	1.38	0.78
Melting point (°C)	471.1	1427	840–850	688
Boiling point (°C)	925	1527		

concluded that lithium is not a major human teratogen; women with major affective disorders who wish to have children may continue lithium during pregnancy, and do not need to terminate the pregnancy provided that level II ultrasound and fetal echocardiography are done on the pregnant women (Jacobson et al., 1992; Kallen and Tandberg, 1983; Kallen, 1988; Zalstein et al., 1990). The outcome of various studies, including cohort, prospective, retrospective and small number of case reports show that lithium is a “weak” teratogen in humans. The main teratogenic effects of lithium are cardiac malformations and babies with increased birth weight. There is a possibility that, in particular, lithium may be associated with the Ebstein anomaly but current evidence cannot definitely affirm or deny this association. Animal studies with lithium using doses comparable to human therapeutic serum levels have not reported any abnormalities. However, higher doses have produced exencephaly, skeletal and craniofacial defects, and abnormalities of blood vessel development in animals (Wright et al., 1970). Experiments with other vertebrates have shown that lithium affects dorsoventral specification and inhibition of vasculogenesis. Both these effects can be prevented by pretreatment with myoinositol indicating that lithium interferes with the phosphatidyl inositol cycle. More recent findings have shown that the effects of lithium on invertebrates may be mediated through inhibition of GSK-3b in the Wnt-GSK-3 pathway (Giles and Bannigan, 2006).

Carcinogenicity, Mutagenicity, and Genotoxicity No cancer studies have been found on possible carcinogenic effects of lithium compounds in the literature (Léonard et al., 1995). Mutagenicity is the capability of drugs/chemical substances to cause genetic mutations in sperm, eggs, and other cells. Lithium can affect DNA on several mechanisms such as binding selectively to DNA and competes with Mg²⁺ potentially impairing DNA synthesis and repair (Kuznetsov et al., 1971; Becker and Tyobeka, 1990). However, results on several bacterial strains and isolated systems were inconclusive to support mutagenicity of Li (King et al., 1979; Kanematsu et al., 1980).

Acute Effects

Lithium hydride is respiratory irritant and occupational exposure to workers. A compilation of the signs and symptoms that may occur following lithium exposures is provided in Tables 21.2 and 21.3. Lithium hydride at the high concentrations may also cause pulmonary lesions through caustic action (Birch, 1988).

Dermal exposure to lithium/aluminum alloys dusts cause severe irritant action and long-term exposure to these dusts causes hydrolytic destruction of the epidermis (Bencze et al., 1991). This effect is the result of the formation of strong basic lithium hydroxide in the presence of water. Lithium

TABLE 21.2 Possible Signs and Symptoms at Specific Exposure Levels

Exposure Level (mg/m ³)	Effects
0–0.025	No effect
0.025–0.10	A tickling sensation in the nose, some nasal discharge, tolerated by workers who continuously exposed
0.05	Workers readily adopt, discomfortness for unacclimated individuals
0.10–0.50	Definite nasal irritation with some coughing, not tolerated by workers
>0.1	Eye and nose irritation with some degree of adaption
>0.2	Itching of exposed skin
0.5	Maximal tolerable concentration for brief periods
0.50–1.0	Severe nasal irritation with coughing, in some workers eye irritation
1.0–5.0	Severe irritant effects, skin irritation

Source: Beliles (1994).

carbonate is used for several medical purposes so acute lithium toxicity can develop in patients using lithium for therapeutic purposes.

The lithium as a medicine has very narrow therapeutic index, and the plasma concentration of lithium should not exceed 1.5 mEq/l (10 mg/l) (Goodrich, 1991; Austin et al., 1990; Tilkan, 1976). Lithium toxicity occurred during therapy as attempted suicide, medication errors, and drug interactions (Simon, 1988), and simultaneous medical conditions (Table 21.4), resulting in a higher plasma lithium level (over 2 mEq/l). A patient’s lithium level should be checked regularly; particularly patients with a concomitant medical condition or those taking other medications that can interact with lithium.

Chronic Effects

Chronic lithium toxicity occurs in patients receiving chronic lithium therapy (Table 21.5). Chronic lithium toxicity occurs in patients whose lithium dosage has been increased or in

TABLE 21.3 Signs and Symptoms of Lithium Toxicity

Lithium Level (mEq/l)	Signs and Symptoms
2	Nausea, diarrhea, polyuria (nephrogenic diabetes insipidus), confusion and obtundation, muscle fasciculations
2.5	Myoclonus, choreoathetosis, stupor progressing to coma
3	Cardiac arrhythmia, tonic-clonic seizures
4	Cardiovascular collapse (hypotension, cardiac electrochemical dissociation)

TABLE 21.4 Factors that Increase the Risk of Lithium Toxicity

Medical conditions	Acute	Vomiting and diarrhea, leading to dehydration Low salt diet Low food intake Recent increase in lithium dosage Intentional overdose
	Chronic	Increased age Hypertension Diabetes mellitus Congestive heart failure Chronic renal disease Schizophrenia Addison's disease
		Thiazide diuretics Nonsteroidal anti-inflammatory drugs (NSAIDs)
		Methyldopa Phenytoin Carbamazepine Tetracycline
		Angiotensin-converting enzyme inhibitors (ACE inhibitors)
Drugs		

patients whose renal function is impaired, resulting in an increase in serum lithium levels (Ellenhorn et al., 1997). Chronic poisoning developed neurological manifestations such as memory deficits, Parkinson's disease (cogwheel rigidity, tremor), pseudotumor cerebri, and psychosis in the patients (Ellenhorn et al., 1997; Timmer and Sands, 1999; Henry, 1998; Sansone and Ziegler, 1985; Hall et al., 1979). Permanent brain damage has been observed in several patients undergoing long-term lithium therapy (Gosselin et al., 1984).

Chronic lithium therapy has been associated with changes in renal function such as polydipsia/polyuria, nephrogenic diabetes insipidus, transient natriuresis, partial renal tubular

acidosis, minimal change disease, and nephrotic syndrome (Ellenhorn and Barceloux, 1988). Chronic use of lithium is also associated with degenerative changes in kidney, which may occur in the glomeruli or in distal convoluted tubules or collecting ducts (Richman et al., 1980; Hestbech et al., 1977).

Mechanisms of Action

Lithium's mechanism of action is not very well understood. Lithium competes and substitutes with other ions such as sodium, potassium, magnesium and calcium, and modifies neurotransmitters actions and also affects the secondary messenger system (cAMP, cGMP) (Ward et al., 1994). At the cellular level, two major lithium transporting proteins are the sodium channel and the sodium-proton exchanger; both these transporters are inhibited by amiloride (Lenox et al., 1998; Holstein-Rathlou, 1990; Greger, 1990). The amiloride-sensitive sodium channel (ENaC) is an important transporter, which is involved in sodium equilibrium in the collecting duct. This channel has the same permeability to lithium and sodium and is a major pathway for lithium accumulation in collecting duct cells (Lenox et al., 1998; Holstein-Rathlou, 1990; Greger, 1990). Another lithium transporter is the Na-K-2Cl co transporter (NKCC2, BSC1) that is found in the apical membrane of the thick ascending limb of loop of Henle and is inhibited by furosemide (Lenox et al., 1998; Holstein-Rathlou, 1990; Greger, 1990). Na/K-ATPase ("the sodium pump") can also play a role in the transport of lithium across the cell membrane (Lenox et al., 1998; Holstein-Rathlou, 1990; Greger, 1990).

Chemical Pathology

There is a correlation between chronic lithium therapy and development of chronic interstitial nephritis in the patients over a period of time (Boton et al., 1987). The biopsy findings in these patients showed tubular atrophy and dilatation, sclerotic glomeruli, cyst formation, and cortical and

TABLE 21.5 Clinical Features of Lithium Poisoning

Target Organ	Acute Poisoning	Chronic Poisoning
Endocrine	None	Hypothyroidism
Gastrointestinal	Nausea, vomiting	Minimal
Cardiac	Prolonged QT interval, ST, and T wave changes	Myocarditis
Hematologic	Leukocytosis	Aplastic anemia
Neurologic	Fine tremor, weakness, apathy, slurred speech, tinnitus, drowsiness, clonus, coma, confusion, seizures, muscular irritability	Memory deficits, Parkinson's disease, pseudomotor cerebri, psychosis
Renal	Urine concentration defect	Chronic interstitial nephritis, nephrogenic diabetes insipidus, renal failure
Skin	Irritation, itching	Dermatitis, localized edema, ulcers

Source: Hermansen (2001).

medullary fibrosis (Boton et al., 1987; Timmer and Sands, 1999). Renal function of these patients must be followed after the course of lithium therapy because the development of diabetes insipidus and chronic interstitial nephritis is often irreversible, even though lithium is discontinued (Boton et al., 1987; Timmer and Sands, 1999). It is important to detect any changes in renal function early so that lithium can be discontinued, or the dose decreased, before severe loss of kidney function (Boton et al., 1987). While lithium hydride most commonly used in the industry is an alkaline corrosive and may cause liquefaction necrosis. In the gastrointestinal tissue, LiH can develop tissue necrosis followed by granulation and finally stricture formation (Cracovaner, 1964; Hathway and Proctor, 2004).

SOURCES OF EXPOSURE

Occupational

Occupational exposure to lithium may occur during extraction of lithium from its ores, manufacturing of various lithium compounds, and other activities such as welding, brazing, and enameling. Lithium fumes are a significant source of exposure during welding and brazing, particularly from leakage and accidents in the use of lithium hydrides (Beliles, 1994). Occupational exposure to lithium to workers in the pharmaceutical industries is not significant (Léonard et al., 1995). Other possible activities where lithium exposure may occur are extraction of crude oil and natural gas, in the iron and steel industries, in the production of pumps and compressors, in the ship building and reparation industries and in the distribution of electricity (Birgitta and Birgitta, 2002).

Environmental

Lithium is naturally found in the aquatic and terrestrial environment (Bowen, 1979, Wedepohl, 1995; Sposito, 1986; Birch, 1988; Ribas, 1991). Lithium is found mainly in the ionic form in the water; reacts with water, and forms lithium hydroxide and hydrogen. Worldwide mineral water has 0.05–1 mg/l lithium, though higher levels up to 100 mg/l can be found in some natural mineral waters (Schrauzer, 2002). While in terrestrial environments, lithium is found as lithium carbonate (LiCO_3), lithium chloride (LiCl), or lithium oxide (Li_2O). Lithium is found in smaller amounts in all soils mainly in the clay fraction, and to a lesser extent in the organic soil fraction in the range from 7 to 200 $\mu\text{g/g}$ (Schrauzer, 2002). The source of lithium in the terrestrial environmental is from sedimentary rocks (Chan et al., 1997). Environmental exposure to lithium can occur through anthropogenic activities such lithium-based grease (lithium hydroxide monohydrate) in vehicles and disposal of lithium batteries in the municipal solid waste (Aral and Vecchio-Sadus, 2008).

Lithium batteries are generally not considered hazardous to the environment, this is supported on the assumption that lithium metal (that reacts extremely with water to produce explosive hydrogen gas) is no longer reactive as the lithium is converted into non-reactive lithium oxide once battery is discharged (Aral and Vecchio-Sadus, 2008). In 1984, the United States Environmental Protection Agency (US EPA) made a regulatory status of spent and/or discarded lithium sulfur dioxide type batteries. These are considered hazardous waste as they contain strips of lithium metal as anode and the nonaqueous sulfur dioxide as an electrolyte (Aral and Vecchio-Sadus, 2008). According to the Australian Capital Territory Environment Protection Regulation, lithium is considered an environmental pollutant with a recommended concentration of $\leq 2.5 \text{ mg/l}$ of lithium entering the waterways (Aral and Vecchio-Sadus, 2008).

INDUSTRIAL HYGENE

Good industrial hygiene practices recommend that engineering controls should be used to reduce occupational exposure to lithium and its compounds to the permissible exposure level. Employees should be provided and required to wear impermeable clothing, gloves, face shields (eight minimum inch), dust, and splash proof goggles, other proper protective clothing to prevent exposure to lithium and its compounds at the work place. Respirators should be used by employees when engineering and work practice control technically not possible and employees required to enter into tanks and closed vessels and in emergency situations. If the use of respirators are mandatory only use respirators approved by the Mine Safety and Health Administration. Preplacement medical examinations are recommended for all employees who will be working with lithium and its compounds. Pre-placement exams should screen for certain medical conditions such as chronic respiratory diseases, skin disorders, and eye disorders which will be exacerbated if they come in contact with lithium and its compounds. Periodic medical evaluations are also recommended for employees working with lithium and its compounds for the above discussed medical conditions. Apart from industrial hygiene, good sanitation at the work place such as washing hands thoroughly before eating, smoking, or using toilet facilities, thoroughly washing body parts that come in contact with lithium and lithium compounds, changing of clothes before leaving from the workplace all reduce occupational exposures.

MEDICAL MANAGEMENT

Acute exposure of patients to lithium and its compounds requires recognition and removal from the source of exposure. In the emergency room, establishing a patient's airway

(oropharyngeal or nasopharyngeal airway), looking for respiratory insufficiency, and assisting for ventilations may be required. Monitor for shock, pulmonary edema and seizures, and treat if necessary. For eye contamination with lithium and its compounds, flush eyes immediately with water, if required irrigate eyes with normal saline during treatment. Cover skin burns with dry sterile dressing after decontamination. In severe intoxicated cases (plasma lithium level ≥ 3 mEq/l), hemodialysis is the treatment of choice after fluid rehydration, resuscitation, and intubation (Jaeger et al., 1985; Currance et al., 2005). Look for cardiac arrhythmias, hypotension, and treat if necessary. Treat seizures with diazepam or lorazepam; consider fluid resuscitation and vasopressors for hypovolemia (Currance et al., 2005). In less severe intoxication, discontinue lithium, rehydrate the patients and check serum lithium, sodium, and potassium levels, as well as renal functions as required.

MANGANESE

ALEX LEBEAU

First aid:

Manganese compounds and fumes

Respiratory: Provide respiratory support

Ingestion: Seek immediate medical attention

Manganese cyclopentadienyl tricarbonyl

Eyes: Irrigate eyes

Skin: Wash with soap and water

Respiratory: Provide respiratory support

Ingestion: Seek immediate medical attention

Manganese tetroxide

Eyes: Irrigate eyes

Skin: Wash with soap and water

Respiratory: Provide respiratory support

Ingestion: Seek immediate medical attention

Methylcyclopentadienyl manganese tricarbonyl (MMT)

Eyes: Irrigate eyes

Skin: Wash with soap and water

Respiratory: Provide respiratory support

Ingestion: Seek immediate medical attention

Main target organ(s): Respiratory system and central nervous system

Occupational exposure limits:

Manganese compounds and fumes:

OSHA PEL: C = 5 mg/m³

NIOSH REL:

TWA = 1 mg/m³

ST = 3 mg/m³

IDLH = 500 mg/m³

ACGIH TLV: TWA = 0.02 (mg/m³)

Inhalable Manganese: TWA = 0.1 mg/m³

Manganese cyclopentadienyl tricarbonyl:

OSHA PEL: C = 5 mg/m³

NIOSH REL: TWA = 0.1 mg/m³ [skin]

ACGIH TLV: TWA = 0.1 mg/m³

Manganese tetroxide:

OSHA PEL: C = 5 mg/m³

NIOSH REL: TWA = 1 mg/m³ (Appendix D of NIOSH Pocket Guide)

ACGIH TLV: Not established

Methylcyclopentadienyl manganese tricarbonyl:

OSHA PEL: C = 5 mg/m³

NIOSH REL: TWA = 0.2 mg/m³ [skin]

ACGIH TLV: TWA = 0.2 mg/m³

Reference values:

EPA IRIS:

RfD = 1.4×10^{-1} mg/kg-day

RfC = 5.0×10^{-5} mg/m³

ATSDR:

Chronic inhalation MRL: 0.3 µg/m³

Risk/safety phrases

Manganese dust or powder: Flammable

Manganese: Reactive

MMT: Moderate irritation to eyes

BACKGROUND AND USES

Manganese (CASRN 7439-96-5) is a naturally occurring metal that is widely distributed in environmental media. Pure manganese is not found in nature (Krebs, 2006) but is present in more than 100 ores and minerals, including pyrolusite and rhodochrosite (Krebs, 2006; ATSDR, 2012). Mining for manganese-containing ores occurs in Ukraine, Brazil, Australia, South Africa, Gabon, China, India, and the state of Montana (Krebs, 2006; Lide, 2006). Manganese is primarily used in the metallurgic industry to remove sulfide and oxide impurities from iron, and to create hardened alloys, including carbon, stainless, and high temperature steels (ATSDR, 2012; Krebs, 2006). In addition to iron, manganese has been used to create alloys with aluminum, antimony, and copper (Lide, 2006). Both inorganic and organic manganese have application in a variety of products beyond alloys, including: dry-cell batteries (manganese chloride and dioxide); fertilizer (manganese sulfate); fuel antiknock agent (methylcyclopentadienyl manganese tricarbonyl [MMT]); antiseptic (potassium permanganate); feed additives (manganese sulfate and carbonate); chemical synthesis/catalyst (manganese acetate); dietary supplement (manganese chloride); glass bleacher/pigment (manganese sulfate); pesticides (maneb and mancozeb); fireworks (manganese dioxide); and medical imaging (mangafodipir) (ATSDR, 2012; Toxnet, 2008; Krebs, 2006; Klaassen, 2008; Lide, 2006). In addition to its ubiquitous presence in nature, manganese is considered an essential trace element, found in both plants and animals. Small amounts of manganese are essential in the development of body tissues (bone and connective tissue) (Aschner et al., 2007). Additionally, manganese is essential for fat and carbohydrate metabolism; neurotransmitter synthesis and metabolism (Bowman et al., 2011); and is required for the metalloenzyme manganese-superoxide dismutase, among other enzymes (Davis, 1998).

PHYSICAL AND CHEMICAL PROPERTIES

Manganese is a gray-white, hard, brittle metal that exists in four allotropic forms and has a boiling point of 2061 °C (Lide, 2006). Its brittleness makes it almost impossible to mold it into specific shapes (Krebs, 2006). Manganese must be extracted from the oxide ores that it is colocated with, often requiring reduction with sodium, magnesium, or aluminum, and can also be extracted from the ores via electrolysis (Lide, 2006). Manganese has oxidation states from -3 to +7, with the +2 form as the most stable (Barceloux, 1999). Manganese in the +2 and +3 oxidation states are the most predominant forms in biological systems (Michalke et al., 2007).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Manganese is found to comprise approximately 0.1% of the earth's crust, and is found in various concentrations in environmental media (Barceloux, 1999). The average background concentration of manganese in soil ranges from 300 to 600 mg/kg dry weight (WHO, 2004). Emissions from industrial sources, combustion of petroleum fuels, natural erosion of manganese-containing rocks and soils, and volcanic activity contribute to atmospheric and terrestrial concentrations of manganese (ATSDR, 2012). The majority of the manganese particulate matter (PM) in the atmosphere is removed via dry deposition, with transport distance of the PM dependent on the bound particle size (ATSDR, 2012).

Manganese is found to occur naturally in surface water and groundwater at various concentrations. For example, manganese found in bodies of water that were assumed to be relatively free of anthropogenic influences ranged from 10 to >10,000 µg/l, although dissolved natural concentrations were found to rarely exceed 1,000 µg/l and most concentrations were usually <200 µg/l (WHO, 2004). An evaluation of 286 rivers and streams in the United States found a median manganese concentration of 24 µg/l, and seawater concentrations ranged from 0.4 to 10 µg/l (USEPA, 1984). Manganese bound to PM may also contribute to surface water concentrations, depending on the chemical form and solubility of the bound manganese (ATSDR, 2012). Particulate matter deposited in surface water will contribute to sediment deposition of manganese.

Studies have indicated that manganese may bioaccumulate in lower trophic organisms when compared to higher organisms (i.e., plankton, algae, and some fish versus humans) (ATSDR, 2012). Because mollusks have been shown to bioaccumulate manganese, the United States Environmental Protection Agency (USEPA) has established a threshold of 0.1 mg/l for marine water (USEPA, 1984). This threshold has been established to protect individuals who consume marine mollusks. It does not appear that any significant biomagnification occurs from lower organisms to humans.

ECOTOXICOLOGY

There is a paucity of information regarding the aquatic toxicity of colloidal, particulate, and complex manganese; most evaluations have been carried out with inorganic manganese (WHO, 2004). The toxicity of manganese in other forms is assumed to be less toxic than that of the aquo ion form (WHO, 2004). Toxic effects reported below are for fish species. Information for other aquatic organisms exists.

Acute Effects

Acute effects were evaluated in freshwater fish. The 96-h lethal concentration in 50% of the population (LC_{50}) for rainbow trout (*Oncorhynchus mykiss*) was determined to be 4.8 mg/l (form of manganese not reported), and the 96-h LC_{50} for coho salmon (*Oncorhynchus kisutch*) was found to range from 2.4 to 17.4 mg/l (form of manganese not reported) (WHO, 2004). The upper range for the 96-h LC_{50} was found to be 3,350 mg/l for Indian catfish (*Heteropneustes fossilis*) ($MnCl_2$) (WHO, 2004).

Chronic Effects

A 7-day LC_{50} was determined to be 8.2 mg/l for goldfish (*Carassius auratus*), and a 28-day LC_{50} for rainbow trout (*Oncorhynchus mykiss*) was 2.9 mg/l (WHO, 2004).

MAMMALIAN TOXICOLOGY

Acute Effects

Inorganic and organic manganese compounds elicit different toxic effects. Animal and human studies suggest that, overall, exposures to inorganic manganese compounds via all routes result in a very low acute toxicity. Some exceptions do exist. Potassium permanganate, due to its oxidizing potential, has the ability to cause severe corrosion of the skin and mucosa at the point of contact (ATSDR, 2012; Southwood et al., 1987). Potassium permanganate has a high oxidation potential. Over-exposures to manganese dust and fumes have been attributed to respiratory inflammation and impairment. Individuals over-exposed to manganese may present with cough, bronchitis, pneumonitis, and reductions in the lung function (ATSDR, 2012). Respiratory impairment has been observed among workers handling manganese ores (Rodier, 1955). Studies on manganese dioxide and potassium permanganate-exposed workers have also reported similar respiratory effects (Davies, 1946). A study evaluating potassium permanganate exposures in factory workers observed an 8-year average pneumonia incidence of 26 cases per 1,000. This finding was elevated when compared to the incidence of 0.73 cases per 1,000 in the control group (Davies, 1946; Davies and Harding, 1949).

Pneumonitis and other respiratory impairments resulting from overexposures to dusts are not unique to manganese. Caution is needed when relating these disease outcomes with exposures to manganese dusts. While empirical evidence has indicated that acute overexposures to manganese may result in respiratory impairment, it must be recognized that similar responses have been observed when evaluating other forms of PM. The respiratory impairments observed may not depend on the presence of manganese.

Inhalation of manganese and manganese oxides fumes is reported to cause a condition called metal fume fever (MFF)

(OSHA, 1978). Symptoms of this illness include fever, chills, upset stomach, cough, weakness, body aches and headaches, vomiting, and dry throat (OSHA, 1978). These symptoms can appear several hours after exposure to the fumes and typically last no more than a day. This condition is not unique to manganese (reports of MFF are common in the literature following exposures to zinc or cadmium oxide), and there is a paucity of published information relating manganese exposure to MFF.

Organic forms of manganese, MMT and manganese cyclopentadienyl tricarbonyl, have been used as fuel additives in some countries around the world. These compounds are somewhat irritating to the skin and eyes. Additionally, organic forms of manganese can readily pass through the skin. Dermal contact and apparent absorption has been observed to result in nausea, headache, giddiness, and abdominal distress (HSDB, 2001). Animal studies have suggested that the liver and kidney may be affected from exposure to MMT. No study was identified that observed a similar outcome in humans. Data suggest that MMT is only used sparsely in the developed world, including the United States (ATSDR, 2012). Major petroleum refineries in Canada have voluntarily ceased the use of the additive (ICCT, 2004) due to the harm it may cause to the automobile on-board diagnostic equipment (ATSDR, 2012).

Chronic Effects

The deleterious effect most commonly associated with chronic overexposures to inorganic manganese compounds is a disease referred to as manganism, a neurological disorder caused by manganese affecting the central nervous system (CNS). Manganism, an illness similar in presentation to Parkinson's disease (PD), is viewed as a form of Parkinsonism; however, evidence has indicated that manganism is physiologically differentiated from PD. In addition to the duration and concentration of the exposure, the development of neurotoxic effects following chronic overexposures to manganese will depend on individual factors (Michalke and Fernsebner, 2014). Exposure most often occurs by the inhalation route and the disease progresses through several stages, with the onset and timing of symptoms varying in the literature.

Initially, an individual who is overexposed to manganese may develop headache, insomnia, memory loss, muscle cramps and weakness in the lower extremities, bent posture, and irritability (Barceloux, 1999). As the disease progresses further, hypokinesia, hand tremor, loss of balance, postural instability, mask-like face, speech disturbances, a "cock-like" gait, and other gait abnormalities will develop (Barceloux, 1999; Jankovic, 2005). Symptoms may persist even after removing an individual from the exposure. Diminished libido and impotence in male workers is also reported to

accompany manganism. An overexposed individual may develop a condition known as manganese madness (*Locura manganica*), which may proceed or accompany the neurological signs. Manganese madness is characterized by irritability, aggression, sporadic laughter, impulses to sing or dance, aimless running, apathy, somnolence, confusion, hallucinations, poor memory, and anxiety (Barceloux, 1999). Individuals with manganese madness appear to be aware of their inappropriate and irregular actions, but are not capable of controlling them.

Chemical Pathology

Evaluating respiratory effects following inhalation of manganese dusts must be done through pulmonary function testing. No biomarker is recognized for evaluating and determining manganese overexposures and any resulting respiratory issues.

Determining biomarkers of exposure or effect is difficult when evaluating the onset of manganism. There is no validated and/or well-recognized biomarker for manganese exposure (Eastman et al., 2013), which will allow the relationship between an exposure and the presence of manganese within the body to be determined. Individual levels of manganese in the blood or urine are not reliable predictors of chronic workplace exposure; however, determining biological levels of manganese may be useful when evaluating a group exposure in a workplace (Jarvisalo et al., 1992). Evaluations of blood and urine in individuals would only aid in confirming the extent of a current exposure (Barceloux, 1999). While manganese is an essential element and is present at low levels in the body, excess is quickly removed from the blood by the liver. The majority of manganese removed by the liver is excreted in bile and eliminated. Further, there are currently no biochemical indicators that would aid in the detection of early manganese neurotoxicity or any biomarker that would indicate long-term overexposures to manganese. Chronically elevated levels of manganese in the blood may indicate that further evaluation of exposures may be warranted. Individuals with potential overexposures to manganese may show a greater signal intensity in the globus pallidus, striatum, and substantia nigra bilaterally when examined with a T1-weighted magnetic resonance imaging (MRI) scan (Michalke and Fernsebner, 2014; Racette, 2013). Decreased excretion of dopamine in manganese-exposed workers has been observed, but there is no clear relationship between central and peripheral dopamine levels and manganese overexposure.

Mode of Action(s)

Neurological damage from overexposures to manganese does occur; however, the exact manner in which manganese exerts its neurotoxicity has not been fully elucidated. The central

nervous system is the principal target of manganese toxicity. Inhalation can transfer manganese to target brain tissue via pulmonary uptake and particulate transfer (Farina et al., 2013), although the exact toxicokinetic mechanism is not yet fully known. Neuropathological changes in the brains of those affected by manganism have been found in the globus pallidus, caudate nucleus, the putamen, and, to some extent, the substantia nigra pars reticulata; these areas have been shown to contain the highest manganese concentrations following overexposures (Guilarte, 2013). The degree of which manganese affects some of these regions is still up for debate.

Manganism differentiates itself from PD, although both diseases do affect functional regions of the brain. Parkinson's disease is characterized by the progressive loss of dopamine-containing neurons in the substantia nigra pars compacta, resulting in the structural loss of dopamine terminal markers in the caudate and putamen (Racette, 2013). A proteinaceous biomarker that is found to be associated with dopamine neuron degeneration, the Lewy body, is found in individuals affected by PD (Guilarte, 2013), but they are absent in the majority of manganism cases. As Lewy bodies are not usually found in individuals with manganism, their absence suggest that the disease affects pathways that are post-synaptic to the nigrostral system. This is supported by the fact that some PD patients who were given levodopa as a treatment experienced relief in some symptoms associated with the disease. Studies indicate that, in most cases, individuals affected by manganism and treated with levodopa do not respond to the treatment (Pal et al., 1999), suggesting that the mechanism of the toxicity is different than that of PD. Although the mechanism leading to the destruction of dopaminergic neurons is unknown, research has indicated that the toxicity is exerted through an oxidative stress mechanism (Michalke and Fernsebner, 2014).

SOURCES OF EXPOSURE

Occupational

Occupational exposures to manganese and compounds occur in a limited number of settings. The first identification of manganese-induced Parkinsonism is attributed to Couper in his 1837 description of health effects observed in workers grinding manganese oxide ore (Aschner and Aschner, 1991; Bowman et al., 2011; Guilarte, 2013; Racette, 2013).

Occupational overexposures to manganese will most likely occur by inhalation of fumes or dusts. In the United States, welders, iron- and steel-manufacturing workers, dry-cell battery production employees, ferromanganese workers (WHO, 1999), power plant employees, and operators of coke ovens (USEPA, 2013) have the potential for overexposures from inhalation of manganese-containing dusts and fumes. Employees of ore mining operations also have the

chance for overexposures to manganese; however, this exposure is rare in the United States as only a small amount of ore is still mined in North America.

Employees working with MMT have the opportunity for an exposure. Due to its use as a fuel additive, mechanics, garage workers, and taxi drivers may also have the potential to inhale particulates containing manganese (ATSDR, 2012). However, indirect exposures to MMT are thought to be low. This is due to the fact that MMT undergoes a rapid photodegradation (Davis, 1998), reducing to manganese in the atmosphere.

Environmental

The ubiquitous nature of manganese in the environment from both naturally occurring and anthropogenic sources suggests that the general population can be exposed to various concentrations. Additionally, because manganese is an essential trace element, human blood will always have a detectable concentration. The average level of manganese in blood is approximately 9 µg/l (approximate range of 4–15 µg/l) (Barceloux, 1999). Points of exposure to manganese in the general population include ingestion of food and water, inhalation of manganese particulates and fumes, and dermal contact with manganese-containing media. Food is the most significant exposure point for the general population (Frumkin and Solomon, 1997); intake can vary between individuals and will depend on the diet. Food items that contain manganese include nuts, grains, tea, and legumes (Jankovic, 2005). There have been numerous attempts to quantify the average daily intake of manganese. The greatest range reported for daily intake of manganese was 0.7–10.9 mg/day (WHO, 2004). Although oral exposure is the primary point of exposure for the general population, the absorption of manganese in the gastrointestinal track is low; approximately 2–5% is absorbed while the rest is excreted (Jankovic, 2005).

In addition to manganese-containing foods, consumer products may be an additional exposure source for the general population. Beyond the use of fertilizers, paints, and cosmetics, individuals who smoke tobacco can be exposed to manganese; the concentration in tobacco was found to range from 155 to 400 µg/g (Bernhard et al., 2005). Individuals in countries who still use MMT as a fuel additive may be exposed to manganese via automobile exhaust, although exposures are thought to be low due to the assumed limited use of this product.

Residents living near production facilities using manganese may be an additional point of exposure for the general population. A study of residents living in close proximity to a ferromanganese plant had significant increase in respiratory problems (ATSDR, 2012). A follow-up study of those individuals living closest to the plant found that there was a reduction in symptoms after emission controls were implemented at the facility.

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration's (OSHA) permissible exposure limits (PEL) (NIOSH, 2005), the National Institute for Occupational Safety and Health's (NIOSH) recommended exposure limits (REL) (NIOSH, 2005), and the American Conference of Governmental Industrial Hygienists' (ACGIH) threshold limit values (TLV) (ACGIH, 2013) for manganese and related compounds are summarized below:

Manganese compounds and fumes:

OSHA PEL: Ceiling (C) = 5 mg/m³

NIOSH REL:

Time weighted average (TWA) = 1 mg/m³

Short term (ST) = 3 mg/m³

IDLH = 500 mg/m³

ACGIH TLV: TWA = 0.02 mg/m³

Inhalable Manganese: TWA = 0.1 mg/m³

Manganese cyclopentadienyl tricarbonyl:

OSHA PEL: C = 5 mg/m³

NIOSH REL: TWA = 0.1 mg/m³ [skin]

ACGIH TLV: TWA = 0.1 mg/m³

Manganese tetroxide:

OSHA PEL: C = 5 mg/m³

NIOSH REL: TWA = 1 mg/m³ (Appendix D of NIOSH Pocket Guide)

ACGIH TLV: Not established

Methylcyclopentadienyl manganese tricarbonyl:

OSHA PEL: C = 5 mg/m³

NIOSH REL: TWA = 0.2 mg/m³ [skin]

ACGIH TLV: TWA = 0.2 mg/m³

Inhalation is the primary route of exposure for manganese and related compounds in occupational settings. When working with manganese-containing materials, proper ventilation will aid in reducing employee overexposures. For welders, OSHA recommends natural or forced movement of fresh air, or local exhaust ventilation, to remove fumes from the welders breathing zone (OSHA, 2013). If engineering controls cannot reduce the welder's exposure to fumes, respiratory protection and other personal protective equipment (PPE) may be necessary.

RISK ASSESSMENTS

The USEPA Integrated Risk Information System (IRIS) database lists a reference dose (RfD) for manganese of

1.4×10^{-1} mg/kg-day, which is based on human chronic ingestion data. This represents an intake of 10 mg/day; studies have indicated that this is a safe level of intake. As most individuals will consume 2–5 mg manganese per day (USEPA IRIS, 2012), this RfD is conservative in its protection of the human population, including sensitive subgroups. The IRIS database cautions that, when performing a risk assessment, the essential nature of manganese must be taken into consideration.

The inhalation reference concentration (RfC) reported in the EPA IRIS database is 5.0×10^{-5} mg/m³. This concentration was determined using studies that evaluated the relationship between occupational exposure to manganese dioxide and impairment of the neurobehavioral function. This value was determined using an uncertainty factor of 1,000 and a modifying factor of 1.

The USEPA IRIS system has assigned a “D” classification to manganese with relation to the potential for an exposure to result in the development of cancer in humans: not classifiable as to human carcinogenicity (USEPA IRIS, 2012). IRIS indicates that the basis for this classification stems from the inadequacy of the existing studies that attempt to assess the carcinogenic potential of manganese.

The Agency for Toxic Substances and Disease Registry (ATSDR) lists a chronic inhalation Minimal Risk Level (MRL) concentration of 0.3 µg/m³ (ATSDR, 2012). The MRL is established as an estimate of a chronic daily exposure of manganese that is likely to be without an appreciable risk of a noncancer adverse health outcome over a specific time period.

23

MERCURY

FRANK D. STEPHEN

First aid: Eye contact: Immediately flush eyes with plenty of water for at least 15 min, lifting lower and upper eyelids occasionally. Get medical attention immediately; skin contact: Immediately flush skin with plenty of water for at least 15 min and remove contaminated clothing and shoes. Get medical attention immediately. Wash clothing before reuse. Thoroughly clean shoes before reuse. Ingestion: Do *not* induce vomiting. Never give anything by mouth to an unconscious person. Get medical attention immediately. Inhalation: Get medical aid immediately. Remove from exposure and move to fresh air immediately. If breathing is difficult, give oxygen.

Target organ(s): Nervous system and kidney.

Occupational exposure limits: OSHA PEL 0.1 mg/m³ (8-h workday). NIOSH REL 0.05 mg/m³ (10-h TWA). ACGIH TLV 0.01 mg/m³ (alkyl forms of mercury). STEL 0.03 mg/m³ (inorganic mercury). TWA 0.0025 mg/m³ (inorganic mercury). TWA 0.1 mg/m³ (aryl forms of mercury).

Reference values: MRL chronic inhalation: 0.2 µg/m³. Acute oral: 7 µg/kg/day. Chronic oral: 0.3 µg/kg/day. RfD oral methylmercury: 1×10^{-4} . Phenylmercuric acetate: 0.08 µg/kg/day.

RfC Elemental mercury: 3×10^{-4} mg/m³.

Risk/safety phrases: *R26-61-48/23-50/53*: Mercury is very toxic if inhaled. May cause harm to the unborn child. Harmful: danger of serious damage to health by prolonged exposure through inhalation. Very toxic to aquatic organisms and may cause long-term adverse effects in the aquatic environment. *S45-53-60-61*: In case of accident or if you feel unwell, seek medical advice immediately (show label where possible). Avoid exposure—obtain special

instructions before use. This material and its container must be disposed of as hazardous waste. Avoid release to the environment. Refer to special instructions/safety data sheets.

BACKGROUND AND USES

With all due respect to Lewis Carroll and the World of Alice's Looking-Glass, for almost 300 years the English language has known the colloquial phrase "mad as a hatter," which has been/is used to describe the psychologically unbalanced or insane. The phrase derives from behaviors displayed by hat makers who were exposed daily to trace amounts of mercury that remained in the felt used to produce popular hats of that era. However, recognition that mercury exposure causes poisonings goes back to the time of ancient Rome. Mercurialism has been documented in a diversity of occupations such as miners, hat makers, and in producers of detonators, thermometers, and barometers. Today, the most common risk of mercury exposure for humans comes from eating contaminated flesh from marine mammals and other fish species or through the release of elemental mercury and mercury vapor from dental amalgams.

The dangerous use of mercury and mercury-based compounds can be traced back to the earliest recorded human civilizations. As long ago as 3000 years mercury was used in pharaoh's tombs in Egypt; and to prepare red ink in China (Goldwater, 1972). Mercurialism in Idrian quicksilver miners was described by Paracelsus as early as the 1550s (Hunter, 1974). Similarly, as early as 1713 Bernardino Ramazzini

documented that few miners “reach old age, and even when they do not die young their health is so terribly undermined that they pray for death” and that mirror makers “become palsied and asthmatic from handling mercury.”

Medicinal use of mercury in treating human diseases is well documented. For example, throughout the Middle Ages mercury-based compounds were incorporated into creams that were used to treat infections. Mercury was once thought to be a treatment for syphilis and calomel (mercurous chloride) has been used in a variety of medicines intended to treat various maladies, including teething, yellow fever, and constipation; as well as in cosmetics and skin lightening creams. Famed signer of the Declaration of Independence, Dr. Benjamin Rush, even used it as a purgative and to induce salivation in patients as a therapy to rid the body of “impurities.” Various forms of organic mercury were used as antifungal agents in seed grains. Mercurochrome was used for decades as a topical anti-septic. Most recently, thimerosal (also known as Merthiolate) has been used as a bacteriostatic agent in the preparation of vaccines.

Human avoidance of exposure to mercury is almost impossible. Due to anthropogenic and natural sources mercury is ubiquitously present in the environment as elemental, inorganic, and organic forms. Also known as quicksilver, mercury is an extremely toxic liquid metal (Hg^0) but due to its high vapor pressure is readily released into the surrounding as a vapor. Inorganically, mercury is mined as mercuric sulfide in cinnabar and can be found bound to chlorine and oxygen. Organically, with regard to human exposure, the most important species of mercury is methylmercury. Human health risks have been reported for exposure to all forms of mercury but methylmercury exposure may be of greatest concern.

The use of mercury in the United States is slowly being phased out. Consumption of mercury-contaminated seafood and fish accounts for over 95% of ingested methylmercury in the United States (Mahaffey et al., 2004). Many of the historical uses of mercury have ended and the use of mercury in various instruments (e.g., barometers and thermometers) is ending. Several current uses for mercury include batteries, mercury vapor lamps, dental amalgam, and preservatives. Other folk uses of mercury include religious ceremonies, skin-lightening creams, and herbal medicines. The Agency for Toxic Substances and Disease Registry (ATSDR) concluded that industrial hygiene controls are resulting in a decrease in the amount of and risk from exposure.

PHYSICAL AND CHEMICAL PROPERTIES

Mercury (symbol Hg; Cas # 7439-97-6) is the only metal that is a liquid metal at room temperature. Occurring naturally as

TABLE 23.1 Physical and Chemical Properties of Mercury

Molecular weight	200.59
Color	Silver-white
Physical state	Liquid
Flash point	Not flammable
Melting point	-38.87 °C
Boiling density	356.72 °C
Density at 20 °C	13.534 g/cm ³
Water solubility	0.28 µmol/l
Vapor pressure	2×10^{-3} mmHg

mercuric sulfide (in cinnabar ore) because of its low boiling point can be isolated readily from the ore and condensing the resulting vapor to form a metal that is 99.9% pure. Solid mercury is ductile and very malleable and is soft enough to cut with a knife. A poor conductor of heat, mercury can conduct electricity but behaves much like a noble gas. It does not react with most acids but can react with very strong acids and dissolves readily to form amalgams with many metals, including gold, zinc, and aluminum. Important physical and chemical properties are listed in Table 23.1.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Mercury cycles through various environmental phases by exchange from ground to air and back again. Metallic and dimethylmercury, which are volatile, will be released as mercury vapor that can travel long distances before being redeposited. When found in surface waters and soils it will degas into the surrounding air where natural currents and winds spread the materials until they are deposited back on the surface waters and soils. The majority of mercury returned to the soil or water is by wet partition and accounts for almost all of the mercury found in lakes with no other input source. Inert mercury will deposit bound to particulates in aerosols. Once deposited, mercury must adsorb to soil or sediment particulates or be returned to the atmosphere. This cycle continues with a portion of the mercury revolatilizing into the atmosphere in each cycle.

Mercury can exist as either mercurous or mercuric mercury in soil and sediment. Transport is dependent on the form of the compound and the predominant form is mercury in the mercuric state. Bound to particulates in the water table, these compounds will be transported through the water column to the sediments. Very little of the mercury that reaches sediments is returned to the water column (Bryan and Langston, 1992). Conversion of the soil- or sediment-bound mercury to mercury sulfide precedes bioaccumulation into the food streams or bioconversion into more volatile or soluble forms that reenters the atmosphere (EPA, 1984).

Various factors affect the rate of mercury vaporization from and absorption to surface waters, sediments, and soils. In warmer weather, the amount of microbial reduction of mercury increases resulting in more mercury volatilizing from the soil (Lindberg et al., 1991). Once bound to particulate matter, mercury does not desorb readily, therefore, leaching is not likely to occur in soils. Presence of other metals, such as aluminum, is favorable for mercury adsorption. An inverse relationship between acidic soils and mercury absorption exists (Schuster, 1991).

Of great concern with regard to human mercury exposure is the bioaccumulation of methylmercury in the aquatic food chain. Methylmercury, the most common form of mercury, is highly soluble. Once in water columns it can enter and accumulate in the tissue of various sea organisms. Greater biomagnifications have been reported in waters with lower pH (Ponce and Bloom, 1991). Mercury levels will continue to biomagnify through the food chain and be highest in fish at the high end of the food chain, which are then consumed by humans.

ECOTOXICOLOGY

Mercury, in various speciated forms, occurs naturally and is found throughout the environment. As described previously, a continual cycle of deposition/volatilization/reemission occurs in soils and sediments resulting in bioaccumulation and biomagnifications in many terrestrial and aquatic food chains. The presence of mercury in some wetland results in game fish with tissue mercury levels equal to or greater than that seen in waters contaminated by chlor-alkali processing plants. Predatory fish (e.g., shark, tuna, and mackerel) have up to 20 times as much methylmercury as non-predatory fish (e.g., pollock and cod) or shellfish (e.g., scallops) (Mahaffey et al., 2004). Wetlands, waterways adjacent to wetlands, and fresh water lakes with low pH or low alkalinity are extremely sensitive to mercury poisoning. Of great concern in the food chain is methylmercury due to its potential to cause neurotoxic effects in humans.

Acute Effects

Contamination of aquatic systems with high levels of methylmercury is well documented. Over 60 years ago at Minamata Bay, Japan, methylmercury poisoning was observed in a variety of species. Mercury, used as a catalyst by the Chisso Company, was being discharged into the waters of Minamata Bay. In 1956, neurological diseases in over 30 residents around the bay were documented. Fish in the bay area were being killed in such great numbers that they could be picked out of the water by hand. Within several years other terrestrial species, such as crows and cats, also began dying and similar occurrences were reported in nearby areas.

Mercury-based fungicides had also been used for decades as a coating sprayed onto seeds. In Sweden, in the late 1960s, mercury pollution from chlor-alkali plants, the paper industry, and seed coatings were responsible for methylmercury food chain accumulation. As the decade progressed, an increased mortality among seed-eating and predatory birds occurred.

Chronic Effects

A major effect of mercury poisoning on nonmammalian species is reproductive failure. Methylmercury's reproductive effects on various species of fish include decrease in adult spawning success by decreasing hatching success or embryological development and by inhibiting gonadal development in early adult members. Biomagnification of methylmercury in aquatic food systems has led to a parallel increase in methylmercury in avian food systems. Cases of poisonings and reproductive failures (e.g., impaired laying and reduced breeding, hatching, and nesting) were reported in Sweden among Sea eagles, ospreys, and other fish-eating birds. Chronic wasting and emaciation correlated with high tissue mercury levels in Great White Herons in the Florida Everglades, Grey Herons in the Netherlands, and Common loons in Eastern Canada.

MAMMALIAN TOXICOLOGY

Acute Effects

In any chemical form mercury is toxic. Observed effects are dependent on the form of mercury, dosage, and route of exposure. Ingestion of corrosive sublimate, another name for mercuric (II) chloride, produces failure of kidney function and gastric distress and as little as 1 g may be fatal. Upon ingestion other gastrointestinal (GI) manifestations include a burning sensation followed by tightening of the esophagus, "whitening" of the mucous membranes of the mouth and throat, and abdominal pain with bloody vomit may occur. Subsequently, the exposed individual may have a persistent feeling of having to move their bowels and passage of bloody fecal material may result.

Although more likely to produce acute symptoms, inhalation of mercury vapor is not as immediately dangerous as the ingestion pathway. Effects of inhalation can be delayed and exposure manifests itself in nondescript signs and symptoms. Initial signs mimic "metal fume fever" and include coughing and sneezing, fever and chills, dry mouth, difficulty in breathing, and muscle and headache. Lingering effects may include GI distress, stomach pain, nausea and vomiting, and changes in the urinary output, including increased albumin levels.

As observed with fish and avian species, mortality is also found among mammals poisoned with mercury. Exhibition of classical mercury poisoning, including convulsions, weakness, ataxia, lethargy, tremors, and paralysis all occurred in animals that died from methylmercury intoxication. The decline of mink and otter populations in the Southeastern United States has been correlated to soil mercury concentrations.

Chronic Effects

Metallic and Inorganic Mercury Modern industrial mercury poisonings do not result in the prototypic signs and symptoms of classical mercury poisonings. Workers exposed chronically to low levels of inorganic mercury exhibit inflammation of the mouth, muscle tremors, and psychotic irritability. The severe symptoms associated with other uses of mercury (e.g., GI irritability and pain, nausea, vomiting, bloody stools, and kidney involvement) are rare in industrial poisonings.

Industrial exposures to metallic mercury generally involve mercury vapor or aerosols containing mercury salts. Mercury absorption from the GI tract is poor (Cantor, 1951), thus ingestion of mercury is not considered as an important route of entry for humans. Skin penetration has been calculated to be very slow (0.01–0.04 ng Hg/cm²/min/ng Hg/cm³ air) and is considered as a minor route of entry. Thus, the most likely and potentially dangerous route of exposure is inhalation of metallic mercury vapor.

Historically, investigators have examined the effects of inhalation of metallic mercury while research into the effects of mercury salt inhalation has not been performed. Death due to respiratory failure has been documented after high level acute exposure to volatile mercury released during heating; however, accurate levels of atmospheric mercury were not obtained for those case studies. Systemic toxicity is rare but specific target organs of mercury toxicity are the kidneys and the central nervous system, however, effects have been seen in the cardiovascular and respiratory systems after very high levels of exposure.

Mercurialism has been observed in a variety of industrial settings and has been scientifically documented for almost 100 years and anecdotally documents for half of a millennia. In the Spanish mines at Almaden, slaves and later convicts, who were used to mine cinnabar for the isolation of mercury, displayed the classic signs of mercury poisoning. More famous, and as described earlier in the chapter, hat makers from France, and later England and the United States, used mercury in the production of felt. An unhealthy occupation at best, hatters suffered from tremors known as “hatters shakes” and studies conducted in the early twentieth century found that American hat makers suffered gum swelling, loss of teeth, malodorous breath, as well as classical “hatter shakes.” Studies by the U.S. Public Health Service found that 10% of

all hatters studied suffered various neurological psychosis, as well as the other classical signs and symptoms of mercury poisoning. In 1941, the Connecticut Commissioner of Health conference on mercury poisoning banned the use of mercury in American hat production.

Although the toxicity of mercury and mercury-based chemicals was well known even early twentieth century industry was not free of the risks to health from mercury use. The manufacture of detonators used in World War I exposed workers to mercury fulminate (Hg(CNO)₂) causing dermatitis, ulceration of the face, neck, arms and hands, and genitalia, as well as neurological problems and nephrosis. Paresthesia, erratic eye movements, dexterity and fine motor speed, and verbal memory have been associated with lower body mercury concentrations (as measured by parameters such as blood and hair) than previously thought needed to produce such effects. Due to mercury’s ability to volatilize at room temperature workers were easily exposed during the production of several products, including thermometers, barometers, batteries, solder, and chlorine. Exposure to high levels of calomel (HgCl) from tracer ammunition and calomel electrodes, as well as low level exposure from its use in teething powders and laxatives, can induce mercury poisoning or acrodynia.

The risk of mercurialism even exists in dental practices and continues to be of concern today. First introduced into dentistry over 150 years ago, dental amalgam is the principal source of mercury vapor exposure to all workers in the dental field, including dentists, hygienists, and technicians. Debate over the safety in preparation and handling of amalgam has raged for over 100 years. Dental amalgam is around half metallic mercury and half other metals, including zinc, silver, and copper. The amalgam is sold, encapsulated, with the liquid mercury separated from the other metals (in powder form) by a plastic divider. During preparation, the divider is broken and the components mixed. Several studies documented cases of mercury poisoning in dental offices. Today, there is still debate and there is no accepted answer as to whether working with amalgam poses any long-term dangers to the dentists, their workers, or their patients. Finally, it is not known how much mercury vapor is given off by the solidified amalgam once set into the teeth and a dentist may never see a case of poisoning in a patient during their practice.

Chronic effects of mercury exposure are not limited to the nervous system. Recently conducted studies have correlated various cardiovascular (increased myocardial infarction and carotid atherosclerosis), endocrine (increased serum T4 levels and T4/T3 ratios), and male (decreased sperm number, motility, and morphology) and female (decreased conception and increased stillbirths) reproductive endpoints, and body mercury concentrations.

Organic Mercury Similar to metallic mercury the effect of organic mercury is route dependent with target organs,

including the central nervous system, liver, and the GI tract. The main forms of organic mercury to which people have been exposed include methylmercury, ethylmercury, and diethylmercury. However, organic mercury compounds are much more toxic than their inorganic counterparts and can produce severe symptoms through skin absorption.

Alkyl mercury compounds (methyl- and ethylmercury) have long been used in agriculture as pesticides and fungicides. Organomercury compounds also can produce a variety of responses when exposure is via the dermal route. Exposed workers exhibited difficulty with speech, ataxia and unsteady gait, slurred speech (dysarthria), and tremors (Hunter et al., 1940). Skin rashes and blisters, burns, itchy and pruritic, papular eruptions, and erythema and urticaria (Morris 1960; Torresani et al., 1993) have all been observed in workers after short-term and long-term exposures.

Consumption of organic mercury-containing food produced widespread poisoning during the mid-twentieth century. Over 900 individuals died and nearly 9000 individuals suffered severe health effects, including paralysis, after eating methylmercury-contaminated fish from Minamata Bay. Epidemics of neurological disease in 1956, 1960, and 1971–1972 were observed in Iraq when grain treated with organic mercury fungicides were ground into flour (Bakir et al., 1973; Al-Mufti et al., 1976). More than 6000 people were affected during the 1971–1972 incident. One of the largest exposures was an outbreak documented by Clarkson in which almost 8000 individual in Iran, Iraq, Pakistan, Ghana, and Guatemala were poisoned when mercury-containing fungicide-coated seed grains intended for planting were eaten (Clarkson, 1977). Workers exposed to organic mercury in pharmaceutical, seed-treating, farming, and pesticides industries also exhibited neurotoxicity due to mercury poisoning (Bidstrup, 1964; Dales, 1972).

The most controversial use of an organic mercury compound involves thimerosal. Used in vaccines for decades as a preservative, concern over thimerosal use peaked in the 1990s as to whether the dose of organic mercury delivered might cause neurological conditions (e.g., autism) in children. Rationale for this concern was based on three major factors, namely, the Minamata Bay poisonings, Iraqi wheat contamination (described above), and an expanded infant vaccine schedule. Several scientific and medical bodies, such as the Institutes of Medicine, U.S. Food and Drug Administration (FDA), and the World Health Organization, conducted extensive investigations and rejected the hypothesis that link between autism and thimerosal use exists. In 2001, vaccine manufacturers eliminated the use of thimerosal as a preservative in products intended for infants. Interestingly, in the decade of thimerosal, removal rates of autism have continued to increase (Doja and Roberts, 2006).

Chemical Pathology

Although occurring in inorganic and organic forms, ultimately it is the mercuric divalent cation, mercuric mercury (Hg^{2+}), that is responsible for the toxic effects of mercury. The divalent ion has a high affinity for sulphydryl groups and is able to quickly react and move between thiol-containing compounds (Rabenstein et al., 1982; Govindaswamy et al., 1992). In this way, the mercuric ion acts to precipitate protein and to inhibit enzymes-containing sulphydryl groups. Regardless of the form of mercury to which a person is exposed, ultimately toxicity is dependent on mercury accumulation in sensitive tissues.

Absorption rates of mercury are dependent upon the form of mercury and the route of entrance into the body. Inhaled metallic mercury and mercury vapor rapidly diffuse through the lungs across the alveolar membrane (Berlin et al., 1969; Clarkson, 1989) whereas inorganic mercury compounds are absorbed poorly in the lungs. This difference may be due to the rapid clearing of larger inorganic particles, which are deposited in the upper respiratory system (Friberg and Nordberg, 1973). Inhaled mercury vapor is a monatomic gas released from liquid metallic mercury. Absorbed mercury vapor can also be converted to the toxic divalent cation, and when deposited into tissue can exert the same toxic effects as observed with inorganic mercuric mercury. Due to its property as a vapor, this form of mercury will readily diffuse through tissues and is soluble in lipids. Mercury vapor can dissolve into the bloodstream and pass quickly across the blood-brain barrier.

While the oral absorption rates of metallic and inorganic mercury are low the mechanism for absorption appears to differ. Metallic mercury is poorly absorbed in the GI track and the vapor given off from metallic mercury is of more concern. It is thought that metallic mercury is converted to the divalent form, which is then able to bind sulphydryl groups and produce its effects. Inorganic mercury absorption in the GI track depends on solubility, molecular dissociation, and intestinal lumen concentration (Piotrowski et al., 1992). Mercurous compounds are not well absorbed due to their low solubility (Friberg and Nordberg, 1973). However, upon entry into the body, dissociation of the molecule occurs releasing a divalent cation and an uncharged mercury atom (which is later converted into the divalent form).

Absorption of mercuric mercury is better understood thanks to a study conducted in Finland in the early 1970s. Volunteers were given known quantities of radioactive mercuric mercury. Two half times were discovered; a 2-day half-time in which unabsorbed mercury was released from the body and a longer 41-day half-time. It was calculated that about 7% of the dose was absorbed (Rahola et al., 1973; Hattula and Rahola, 1975).

The mechanism(s) by which mercury is absorbed by the intestine is not clear. Upon absorption, a diffusible form of

mercury readily enters the blood stream while a nondiffusible form remains in the tissues (Halbach and Clarkson, 1978; Magos, 1967). In the first few days post-exposure, body clearance is first accomplished by fecal excretion of unabsorbed mercury. Absorbed mercury can travel to the liver and was shown to be incorporated into bile salts (Harris et al., 2003), and secreted as a conjugate with reduced glutathione (Ballatori and Clarkson, 1985). Although the exact mechanisms by which mercury is dispersed throughout the body are not well understood, once released into the circulatory and digestive systems, mercury can be dispersed throughout the body with storage occurring in the kidneys, liver, spleen, intestinal wall, heart, skeletal muscle, and lungs.

Perhaps the most hazardous form of methylmercury exposure occurs prenatally. Damage included psychomotor retardation and severe mental retardation along with diffuse and widespread damage to the developing brain (Choi, 1991). A prenatal threshold of 10–20 mg Hg/g of hair was calculated; nearly 1/5th that for an adult threshold (Clarkson, 1992). In rodents, the mechanism for this damage appeared to involve a combination of mitotic arrest (Sager et al., 1984) and inhibition of neuronal migration during development, probably due to depolymerization of microtubules (Abe et al., 1975).

Mode of Action(s)

As described earlier in the chapter, divalent mercury has an affinity for the sulphydryl groups present on proteins. Since the majority of membranous and cellular proteins contain sulphydryl groups it is not clear whether there is a specific target for mercury binding that helps it get into the cell. Further, this happenstance binding may explain the large potential number of targets affected by mercury. The formation of mercaptides may alter cell membrane permeability (Sahaphong and Trump, 1971). Nonspecific binding to cellular proteins would also explain the wide variety of affected cellular systems such as enzymes, transport processes, and even affecting cells structural proteins (Bulger, 1986). Mercury may also bind to other reactive groups that are not as preferred as sulphydryl groups, including amine and carboxyl groups, thus, making proteins a prime target. Thus, other potential cellular targets could include any cellular process that is protein dependent such as DNA replication and protein synthesis, immune function, neuronal transmission, and calcium homeostasis.

While the inorganic and organic forms of mercury appear to have a similar mechanism of toxicity the degree of their toxicity appears to be dependent on their accumulation in sensitive tissues. The primary targets of mercury toxicity are the central nervous system and the kidneys and it has been observed that mercury rapidly accumulates in these tissues (Rothstein and Hayes, 1960; Somjen et al., 1973).

In neurons, mercury has been found in the cytoplasm resulting in degradation of cellular organelles. Neuronal protein synthesis was inhibited after rats were exposed to

methylmercury (Syversen, 1977). Interperitoneal injections of methylmercuric chloride in rodents produced an increase in oxygen species formation in brain tissue (Ali et al., 1992; LeBel et al., 1990, 1992) leading to the theory that oxidative stress may be a mechanism by which neuronal degeneration occurs (Sarafian and Verity, 1991). Further, neurons may demonstrate high mercury sensitivity due to the lack of endogenous glutathione content and/or redox activity.

Mercury toxicity in the kidney appears to be related to its accumulation in the proximal tubules of the nephron where it binds to proteins resulting in inhibition of protein synthesis. As observed in neurons, oxidative stress is another mechanism by which mercury may exert its effects on cells. Alterations of the mitochondrial membrane result in an increase in hydrogen peroxide formation and increased susceptibility to iron-dependent lipid peroxidation (Lund et al., 1993). Oxidative stress in kidney cells due to alteration in mitochondrial calcium homeostasis has also been postulated. Increases in porphyrinuria have been observed after mercury-induced oxidative damage.

Intracellular mercury may also have direct effects on the function of the cytoskeletal protein, tubulin. Methylmercury binds to tubulin resulting in inhibition of microtubule formation (Vogel et al., 1985), as well as microtubular polymerization inhibition and the disruption of already existing microtubules (Duhr et al., 1993). Mercury binding to tubulin induced microtubule damage (Sager et al., 1982) and subsequently inhibited mitosis (Sager et al., 1983) causing cell injury. Damage to the cerebral cortex, including a decrease in mitotic figures, was also observed in developing rats exposed to methylmercury. Disruption of the developing nervous system by methylmercury has been hypothesized since cell migration is also microtubule dependent.

Another potential mechanism of mercury-induced neurotoxicity is the inhibition of certain nervous system's enzymatic function. Protein kinase C activity was decreased after exposure of rat brain homogenates to either mercuric chloride or methylmercuric chloride (Rajanna et al., 1995). One dose of mercuric chloride given intraperitoneally was sufficient to inhibit, as well as alter the location of cerebral alkaline phosphatase (Albrecht et al., 1994).

DNA synthesis is yet another target of mercury-induced toxicity. In a human *in vitro* model, mercuric ion was found to inhibit elongation of new DNA strands by decreasing DNA polymerase activity and fidelity (Sekowski et al., 1997).

SOURCES OF EXPOSURE

Occupational

Historically, the potential for mercury exposure existed in a large variety of occupations. The highest mercury occupational exposures have been found in chlor-alkali production

facilities, cinnabar mining, as well as the manufacture of barometers, thermometers, fluorescent lights, and other industrial instruments. The main route of this occupational exposure is inhaled mercury vapor. At the end of the twentieth century it was estimated that over 150,000 American workers were still being exposed to mercury in the workplace (RTECS, 1998). The use of dental amalgam is still a source of mercury vapor among dentists, hygienists, and technicians. Exposure to mercury vapor can occur in painters using exterior paints containing phenylmercuric acetate. Mercury-based pigments are found in paints and pastels used by commercial artists. The analysis of biological and environmental samples and the synthesis of mercury-containing compounds is a potential source of exposure among chemists. Other occupations with a potential for exposure include individuals handling or analyzing mercury-containing environmental samples, and workers disposing of or recycling mercury-contaminated wastes.

Environmental

Although historically present in a wide variety of commercial and household products, current potential sources of mercury exposure to the general population is limited. It has been estimated that the European and North American daily mercury intake, from all sources, is found to be 6.6 µg (WHO, 1990). Currently, the greatest potential nonoccupational sources of this exposure are consumption of mercury-contaminated seafood and dental amalgam. Subsistence and recreational hunters/anglers consuming mercury-tainted fish and/or marine mammals or other species living near mercury-contaminated waters are at highest risk. Citizens in communities near mercury mining or production sites, public and medical incinerators, or recycling plants risk exposure through airborne contamination. Finally, a risk still exists from other minor use of mercury-containing products such as cosmetics or herbal remedies, religious usage, or unintentional mercury spills.

INDUSTRIAL HYGIENE

Exposure Limits

ACGIH The American Conference of Industrial Hygienists (ACGIH) has established a threshold limit value (TLV) of 0.01 mg/m³ for alkyl forms of mercury and a STEL of 0.03 mg/m³, an 8-h time-weighted average (TWA) of 0.025 mg/m³ for inorganic forms of mercury, and 0.1 mg/m³ for aryl forms of mercury.

NIOSH The National Institute for Occupational Safety and Health (NIOSH) has established a recommended exposure limit (REL) (10-h TWA based on a 40-h work week) of

0.05 mg/m³ based on the risk of central nervous system damage, eye, skin, and respiratory tract irritation.

OSHA The Occupational Safety and Health Administration (OSHA) has established a PEL (8-h TWA) of 0.1 µg/m³ for mercury vapor. Engineering controls and work practices must be instituted when workers could be exposed to mercury such that mercury concentrations do not exceed the ceiling value of 0.1 mg/m³ (OSHA, 1974).

RISK ASSESSMENTS

Listings as Hazardous Waste

Mercury has been classified as a hazardous waste and has been registered in various publications as such, including:

Section 112 of The Clean Air Act lists mercury compounds as one of the 188 chemicals inventoried as a hazardous air pollutant.

Section 313 of Superfund Amendments and Reauthorization Act (SARA) designate mercuric acetate, mercuric chloride, and mercuric oxide as extremely hazardous substances.

Title III of the Emergency Planning and Community Right-To-Know Act of 1986 requires operators of facilities that use or store mercuric acetate, mercuric chloride, and mercuric oxide in or on their facility to establish a program for emergency response and for notifying the public of accidental releases.

Section 307 of The Clean Water Act lists mercury as a "priority pollutant."

Mercury is listed as a hazardous waste under Resource Conservation and Recovery Act (RCRA) and has been assigned Environmental Protection Agency (EPA) Hazardous Waste No. U151 and is banned from land disposal until mercury-containing compounds are treated by retorting or roasting.

IRIS The EPA's Integrated Risk Information System (IRIS) oral and carcinogenicity assessments for mercury were last revised in 1997. Based on the limited human evidence, the EPA has listed mercury as a class D, not classifiable as to human carcinogenicity based on inadequate data. The reference concentration (RfC) for mercury is 3×10^{-4} mg/m³ in air and is based on a lowest observed adverse effect level (LOAEL) of 0.025 parts per million (ppm) obtained through human occupational inhalation studies, which found that exposure caused hand tremors and increase in memory disturbances.

WHO The World Health Organization (WHO, 1984) has set a mercury drinking water guideline of 0.001 mg/l, as well as permissible tolerable weekly uptake of 5 µg/kg.

ATSDR The ATSDR has established minimal risk levels (MRL) for chronic and acute, oral and inhalation exposures to mercury.

Inhalation The chronic-duration MRL of $0.2\text{ }\mu\text{g}/\text{m}^3$ was calculated based on chronic-duration industrial inhalation exposure (365 days or more) to metallic mercury vapor for an average of 15.3 years (based on the studies of Fawer et al., 1983).

Oral The acute-duration MRL of $7\text{ }\mu\text{g}/\text{kg}/\text{day}$ is based on a no-observed-adverse effect level (NOAEL) of $0.93\text{ mg mercury/kg}$ for renal effects on rats that were exposed to mercuric chloride for 2 weeks (NTP, 1993).

The intermediate-duration MRL of $2\text{ }\mu\text{g}/\text{kg}/\text{day}$ is based on a NOAEL of $0.23\text{ mg mercury/kg}$ for renal effects in rats (Dieter et al., 1992; NTP, 1993).

The chronic-duration oral MRL of $0.3\text{ }\mu\text{g}/\text{kg}/\text{day}$ is based neurodevelopmental outcomes in a study by Davidson et al. (1998) on *in utero* exposure to methyl mercury from maternal fish ingestion.

IARC The International Agency for Research on Cancer (IARC) review of mercury as a carcinogen was last revised in 1997. Based on limited human studies, this review listed metallic and inorganic mercury as Group 3 carcinogens: not classifiable as to their carcinogenicity to humans whereas methylmercury compounds are listed as Group 2B carcinogens: possibly carcinogenic to humans.

ACGIH The ACGIH has listed mercury as an A4 carcinogen: not classifiable as a human carcinogen (ACGIH, 1996), with a skin notation that indicates the potential for dermal absorption.

EPA The EPA has not established a reference dose (RfD) for metallic mercury. Based on neurological abnormalities in infants an oral RfD of 1×10^{-4} has been established for methylmercury (IRIS, 1997). An oral RfD for mercury has been established from phenylmercuric acetate of 0.08 ug/kg/day (IRIS, 1997). Based on detectable kidney damage in rats the RfD is based on a LOAEL of 0.5 ppm (Fitzhugh et al., 1950). Mercuric chloride and methylmercury have been listed as a C carcinogen, meaning they are possible human carcinogens (IRIS, 1997). Finally, the EPA has established a safe drinking water standard of $2\text{ }\mu\text{g/l}$ for mercury (FSTRAC, 1995).

CalEPA The California Environmental Protection Agency in October 1990 listed mercury as a developmental toxicant under Proposition 65.

FDA The U.S. FDA limits mercury levels in bottled drinking water at 0.002 ug/l (FDA, 1995). The FDA has set an action level for methylmercury in foods such as aquatic animals (fish, shellfish) at 1 ppm (FDA, 1995). Further, the FDA regulates the amount of allowable mercury in cosmetics and is generally restricted to eye-area cosmetics and must measure $<1\text{ ppm}$ or 0.0001% mercury metal (FDA, 1974).

MOLYBDENUM

PAUL JONMAIRE

First aid: Since there are many molybdenum compounds in commercial use, there are no special first aid recommendations. General first aid recommendations are often appropriate. For dermal overexposure, remove contaminated clothing and flush with plenty of water for 15 min. For ocular overexposure, flush with water for 15 min.

Target organ(s): Eye, respiratory tract, kidney, and liver

Occupational exposure limits: OSHA PEL TWA: 15 mg/m³; ACGIH TLV TWA: 10 mg/m³ (dust); 3 mg/m³ (respirable) [As molybdenum and insoluble compounds]; OSHA PEL TWA: 5 mg/m³; ACGIH TLV TWA: 0.5 mg/m³ (respirable) [as soluble compounds]

Reference values: Inhalation RfD: 0.005 mg/kg/day UF 30, MF 1 (EPA [2012]); TDI: 0.009 mg Mo/kg/day

Risk/safety phrases: None

BACKGROUND AND USES

In 1768, the Swedish scientist Carl Wilhelm Steele determined that the mineral molybdenite was a sulfide compound containing an unidentified element by decomposing it in hot nitric acid to yield a white powder (IMOa, 2013b). This powder was found to be molybdenum oxide, the most common molybdenum compound in use today (NTP, 1997). A second scientist, Peter Hjelm, reduced the oxide with carbon obtaining a dark metal compound which he called molybdenum. Late in the nineteenth century, it was shown that molybdenum could replace tungsten as an alloying agent for steel.

The material derives its name from *molybdos*, meaning “lead-like.” Originally, the metal was thought to be lead because of its gray color and greasy feel (Kropschot, 2010). After World

War I, Bartlett Mountain in Colorado became a major source of molybdenum, with the Climax Molybdenum Company mine providing three-quarters of the world’s molybdenum. The Climax Mine stopped supplying molybdenum in 1995, but reopened and again began supplying molybdenum in 2012 as a subsidiary of Freeport-McMoRan (Climax Molybdenum, n.d.). In 2012, approximately 57,000 tons of molybdenum were produced in the United States (USGS). Approximately half or the world’s known molybdenum reserves are in the United States (Stiefel and Murray, 2002).

Molybdenum can be obtained from several different minerals, including molybdenite (MoS_2), wulfenite (PbMoO_4), and powellite (CaMoWO_4) (Stiefel and Murray, 2002). Substantial amounts of molybdenum are produced through the processing of molybdenite. Molybdenite is the mineral of greatest commercial importance (Shamberger, 1979).

Additional supplies are obtained in association with the processing of copper, of molybdenum, and tungsten ores. Molybdenum is used primarily to create metal alloys, especially with iron. Moly-steel is known for its hardness and resistance to chemicals. It also is used in the production of ceramics, in pigments, in the electronics industry as corrosion inhibitors and as a lubricant (Browning, 1969; IMOa, 2013a; Stiefel and Murray, 2002). Molybdenum is an essential element for both plants and animals, and is important for the fixation of nitrogen (NTP, 1997; Shamberger, 1979). Soluble molybdates are key elements in some fertilizers (ACGIH, 2008; IMOa, 2013a).

PHYSICAL AND CHEMICAL PROPERTIES

Molybdenum (symbol Mo: CAS #7439-98-7) is a silvery-white metal or gray-black powder of the refractory metal

family that is not normally found in its elemental state (Barceloux, 1999). Elemental molybdenum has a molecular weight of 96, a specific gravity of 10.2 g/cc and a melting point of 2610 °C (NIOSH, 2005). It makes up about 0.0015% of the earth's crust (NLM, 2013). Almost 100 compounds of molybdenum are listed in the EPA Toxic Substances Control Act inventory (U.S. EPA, 2013). There are two basic types of molybdenum substances—soluble and insoluble—to be considered from an occupational health perspective. The insoluble type includes elemental molybdenum, molybdenum disulfide, and molybdenum dioxide. Soluble molybdenum compounds include most molybdates, oxides (most notable is molybdenum trioxide), and halides (ACGIH, 2008). Molybdenum functions both as a metal and a metalloid (Eisler, 2000).

MAMMALIAN TOXICOLOGY

Acute Effects

Molybdenum is generally considered to be of low toxicity for animals and plants (CDC, 2013; Stiefel, 2002). Few adverse acute health effects are linked to molybdenum and molybdenum compounds. Molybdenum toxicity is closely related to the amount of copper available in the system, therefore any toxic effects of molybdenum observed must be evaluated in conjunction with copper levels (Vyskocil and Viau, 1999). There have been no reports of accidental occupational deaths due to molybdenum poisoning (Browning, 1969). Insoluble molybdenum substances are considered to be of low toxicity (CDC, 2013). Molybdenum trioxide, a soluble molybdenum compound, is considered to be a skin, eye, and mucous membrane irritant (Honeywell Product Summary, 2012; NIOSH/OSHA, 1978).

Although the literature reports some symptoms from occupational overexposure to molybdenum, they are quite uncommon. Overexposure to molybdenum compounds in the workplace may cause some transient symptoms such as fatigue, joint pain, headaches, backaches, and other non-specific symptoms (ACGIH, 2008; Friberg, 1975; Lener and Bibr, 1984).

There have been no reports of adverse effects in workers exposed to molybdenum dust in the crushing and milling of ore. Similarly, no adverse health effects have been reported among workers exposed to the fumes of molybdenum oxide in the rolling of red-hot billets of molybdenum steel. (Friberg and Lener, 1986) reported that workers exposed to molybdenum in a copper-molybdenum plant experienced increased blood uric acid levels and gout-like symptoms. Respiratory damage associated with overexposure to molybdenum has been reported as pneumoconiosis (ACGIH, 2008). Workers exposed to molybdenum dust in a molybdenite roasting plant producing molybdenum trioxide and other soluble oxides were

found to have a substantially elevated serum ceruloplasmin and a smaller increase in serum uric acid. The estimated daily intake of molybdenum inhaled as dust particles averaged 10.2 mg, and both plasma and urine molybdenum levels were elevated in these workers. The average air concentration of molybdenum in the plant was 9.4 mg/m³. No long-term adverse health effects were demonstrated by Walravens et al., (1979) in this study. Their major finding in a study of 26 workers was elevated mean serum uric acid levels and serum ceruloplasmin but no gout-like symptoms. A questionnaire of the workers in the study found that joint pain, headache, backache, and skin and hair changes were the most frequently reported complaints.

Chronic Effects

Besides the short-term symptoms reported by Walravens et al. (1979), there are few other consistently reported adverse workplace molybdenum exposure findings. Some reports describe three other effects associated with overexposure to molybdenum which are gout, pneumoconiosis, and the disruption of copper levels in the body. Workers exposed up to 19 mg/m³ of molybdenum showed signs of pneumoconiosis related to their workplace exposure (ACGIH, 2008).

Selden et al. (2005) describes a case of an electrician who developed gouty symptoms associated with working on the manufacture and maintenance of specialized molybdenum-lined furnaces. Nothing in his history or his family history suggested a predilection to gout. The symptoms subsided after the initial exposure was greatly reduced and returned about a year later when exposures again increased. The authors concluded that the association between gouty symptoms may be circumstantial, but it could also be causal.

Molybdenum and its compounds have not been identified as carcinogenic by the International Agency for Research on Cancer (IARC), the EPA through IRIS, or California's Proposition 65. The American Conference of Governmental Industrial Hygienists (ACGIH) has assigned molybdenum an A3 carcinogen, "Confirmed Animal Carcinogen with unknown relevance to Humans." This rating is based primarily on the NTP (1997) bioassay results. The study discussed below is considered insufficient by ACGIH to assign a higher ranking based on human data. In a 1999 Belgian case-control study investigating lung cancer among workers potentially exposed to 16 carcinogens, including arsenic, nickel, wood dust, asbestos, and polycyclic aromatic hydrocarbons [PAHs], the strongest association for lung cancer after being controlled for smoking cigarettes was having ever been exposed to molybdenum for an extended length of time (Droste et al., 1999). This study suggested that there is some evidence of molybdenum carcinogenicity. Although the study was performed appropriately, it experienced the typical limitations associated with most case-control studies, e.g., lack of documented workplace levels of exposure, self-reporting, and

fewer smokers in the control group. Breise (1976) studied molybdenum workers in Colorado and found no evidence that high or low exposures to molybdenum presented mutagenic, teratogenic, or carcinogenic hazards.

Inhalation studies on mice and rats performed as part of the National Toxicology Program using molybdenum trioxide, a compound used in metallurgical alloys, in cosmetics as a pigment, and in contact lens solution, produced equivocal results of carcinogenic activity in male F344/N rats, but no evidence of carcinogenicity in female F344/N rats. In B6C3F mice of both genders there was some evidence of carcinogenic activity. A review, as part of this study, found no indication that molybdenum trioxide is a human carcinogen. Some early studies in Africa, China, and Russia suggested that molybdenum deficiencies could be linked to esophageal cancer (NTP, 1997). Some evidence exists regarding potential mutagenesis of molybdenum compounds. Molybdenum trioxide was studied by Zeiger et al. (1992) in five *Salmonella* strains with and without metabolic activation, and showed no mutagenicity. Workers exposed to molybdenum, molybdenum trioxide, and molybdenite were reported to have an elevated number of chromosomal aberrations in lymphocyte studies (Babaian et al., 1980).

Mechanism of Action

Molybdenum is an essential nutrient for most forms of life, plant, animal, and microbial. Molybdenum is an essential dietary nutrient and a critical component of several mammalian enzymes, including xanthine oxidase, sulfite oxidase, and aldehyde oxidase (CDC, 2013; Kisker et al., 1997). Soluble molybdenum, usually as a molybdate, is readily absorbed through the intestinal tract into the liver. High levels of copper and sulfur in the diet enhance elimination of molybdenum reportedly by blocking a protein carrier and, therefore, inhibiting reuptake by the kidneys. In mammals, molybdenum can protect against poisoning by metals, such as copper and mercury, and may have anticarcinogenic activity. Excretion of molybdenum occurs primarily through the kidneys, mainly as molybdate (CDC, 2013; Stiefel and Murray, 2002).

The mechanism of action of molybdenum toxicity is not fully understood. Xanthine oxidase is a metalloenzyme that requires molybdenum as a critical cofactor, and is induced by elevated levels of molybdenum. The activity of xanthine oxidase affects the uric acid levels of the urine and blood by converting purines to uric acid. Increased activity may result in symptoms of gout. Overexposure to molybdenum also may upset the copper balance in the body. This occurs as part of a complex interaction involving copper, molybdenum, sulfur compounds, and several enzyme systems (Friberg and Lener, 1986). Higher levels of molybdenum may actually reduce the activity of molybdenum-dependent enzymes as well as induce copper deficiency (Browning, 1969).

Additional investigation of the possible health effects of excessive exposure to molybdenum came from a drinking water study performed by the EPA in two Colorado cities (U.S. EPA, 1979). The urinary levels of molybdenum and copper and the blood levels of ceruloplasmin and uric acid were compared in two groups over a period of 2 years. The lower exposure group drank water with molybdenum levels ranging from 2 µg/l to 50 µg/l; the higher exposure group drank water with a molybdenum level of 200 µg/l or higher. The group with the greater molybdenum exposure was reported to have a higher urinary level of molybdenum. Although the higher daily level of urinary molybdenum was associated with the higher molybdenum intake, no adverse biochemical or systemic effects were noted in either study group. A higher mean serum ceruloplasmin also was associated with the higher molybdenum intake (40.3 mg/dl compared with 30.41 mg/dl for the lower intake group).

Although exposures were not occupational, some of the most informative data describing potential excessive exposure to molybdenum originate from studies in two Armenian villages. Researchers correlated dietary intake of molybdenum with elevated serum uric acid level and gout-like symptoms. The group exposed to higher amounts of molybdenum in plants and soil had greater swelling and inflammation than the control group. The serum uric acid level was much higher in residents from the high exposure area. The average uric acid level was even higher in those who showed symptoms of gout (Kovalskiy et al., 1961). Both serum molybdenum and serum xanthine oxidase were positively correlated with the serum uric acid level. The EPA chronic oral reference dose of 5×10^{-3} mg/kg/day is based upon this 1961 study. A critique of this study performed by EBRC Consulting GmbH (2010) on behalf of the International Molybdenum Association raises questions regarding the validity of the Kovalskiy study for use in identifying a reference dose based on the application of current standards for evaluating the technical performance of the study as well as based on current medical/toxicological knowledge.

SOURCES OF EXPOSURE

Occupational

Many occupations can present the possibility of overexposure to soluble molybdenum compounds because these compounds are used in the production of molybsteel; as electrodes in welding operations; as coloring agents for ceramics, enamels, and paints; as corrosion inhibitors for water systems; as catalysts in the petroleum industry; as flame retardant for resins; and as components of fertilizer (NTP, 1979). Workers can be exposed to insoluble molybdenum material in the mining and processing of ore that contains molybdenum; when working with molybdenum or

its alloys; when formulating and using lubricants, catalysts, and the base metal for filaments, rocket nozzles, and ceramics (IMOA, 2013a; Stiefel and Murray, 2002).

INDUSTRIAL HYGIENE

The permissible exposure limit (PEL) values are established by the Occupational Safety and Health Administration (OSHA) and the threshold limit values (TLV) are set by the ACGIH. The PEL for insoluble molybdenum compounds (e.g., molybdenum disulfide), molybdenum dioxide, and metallic molybdenum) is 15 mg/m³ total dust and 5 mg/m³ for respirable dust (OSHA, 2008). These values were promulgated in 1971 as part of the original establishment of the OSHA, and have not changed (Federal Register, 1971). The ACGIH TLV for insoluble molybdenum is 10 mg/m³ total dust and 3 mg/m³ respirable dust. The TLV for insoluble molybdenum compounds is based on ACGIH's intent to bring TLV values for low toxicity, poorly absorbed materials into agreement with each other. The TLV for soluble molybdenum compounds of 0.5 mg/m³ (respirable fraction) is based on the NTP (1979) inhalation study of molybdenum trioxide wherein the observed no effect level was 10 mg/m³ (ACGIH, 2008). Several safety factors were then incorporated for the development of this criterion. The observation that sulfide enhances the toxicity of soluble molybdenum compounds suggests the desirability of exercising special care when handling soluble molybdenum compounds (IMOA, 2013c).

From an occupational health perspective, molybdenum and its compounds present a wide range of potential toxicity from essentially inert (elemental molybdenum) to irritation and potential carcinogenicity (molybdenum trioxide). In any industrial operation, excessive exposure to potentially hazardous materials should be avoided through use of appropriate engineering and administrative controls, such as local ventilation. If engineering controls are not feasible, a program requiring respirators and other personal protective equipment is needed. Impervious gloves, clothing, eye protection, and NIOSH-approved respiratory protection should be used to protect workers from overexposure to molybdenum and its compounds. If protective clothing is to be reused, laundering contaminated clothing should avoid additional exposure-related hazards. Soluble molybdenum compounds are more likely to be irritant hazards, whereas insoluble ones may be associated with pneumoconiosis. Precautions should be based on the hazards associated with the specific molybdenum compound or compounds. For operations in which overexposure to one of these materials is possible, good personal hygiene habits are strongly recommended. These include no eating or smoking in the work area; washing the hands and face after leaving the work area and before eating, smoking, or using toilet facilities; and removing

contaminated clothing and showering at the end of the workday (U.S. HHS, 1978).

NICKEL

ROBYN L. PRUEITT AND JULIE E. GOODMAN

First Aid: *Dermal exposure:* May cause skin sensitization. Dermatitis can become evident upon reexposure. In case of skin contact, immediately flush the skin with plenty of soap and water for at least 15 min. Cover the irritated skin with an emollient. *Inhalation exposure:* Inhalation of mist may cause respiratory irritation. If inhaled, remove to fresh air. If breathing is difficult, give oxygen and call a physician. *Oral exposure:* Can cause gastrointestinal irritation with nausea, vomiting, and diarrhea. If ingested, call a physician immediately. Do not induce vomiting unless directed to do so by medical personnel. *Eye exposure:* May cause eye irritation. In case of eye contact, flush with copious amounts of water for at least 15 min. Ensure adequate flushing by separating the eyelids with fingers. Call a physician.

Target organs: Skin; respiratory system; kidney; liver

Occupational exposure limits: The OSHA permissible exposure limit (PEL) for nickel metal and both water-soluble and insoluble nickel compounds, based on an 8-h time-weighted average (TWA) exposure, is 1.0 mg/m³. The NIOSH recommended exposure limit for nickel metal and other nickel compounds, based on a TWA exposure of up to 10 h/day, 40 h/week, is 0.015 mg/m³. The ACGIH threshold limit values (TLVs), based on a TWA inhalable fraction exposure of 8 h/day, 40 h/week, are 1.5 mg/m³ for nickel metal, 0.2 mg/m³ for insoluble nickel compounds, and 0.1 mg/m³ for water-soluble nickel compounds and nickel subsulfide.

Reference values: US EPA reference dose (RfD): 0.02 mg/kg-day (soluble nickel salts). IOM tolerable upper intake level (UL) for adults: 1 mg/day (soluble nickel salts).

Risk/safety phrases: May cause sensitization by skin contact. Irritating to eyes, respiratory system, and skin. Limited evidence of a carcinogenic effect for some nickel compounds but not nickel metal.

BACKGROUND AND USES

Nickel is a metal that is abundant in the environment and widely used in industry. It can combine with other elements to form a large variety of nickel compounds, each with different physical and chemical properties, or with other metals to form alloys. The major source of nickel exposure to the general population is from food, although skin contact with items containing nickel is also common. Inhalation of nickel-containing dusts in occupational settings can result in higher nickel exposures, which are associated with toxicity and carcinogenicity in the respiratory tract. The most common health effect of nickel for the general population is contact dermatitis after dermal exposure, which can be exacerbated by subsequent oral exposure to nickel.

The largest use of nickel is in the manufacture of stainless steel and other corrosion-resistant alloys (Alloway, 1990). Pure nickel metal is used in electroplating, as a chemical catalyst, and in the manufacture of alkaline batteries, coins, jewelry, welding products, magnets, electrical contacts and electrodes, spark plugs, machinery parts, and surgical and dental prostheses (ATSDR, 2005; IARC, 1990). Different forms of nickel are used in electronics, fuel cell electrodes, hydrogenation of fats, colorants in ceramics and glass, catalysts, lithium batteries, electroplating, petroleum products, and dye fixative (Alloway, 1990; ATSDR, 2005; IARC, 1990). Nickel carbonyl is used in the production of high

purity nickel powder and for continuous nickel coatings on steel and other metals.

PHYSICAL AND CHEMICAL PROPERTIES

Nickel is a group VIII transition metal and is the 24th most abundant element in the earth's crust (ATSDR, 2005). It can exist in five oxidation or valence states (-1, 0, +2, +3, and +4). The +2 valence state is the most common under normal environmental conditions, and many different species of nickel compounds are formed from the Ni^{2+} ion (ATSDR, 2005). Nickel can be extracted from sulfidic nickel ores and lateritic ores. Nickel smelting and refining processes use nickel derived from these ores to produce various chemical forms of nickel. Nickel compounds encountered in nickel production processes are divided into four categories, namely, water soluble, sulfidic, oxidic, and metallic. There is great complexity in the physical and chemical properties of nickel species among these four groups.

Water-soluble nickel refers to highly water-soluble nickel salts, such as nickel chloride hexahydrate ($\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$) and nickel sulfate hexahydrate ($\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$) (IARC, 1990) but may also describe nickel species that are easily extracted using mild solutions (e.g., ammonium citrate solution). Nickel sulfate hexahydrate is a blue-colored salt that is the main component of the electrolyte solution in electrolytic refining and is a raw material for the production of catalysts. It is also a common source of Ni^{2+} ions used for electroplating. Upon dissolving in water, it forms a solution containing the octahedral $[\text{Ni}(\text{H}_2\text{O})_6]$ ions (hydrated nickel ions) that are hydrogen bonded to sulfate ions (SO_4^{2-}).

Sulfidic nickel generally consists of nickel sulfide compounds produced as intermediates in many nickel smelting and refining processes. These compounds include nickel subsulfide (Ni_3S_2), nickel sulfide (NiS), and nickel disulfide (NiS_2). The various nickel sulfide compounds are insoluble in water, although nickel subsulfide is somewhat soluble in biological fluids. Nickel subsulfide exists in two forms, namely, the low temperature green form, $\alpha\text{-Ni}_3\text{S}_2$, also known as the mineral heazlewoodite, and the high temperature bronze-yellow form ($\beta\text{-Ni}_3\text{S}_2$) (IARC, 1990). Nickel sulfide occurs in three forms (α , β , and amorphous) as dark green to black crystals or powder.

Oxidic nickel consists of various nickel oxides, nickel hydroxides, nickel silicates, nickel carbonates, and complex nickel oxides such as nickel–copper oxides (NiPERA, 2002). Oxidic nickel compounds are relatively insoluble in water, and their solubility in acids and other properties depend on the method of their preparation. Nickel monoxides include a spectrum of compounds from a high temperature green variety, formed during calcination at temperatures exceeding 900 °C, to the more chemically active, low temperature black nickel oxides formed by calcination at 400 to 800 °C. Nickel

hydroxide rarely occurs as a pure compound due to impurities present during industrial production. Nickel carbonates are insoluble in water, but carbon dioxide dissolved in water may dissolve some nickel as bicarbonate (NiPERA, 2002). Complex nickel oxides are often formed as by-products of industrial processes. For example, copper–nickel oxides may be formed during roasting/calcining processes, and spinels (complex nickel oxides such as nickel–chromium–iron oxides and nickel–iron oxides) may form when grinding stainless steel and high nickel alloys (NiPERA, 2002).

Metallic nickel consists of elemental nickel and its alloys. Elemental nickel is a lustrous silvery metal or a gray powder. It is insoluble in water and ammonia but soluble in dilute nitric acid and slightly soluble in hydrochloric acid and sulfuric acid. Powdered nickel is reactive in air, with the extent of reactivity dependent upon its size distribution (ATSDR, 2005). The silvery metal form of elemental nickel is not reactive in air or water at standard temperatures. Nickel alloys contain 3.5–66.5% nickel by weight and can be categorized as nickel–aluminum, nickel–chromium, nickel–chromium–cobalt, iron–nickel–chromium, copper–nickel alloys, and nickel-containing steels (IARC, 1990).

The direct combination of metallic nickel with carbon monoxide forms nickel carbonyl, a volatile liquid with a vapor pressure at 20 °C and a boiling point of 43 °C. Nickel carbonyl is miscible in organic solvents but essentially insoluble in water. Concentrations of nickel carbonyl in ambient air would tend to settle to ground level before being dispersed, because its vapor density is about four times that of air. Once nickel carbonyl is formed, it tends to remain as the metal carbonyl only in the presence of carbon monoxide. In ambient air, nickel carbonyl is relatively unstable and will dissociate to carbon monoxide and nickel metal with a half-life of about 100 s.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Nickel exists in the atmosphere as particulate matter or is adsorbed to other particulate matter. It is removed from the atmosphere by various processes, such as gravitational settling for large particles (>5 µm) and other forms of wet and dry deposition processes for smaller particles (ATSDR, 2005). Nickel particles are present in a broad range of sizes, with an average size distribution measured as a mass median aerodynamic diameter (MMAD) of 1.0 µm in several U.S. cities (Lee et al., 1972).

Nickel is present in soils as water-soluble compounds, including chlorides and nitrates, and insoluble compounds such as nickel oxides and nickel sulfides. Nickel is strongly adsorbed by soil, with stronger adsorption in alkaline soils, which limits nickel's availability and mobility. Water-soluble nickel compounds tend to exhibit greater mobility

than insoluble nickel compounds (US EPA, 2007a). Most nickel compounds are not expected to volatilize from soil, with the exception of nickel carbonyl (US EPA, 2007a).

The various forms of nickel in soils are transported into streams and waterways in runoff from natural weathering or from disturbed soil. Nickel may also enter bodies of water through atmospheric deposition. This metal is highly mobile in aquatic environments, and this is controlled largely by the capability of various sorbents to scavenge it from solution (US EPA, 2007b). Nickel is removed from the water column by adsorption onto suspended particles that settle into the sediment. It can also be adsorbed onto dissolved organic matter, limiting the amount of nickel that can be removed by the settling of suspended particles (Martino et al., 2003). Nickel in sediment may be strongly bound or may be remobilized by microbial action under anaerobic conditions (Francis and Dodge, 1990).

Although nickel does bioaccumulate, its bioconcentration factors suggest that nickel is not accumulated in significant amounts by aquatic organisms, and there is evidence indicating that nickel concentrations in organisms decrease with increasing aquatic levels (McGeer et al., 2003). Nickel concentrations also decrease with increasing trophic levels in food webs, indicating minimal transfer of nickel in the food chain (McGeer et al., 2003). Uptake and accumulation of nickel into various plant species is known to occur (Peralta-Videa et al., 2002).

ECOTOXICOLOGY

The effects of metals on ecosystems are related to metal bioavailability and not the total metal concentration. The bioavailability and toxicity of nickel in the aquatic environment are dependent on interactions with alkalinity, hardness, salinity, pH, temperature, and complexing agents such as humic acids. For example, the bioavailability and toxicity of nickel to freshwater organisms are negatively correlated to the hardness of water (US EPA, 1986). Nickel is generally not bioavailable and not likely to become toxic under natural aquatic conditions if it is occluded in minerals, clay, or sand or is strongly sorbed to particulate matter. Because toxicity tests with the same aquatic species performed under different water quality conditions can result in different toxicity end points, the data for freshwater systems must be normalized for differences in water chemistry using bioavailability models (NiPERA, 2012a).

Although the survival of aquatic organisms after acute exposure to various water-soluble nickel compounds has been evaluated in several different species, environmental regulations for nickel ecotoxicity are based on chronic toxicity data. The most sensitive end points for chronic nickel exposure in aquatic organisms are related to growth, development, reproduction, and mortality. For various

species of algae in freshwater systems, no observed effects concentrations (NOECs) ranged from 35.9 to 115.3 µg/l nickel (NiPERA, 2012b). Nickel NOECs for several fish species ranged from 99.2 to 324.5 µg/l; for amphibians the NOECs ranged from 293.3 to 1265.9 µg/l (NiPERA, 2012b).

The bioavailability of nickel in natural soils changes over time as bioavailable nickel ions are adsorbed onto natural soil components. Nickel metal and compounds are not considered to be ecotoxic to the terrestrial environment, because they release negligible amounts of bioavailable nickel under naturally occurring soil conditions. In very acidic soils, nickel can cause toxicity to sensitive crops such as oats and barley. Remediation of this toxicity can be achieved by the addition of limestone to increase the soil pH.

MAMMALIAN TOXICOLOGY

In mammals, the health effects associated with exposure to nickel vary greatly depending on the form of nickel and the exposure route. This section describes the acute and chronic health effects of various forms of nickel in humans and experimental animals by the route of exposure.

Acute Effects

Inhalation Respiratory damage is the principal effect of acute inhalation exposure to nickel. Death from respiratory distress syndrome (with histological examination indicating alveolar wall damage and edema in alveolar spaces in the lung as well as tubular necrosis in the kidneys) has been reported after acute exposure to a high concentration of metallic nickel (Rendall et al., 1994). Nickel carbonyl is extensively absorbed after inhalation and is highly toxic. Initial stages of nickel carbonyl poisoning are characterized by headache, chest pain, dizziness, and a metallic taste in the mouth (Morgan, 1992), followed by a second phase of chemical pneumonitis with evidence of cerebral poisoning in severe cases (Shi, 1986). In rat studies, high acute exposures to nickel sulfate resulted in severe hemorrhage of the lungs (Hirano et al., 1994), and acute exposure to nickel chloride reduced lung macrophage activity (Adkins et al., 1979). In 12-day inhalation exposure studies in rats, lung inflammation was observed with the following nickel compounds in increasing order of severity of effects: nickel oxide, nickel subsulfide, nickel sulfate hexahydrate (NTP, 1996a, 1996b, 1996c).

Dermal Absorption of nickel through the skin is very low (1%), even for water-soluble nickel compounds (Tanojo et al., 2001). Contact dermatitis from dermal exposure is the most prevalent effect of nickel in the general population and is more frequently observed in females, particularly younger females, than in males or older individuals (ATSDR,

2005; Uter et al., 2003; Wantke et al., 1996). Nickel contact dermatitis appears to be related to previous nickel exposure rather than increased susceptibility, and the sensitizing source is often prolonged exposure to nickel in consumer products such as jewelry. In animal studies, acute dermal exposure of rats to high concentrations of nickel sulfate resulted in skin effects such as distortion of the epidermis and dermis, hyperkeratinization, vacuolization, hydropic degeneration of the basal layer, and atrophy of the epidermis (Mathur et al., 1977).

Oral High acute exposure to nickel sulfate by accidental ingestion has resulted in cardiac arrest and death (Draldrup et al., 1983), and lower exposures resulted in gastrointestinal distress symptoms (Sunderman et al., 1988). A single, high oral dose of nickel sulfate can result in a flare-up of dermatitis in nickel-sensitive individuals (ATSDR, 2005). In rats, the following oral lethal dose, 50%, (LD_{50}) values were reported: for nickel metal, >5000 mg/kg; for water-soluble nickel compounds, 362 mg/kg nickel sulfate and 500 mg/kg nickel chloride; and for insoluble nickel compounds, 9990 to >11,000 mg/kg nickel oxide and >11,000 mg/kg nickel subsulfide (Henderson et al., 2012).

Chronic Effects

Inhalation Occupational exposure to nickel through the inhalation of nickel-containing dust has been associated with toxicity and carcinogenicity in the respiratory tract. Pulmonary fibrosis, based on X-ray findings, was reported in one study to be associated with cumulative exposure to water-soluble nickel compounds or sulfidic nickel (Berge and Skyberg, 2003). A few cases of asthma symptoms also have been reported in workers exposed to water-soluble nickel compounds (Haber et al., 2000). Increased risks of cancers of the lung and nasal sinuses have been reported in some studies of nickel-exposed workers. Because nickel workers were often exposed to different combinations of several forms of nickel and other non-nickel substances and had other dissimilarities (e.g., smoking habits, lifestyle factors), it is not always evident, based on epidemiology data alone, which specific forms of nickel are correlated with increased risk. The occupational epidemiology data indicate clear associations with respiratory cancers for sulfidic nickel as well as oxidic nickel used in the sulfidic ore nickel-producing industry (which includes a nickel–copper oxide) but no consistent associations for nickel oxides that do not contain copper or for metallic nickel (Goodman et al., 2009, 2011; ICNCM, 1990). Although associations between water-soluble nickel exposure and lung cancer risk were noted in several studies of workers who were also exposed to sulfidic and oxidic forms of nickel, it is possible that the increased risks are attributable to these other forms of nickel, are related to water-soluble nickel exposures, or that water-soluble

nickel accentuates risks of other nickel forms (Goodman et al., 2011).

Studies in rodents demonstrate that chronic inflammation in the lungs is the most prominent toxic effect following chronic inhalation exposure to nickel-containing compounds (NTP, 1996a, 1996b, 1996c; Oller et al., 2008). This toxicity can be ranked in increasing order as follows: nickel oxide, nickel subsulfide, nickel metal powder, and nickel sulfate hexahydrate. Atrophy of the olfactory epithelium was also observed in rats with chronic exposure to nickel sulfate hexahydrate and nickel subsulfide (NTP, 1996a, 1996c). Two-year carcinogenicity studies in rodents indicate that nickel subsulfide (NTP, 1996a) and nickel oxide (NTP, 1996b) are carcinogenic in rats, but not mice, and neither water-soluble nickel sulfate hexahydrate (NTP, 1996c) nor nickel metal powder (Oller et al., 2008) are carcinogenic in either species. The tumors with increased incidence rates in the studies of nickel subsulfide and nickel oxide were lung adenomas and carcinomas, but there were no increases in nasal tumor incidence rates in treated animals. Increased incidence rates of benign and malignant pheochromocytomas were observed in male rats exposed to nickel subsulfide, nickel oxide, and nickel metal, but these tumors appeared to be secondary to lung toxicity rather than directly related to nickel exposure (Oller et al., 2008; Ozaki et al., 2002).

Dermal Dermal sensitivity to nickel remains for many years (Keczkes et al., 1982), but the time interval between exposures can influence the degree of severity. A stronger reaction was observed in nickel-sensitized females after a 1-month period between nickel sulfate exposures compared to a 4-month period, and also with the application of nickel sulfate to an area of the skin with previous allergic contact dermatitis (Hindsén et al., 1997).

Oral Intermediate-duration studies suggest that long-term oral exposure to nickel can be tolerated by some nickel-sensitive individuals and may even desensitize some individuals. Oral exposure before the dermal sensitizing exposure may also help prevent nickel sensitization in some individuals (van Hoogstraten et al., 1991). Two-year carcinogenicity studies of rodents treated orally with nickel sulfate hexahydrate or nickel acetate did not result in an exposure-related increased incidence of any tumor type (Heim et al., 2007; Schroeder et al., 1964, 1974).

Mode of Action(s)

The bioavailability of nickel ions at target sites is assumed to be the determining factor for the toxicity of nickel-containing compounds. The mechanisms for nickel ion toxicity vary depending on the exposure route and specific effect. With dermal exposure, nickel sensitization usually arises from prolonged contact with nickel or exposure to a large dose

of nickel, and the resulting contact dermatitis is an inflammatory reaction mediated by type IV delayed hypersensitivity (ATSDR, 2005). Nickel is bound to albumin in the blood (HSDB, 2007).

The mechanism of adverse respiratory effects following inhalation exposure to nickel has been examined in rabbits exposed to metallic nickel or nickel chloride (Johansson and Camner, 1986; Johansson et al., 1980, 1981, 1983, 1987, 1988, 1989). These studies reported the accumulation of macrophages and granular material (such as phospholipids) in the alveoli and an increase in the volume density of alveolar type II cells with lamellar bodies, indicating a direct effect of the nickel ion on alveolar type II cells. After 6 months of exposure, all of the rabbits had pneumonia, indicating an increased susceptibility to infection, which may be attributable to the decreased function of alveolar macrophages (Johansson et al., 1981).

The mode of action for nickel carcinogenicity is unclear. The bioavailability of nickel ions at the nucleus of respiratory target cells differs among different nickel compounds, which may explain the variation in their carcinogenic effects (Goodman et al., 2009, 2011; Oller, 2002; Oller et al., 2008). This bioavailability has been examined in many *in vivo* and *in vitro* studies (Goodman et al., 2011). Sulfidic forms of nickel are readily taken up by respiratory cells and are predicted to have high nuclear bioavailability. Copper-free nickel oxides are cleared very slowly from the lungs but are not as readily taken up by respiratory cells; therefore, they are predicted to have lower nuclear bioavailability. Water-soluble nickel compounds are predicted to have very low bioavailability in the nucleus because of high toxicity, rapid clearance, and uptake processes that deliver nickel ions to the cytoplasm where they can bind to intracellular ligands. Metallic nickel has relatively high toxicity and is not readily taken up by cells so is predicted to have low nuclear bioavailability. Once in the nucleus of respiratory cells, nickel ions are only weakly genotoxic, but some studies suggest that they are clastogenic and can damage DNA. It is possible that non-genotoxic mechanisms involving indirect interaction of DNA with nuclear-available nickel ions are responsible for nickel-induced carcinogenesis, such as damage to heterochromatin, DNA damage through production of reactive oxygen species, alteration of gene expression through DNA hypermethylation or effects on histones, or inhibition of DNA repair processes.

SOURCES OF EXPOSURE

Nickel releases to the atmosphere occur from natural discharges as well as from anthropogenic activities. Occupational exposures to various nickel compounds occur in nickel production, processing, and using industries, and these industries also release nickel to the environment. The general

population is exposed to low levels of nickel in ambient air, water, food, and cigarette smoke, and through contact with nickel-containing items such as coins, stainless steel, jewelry, and orthodontic appliances.

Occupational

Occupational exposure to nickel occurs through the inhalation of nickel-containing dust, fumes, or aerosols or through dermal contact with nickel solutions. Exposure to airborne nickel is highest in operations that involve grinding, welding, and handling powders (ATSDR, 2005). Exposure to airborne nickel in workplaces has been measured by air sampling in more recent years, or estimated by methods such as ranking of likely exposure in different work areas by workplace managers, or by extrapolation of these rankings or measurements from different times, places, or conditions (Goodman et al., 2009). However, determining exposure to specific nickel compounds is difficult. The initial stages in sulfidic ore nickel processing involved mining, milling, and smelting operations that typically involved higher levels of insoluble than water-soluble nickel compounds, and subsequent stages of processing involved a progressively higher ratio of water-soluble to insoluble nickel (Goodman et al., 2009). The electrolytic process involved predominantly water-soluble nickel, while the roasting process involved almost entirely insoluble forms of nickel. Thus, nickel workers in different industries, and those with different duties within the same industry, were often exposed to different combinations of several forms of nickel.

General Population

Most of the nickel exposure to the general population occurs through the diet. The average daily dietary intake of nickel in food ranges from 69–162 µg/day (ATSDR, 2005). Several studies have indicated that the foods with the highest mean nickel levels are nuts, legumes, oatmeal, cocoa, and grains or grain products (Capar and Cunningham, 2000; IARC, 1990; Pennington and Jones, 1987). Although several studies suggest that nickel may be nutritionally important, an essential function for nickel in humans has not been defined clearly (IOM, 2001; Nielsen and Ollerich, 1974; Schnegg and Kirchgessner, 1978; Uthus and Poellot, 1996). Nickel concentrations in drinking water average between 2 and 4.3 µg/l (FDA, 2007; O'Rourke et al., 1999; Thomas et al., 1999), and intake of nickel from drinking water is estimated to be around 4–8 µg/day (ATSDR, 2005). The average nickel concentration in ambient air in the United States is around 2 ng/m³ (Lippmann et al., 2006; U.S. EPA, 2001). Cigarette smoke is another source of nickel exposure; smoke from five U.S. brands of cigarettes contains a mean concentration of 0.03 µg/g nickel (Torjussen et al., 2003). Exposure to nickel can occur through soil, of which nickel is a natural

TABLE 25.1 Occupational Exposure Limits for Nickel and Other Compounds

Agency	Compound	Parameter	Exposure Guideline	Basis for Guideline	Reference
ACGIH ^a	Elemental nickel	TLV-TWA	1.5 mg/m ³	Dermatitis; pneumoconiosis	ACGIH (2011)
	Soluble inorganic nickel compounds	TLV-TWA	0.1 mg/m ³	Lung damage; nasal cancer	ACGIH (2011)
	Insoluble inorganic nickel compounds	TLV-TWA	0.2 mg/m ³	Lung cancer	ACGIH (2011)
	Nickel subsulfide	TLV-TWA	0.1 mg/m ³	Lung cancer	ACGIH (2011)
	Nickel carbonyl	TLV-TWA	0.12 mg/m ³	Pneumonitis	ACGIH (2011)
OSHA	Nickel metal and insoluble compounds	PEL	1 mg/m ³	Dermatitis; pulmonary effects	OSHA (2009a)
	Soluble nickel compounds	PEL	1 mg/m ³	Dermatitis; cancer; pulmonary effects; respiratory and skin irritation	OSHA (2009b)
NIOSH	Nickel carbonyl	PEL	0.007 mg/m ³	Acute pulmonary and CNS effects	OSHA (2004)
	Nickel metal and other compounds	REL	0.015 mg/m ³	Dermatitis; allergic asthma; pneumonitis	NIOSH (2007)
	Nickel carbonyl	REL	0.007 mg/m ³	CNS, gastric, and pulmonary effects	NIOSH (2007)

Notes: ACGIH: American Conference of Governmental Industrial Hygienists; OSHA: Occupational Safety and Health Administration; NIOSH: National Institute for Occupational Safety and Health; TLV-TWA: Threshold limit value—time-weighted average—average exposure on the basis of an 8 h/day, 40 h/week work schedule; PEL: Permissible exposure limit based on an 8-h TWA exposure; REL: Recommended exposure limit based on a TWA exposure of up to 10 h/day and 40 h/week.

^aACGIH TLVs for nickel and nickel compounds are defined as the inhalable aerosol fraction.

constituent, with typical concentrations reported in the range of 4–80 parts per million (ppm). Dermal exposure can also occur through the handling of coins or jewelry. Nickel is present in U.S. coins as a cupronickel alloy containing 25% nickel and 75% copper (United States Treasury, 2010) and is present in gold and silver jewelry to reduce the oxidation of these metals (ATSDR, 2005).

INDUSTRIAL HYGIENE

Occupational limits for inhalation exposures to nickel compounds have been established by the American Conference of Governmental Industrial Hygienists (ACGIH), the Occupational Safety and Health Administration (OSHA), and the National Institute for Occupational Safety and Health (NIOSH). These limits are provided in Table 25.1.

RISK ASSESSMENTS

Several government and international agencies have performed human health risk and carcinogenicity assessments of nickel-containing substances, including the United States Environmental Protection Agency (US EPA), the Agency for Toxic Substances and Disease Registry (ATSDR) of the Centers for Disease Control (CDC), the National Toxicology Program (NTP), the International Agency for Research on Cancer (IARC), and the Danish Environmental Protection Agency (Danish EPA).

U.S. EPA evaluated several nickel-containing substances in its Integrated Risk Information System (IRIS). Soluble nickel salts were the only nickel compounds evaluated for non-cancer effects. U.S. EPA (1996) established an oral RfD of 0.02 mg/kg-day for effects on body and organ weights in a rat chronic oral study (Ambrose et al., 1976). U.S. EPA (1996) noted that many studies demonstrated dermal effects of nickel in sensitive humans after ingestion of nickel, but a dose–response relationship was difficult to establish, so these studies were not adequate to serve as the basis for the quantitative risk assessment. The RfD for soluble nickel salts is believed to be set at a level that would not cause individuals to become sensitized to nickel; however, those who have developed a hypersensitivity already (e.g., from dermal exposure) may not be fully protected. U.S. EPA has not evaluated soluble salts of nickel for effects from inhalation exposure or for potential human carcinogenicity. U.S. EPA (1991a, 1991b) evaluated nickel subsulfide and nickel refinery dust for carcinogenic effects and classified both as human carcinogens based on increased risks of lung and nasal cancer in humans exposed in the workplace and on animal data indicating tumors in animals by more than one route of administration (inhalation and injection). U.S. EPA (1991a) noted that nickel refinery dust is a mixture of many nickel moieties, and it is unclear what the carcinogenic nickel species is in the refinery dust. U.S. EPA (1991c) also evaluated nickel carbonyl for carcinogenicity, classifying it as a probable human carcinogen based on pulmonary carcinomas and malignant tumors at various sites in rats administered with nickel carbonyl by inhalation and

intravenously, respectively. U.S. EPA (1991c) stated that the human data are inadequate for assessing carcinogenicity of nickel carbonyl, but it noted that no excess risk of cancer was observed in workers in an area where nickel carbonyl exposure was present (Peto et al., 1984).

Nickel was assessed for risks of non-cancer health effects for the general population by ATSDR. ATSDR (2005) concluded that the respiratory tract is the most sensitive target following inhalation exposures of nickel-containing substances, with nickel sulfate being more toxic to the lungs than nickel subsulfide or nickel oxide. ATSDR (2005) derived a minimal risk level (MRL) of 0.0002 mg Ni/m³ for intermediate-duration inhalation exposure to nickel based on lung inflammation in a 13-week rat study of nickel sulfate hexahydrate (NTP, 1996c). ATSDR (2005) also derived a chronic duration inhalation MRL of 9×10^{-5} mg Ni/m³ based on chronic lung inflammation in a 2-year rat study of nickel sulfate hexahydrate (NTP, 1996c). ATSDR (2005) noted that cohort mortality studies did not, in general, find significant increases in risk of dying from nonmalignant respiratory system disease. For effects of nickel from oral exposure, ATSDR (2005) noted that acute oral exposure to water-soluble nickel compounds is associated with allergic dermatitis in previously sensitized individuals and with gastrointestinal upset. Studies in animals indicated potential reproductive and developmental effects with acute and intermediate-duration oral exposures to water-soluble nickel, but reproductive effects were not observed in multigenerational studies of rats and developmental effects often occurred at the same dose levels as maternal toxicity. ATSDR (2005) also noted that chronic toxicity data for ingested nickel were limited at that time, concluding that the available database for effects of oral exposure to nickel is inadequate for deriving an oral MRL for nickel exposure.

The NTP classified nickel compounds as “known to be human carcinogens” based on sufficient evidence of carcinogenicity in epidemiology and mechanistic studies and supported by data from rodent carcinogenicity studies (NTP, 2002). In 2000, NTP classified nickel metal (but not alloys) as “reasonably anticipated to be a human carcinogen” based on sufficient evidence of carcinogenicity from studies in experimental animals, noting that available epidemiology studies of workers exposed to metallic nickel are limited by inadequate exposure information, low exposure levels, small numbers of cases, and short follow-up periods (NTP, 2011).

The IARC classified nickel compounds (including water-soluble and insoluble forms) as “group 1: carcinogenic to humans” based on sufficient evidence in humans for the carcinogenicity of nickel sulfate and the combinations of nickel sulfides and oxides encountered in the nickel refining industry (IARC, 1990). IARC (1990) classified metallic nickel as “group 2B: possibly carcinogenic to humans” based on inadequate evidence in humans but sufficient evidence in

animals. The most recent IARC assessment of nickel carcinogenicity confirmed these conclusions (IARC, 2011).

The Danish EPA performed a risk assessment of metallic nickel (Danish EPA, 2008a) and various water-soluble nickel compounds (Danish EPA, 2008b, 2008c, 2008d, 2008e) for the European Union. It concluded that the effects on human health could not be excluded for occupational inhalation exposure to metallic nickel for repeated dose toxicity, carcinogenicity (suspect carcinogen), and development. It further concluded that for these end points, as well as effects of dermal exposures such as irritation and sensitization, there is no need to further limit the risks beyond current risk reduction measures. For exposures to the general population, the Danish EPA concluded that further information was needed to ensure that a threshold was set at an adequate level to prevent new cases of nickel allergy and sufficient to prevent elicitation of symptoms in a significant proportion of nickel-sensitized individuals. Such individuals are potentially at risk from excessive exposure in food and water, and additional risk reduction measures may be needed to limit exposure to nickel released from food contact materials, appliances, and taps for drinking water. For various water-soluble forms of nickel (nickel carbonate, nickel sulfate, nickel dinitrate, and nickel chloride), the Danish EPA concluded that the effects on human health could not be excluded for inhalation exposure of workers to these compounds for the end points of acute and repeated dose toxicity, respiratory sensitization, carcinogenicity, and development. For developmental toxicity and effects of dermal exposures such as irritation and skin sensitization, it was concluded that there was no need to further limit the risks beyond current risk reduction measures. For the general population, it was concluded that individuals with severe nickel sensitization are a particularly sensitive population to oral challenge with nickel and are potentially at risk from excessive exposure in food and water; additional risk reduction measures may be needed to limit this exposure, but there is no concern for those in the general population who are not sensitized to nickel already. The Council of Europe (2002) has issued recommendations for the release of nickel from food contact materials to food and for the release of nickel from electric kettles into water to be as low as reasonably achievable and not more than 0.1 mg/kg to food and 0.05 mg/l to water.

BACKGROUND AND USES

Niobium (symbol Nb; CASRN 7440-03-1) and tantalum (symbol Ta; CASRN 7440-25-7) are considered chemically similar as they fall within the same vertical group as vanadium in the periodic table. They are both difficult to separate from one another and, thus, typically found together naturally. Niobium is principally found in columbite ((Fe,Mn)(Nb,Ta)₂O₆), columbite-tantalite ((Fe,Mn)(Ta,Nb)₂O₆), and pyrochlore ((Na, Ca)₂Nb₂O₆(OH,F)), compounds which often consist of both niobium and tantalum. Tantalum is found principally in tantalite ((Fe, Mn)Ta₂O₆), as well as in the aforementioned niobium ores.

Niobium is alloyed with steel, aluminum, tungsten, and titanium, among others, which are refractory at high temperatures. High stability in heat makes niobium alloys useful in rocket and jet engine components and as a constituent of nuclear reactor core claddings. Similar to tantalum, niobium alloys have found wide use in joint arthroplasty, especially for high stress applications as composites of niobium and tantalum are both highly biocompatible (Wang et al., 2010).

Given its high weight to strength ratio, a tantalum trabecular metal lattice has been developed to resemble the bone matrix in implants. It is also used as a catalyst for rubber production and in capacitors and rectifiers. Tantalum pentoxide (Ta₂O₅; CASRN 1314-61-0) is utilized within the electronics industry in capacitors.

PHYSICAL AND CHEMICAL PROPERTIES

Tantalum is a blue-gray, ductile metal with melting and boiling points of 2996 °C (5425°F) and 5425 °C (9797°F),

respectively. It is highly resistant to corrosion though corrosion resistance to strong acids and atmospheric oxygen decreases at increasing temperatures. It is incompatible with strong oxidizers and alkalis. Niobium appears as a grey metal with melting and boiling points of 2477 °C (4491°F) and 4741 °C (8566°F), respectively. Both elements have negligible vapor pressures, and in pure metallic powder form, both elements are flammable.

Both elements exist primarily in a +5 oxidation state though niobium may assume a +2 state. Under physiological conditions, both elements form insoluble oxides. Similar physiochemistry makes them difficult to separate from their respective ores.

MAMMALIAN TOXICOLOGY

Acute Effects

In the 1960s and 1970s tantalum powder was used for bronchography. This technique has been replaced by other techniques, but no adverse acute or long-term effects were associated with this procedure (Gamsu and Nadel, 1972; Heitzman, 2000; Nadel et al., 1968). An intraperitoneal injection of solubilized tantalum did not elicit an inflammatory response of the rabbit mesothelium but did exhibit slow absorption with preferential accumulation in lymphatic tissue and systemic distribution. Distribution to and deposition within the pulmonary interstitium did not result in pathologic changes (Lawson et al., 1969; Sailer and Stauch, 1973). Animal studies have documented transient bronchial and alveolar inflammation when tantalum oxide (Ta_2O_5 ; CAS # 1314-61-0) was insufflated by the endotracheal route (Cochran et al., 1950; Gamsu and Nadel, 1972; Schepers, 1955; Smith et al., 1979).

Among some workers who accidentally inhaled radioactive tantalum oxide dust, <10% of the dust remained after 7 days without noticing any adverse effects (Newton, 1977; Sill et al., 1969). The remainder was cleared, as observed by radioactive decay, with a prolonged biological half-life, suggesting that a tiny fraction of inhaled tantalum powder can be retained for years. These results were consistent with experimental animal models (Bianco et al., 1974). No associated health problems have been described.

Niobium pentachloride ($NbCl_5$) (CASRN 10026-12-7) can cause renal damage when ingested or given intraperitoneally to animals (Schroeder and Balassa, 1965). Mild transient hepatocyte hydropic degeneration was observed in mice after an intraperitoneal injection of niobium oxide; assessment for hematological changes were negative (Dsouki et al., 2014). No significant human health problems attributable to niobium metal or niobium alloys have been reported to date.

Chronic Effects

No long-term effects of chronic exposure to either tantalum or niobium in humans have been identified. In one report,

workers exposed to tantalum oxide at concentrations ranging between 0.1 and 7.6 mg/m³ did not significantly show significant pulmonary injury (Chen et al., 1999). Hamsters exposed to 100 mg/m³ tantalum oxide presented abnormal pulmonary pathology, including transient interstitial pneumonia, bronchitis, and hyperemia, all of which cleared 1 year after exposure cessation. Only minor hyperplasia was observed as the residual evidence of exposure (Bingham et al., 2001).

Mechanisms of Action

Tantalum demonstrates a triphasic biological half-life. Gastrointestinal absorption of tantalum is generally <1% and clears within days. When absorbed, tantalum binds to plasma proteins with high affinity and can distribute systemically, remaining in the blood for years after periods of high exposure and this accounts for the prolonged half-life (Morrow et al., 1976; Wibowo, 2004). Respiratory clearance is slow in distal bronchioles and alveoli with an effective biological half-life of 2 years or greater in this region. Pulmonary clearance in dogs resulted in translocation to pulmonary lymph nodes where accumulation was noted.

Solid tantalum metal does not significantly elicit an immunological response though tantalum trabecular metal in prostheses has been shown to elicit a PMN-mediated cytokine response; the incidence is rare and only one account has been documented. Rare incidences of allergic contact dermatitis have occurred (Romaguera and Vilaplana, 1995; Schildhauer et al., 2009).

Chemical Pathology

Radiographic imaging of rats administered the radionuclide niobium-95 showed accumulation in the kidneys, bone, and the spleen, while tantalum-182 accumulated predominantly in bone and kidney tissues (Ando and Ando, 1990). Hamsters exposed to tantalum oxide showed interstitial pneumonia with slight, long-term hyperplasia after cessation of exposure (Bingham et al., 2001).

SOURCES OF EXPOSURE

Occupational

Niobium and tantalum are rarely encountered and present few industrial hazards. Workers within the mining and purification of niobium may be exposed to niobium-containing dusts. Production of ferro-niobium alloys can expose workers to aerosols (Lipsztein et al., 2001). However, the extraction and milling of the ores can involve exposure to other toxic substances such as hydrofluoric acid and manganese. Other constituents composed of niobium- or tantalum-containing

alloys may be more toxic. Metal fabrication, such as grinding and cutting operations, or use as carbide-based cutting bits are the primary sources of inhalable exposures for both elements (Bochmann et al., 2008).

Environmental

No significant environmental exposures have been described for either compound aside from the improper discard of mining waste.

INDUSTRIAL HYGIENE

For tantalum, the National Institute for Occupational Safety and Health (NIOSH), the Occupational Safety and Health Administration (OSHA), and the American Conference of Governmental Industrial Hygienists (ACGIH) have set the recommended exposure limit (REL), the permissible exposure limit (PEL), and the threshold limit value (TLV), respectively, at 5 mg/m³ (ACGIH, 2011; NIOSH, 2007). Additionally, NIOSH has a 15-min short-term exposure limit (STEL) of 10 mg/m³ and an immediately dangerous to life and health (IDLH) value of 2500 mg Ta/m³. Specific exposure limits for niobium have not been established but may be regulated indirectly through the limits established for nuisance dusts (15 mg/m³).

Generally, general ventilation systems maintain the airborne concentration of niobium and tantalum below regulatory limits. The use of respirators is recommended as protection against particulate (NIOSH, 2007). Sources of ignition should be avoided when working with the metallic powder.

MEDICAL MANAGEMENT

Unlike vanadium, niobium and tantalum are virtually inert in human body tissue and fluids (Cochran et al., 1950; Dales and Kyle, 1958). Therefore, standard hygiene practices should be followed to limit exposure. In case of eye contact, flush with copious amounts of water. No specific advanced medical protocols have been established for either of the substances.

PLATINUM GROUP ELEMENTS: PALLADIUM, IRIDIUM, OSMIUM, RHODIUM, AND RUTHENIUM

ALEX LEBEAU

First aid:

Eyes: Irrigate immediately (osmium tetroxide and soluble rhodium compounds)

Dermal: Wash skin with soap (osmium tetroxide). Flush skin with water (ruthenium salts)

Exposure to radioisotopes: Begin decontamination procedures and seek medical attention

Inhalation: Respiratory support (osmium tetroxide, rhodium compounds, metal fumes, and salts)

Ingestion: Seek immediate medical attention (osmium tetroxide, rhodium compounds, metal fumes, and salts)

Target organ(s): Skin, respiratory system, immune system

Occupational exposure limits:

Palladium: No PEL, REL, or TLV established

Iridium: No PEL, REL, or TLV established

Osmium:

TLV: TWA = 0.0002 ppm; STEL = 0.0006 ppm

REL: TWA = 0.002 mg/m³; ST = 0.006 mg/m³

PEL: TWA = 0.002 mg/m³

IDLH = 1 mg/m³

Rhodium:

Soluble compounds: PEL = 0.001 mg/m³; REL = 0.001 mg/m³; TLV = 0.01 mg/m³; IDLH = 2 mg/m³

Metal and insoluble compounds: PEL = 0.1 mg/m³; REL = 0.1 mg/m³; TLV = 1 mg/m³; IDLH = 100 mg/m³

Ruthenium: No PEL, REL, or TLV established

Reference values: No EPA IRIS reference doses or reference concentrations established. No ASTDR minimal risk levels established.

EPA interim AEGL:

	Osmium Tetroxide, ppm				
	10 min	30 min	60 min	4 h	8 h
AEGL 1	NR	NR	NR	NR	NR
AEGL 2	0.015	0.011	0.0084	0.0033	0.0017
AEGL 3	5.0	5.0	4.0	2.5	2.0

NR: Not recommended due to insufficient data.

Risk/safety phrases:

Osmium tetroxide: Toxic and/or corrosive (non-flammable)

Palladium dust: Flammable

Rhodium powder: Flammable

BACKGROUND AND USES

The platinoid metals (interchangeably referred to as the platinum group elements [PGE] or platinum group metals [PGM]) include palladium, iridium, osmium, rhodium, and ruthenium, and can be found together in nature in various concentrations. Platinum group elements belong to the noble metals group of the periodic table (Dubiella-Jackowska et al., 2009). Platinum group elements are mined in South Africa; North and South

America; Siberia (The Ural Mountains); and Sunbury, Ontario (Krebs, 2006; Lide, 2006). They occur naturally in nickel, copper, and iron sulfide seams, and marcasite ore beds, and can also be found in nature as native alloys consisting mainly of platinum (Ravindra et al., 2004; Lide, 2006). Their versatile and unique nature makes PGE attractive to numerous industries. For example, demand for palladium and rhodium has increased in recent years as their use in automobile catalytic converters has grown (Johnson Matthey, 2013). Palladium is used by the jewelry industry, by chemical manufacturers (as a catalyst), by electrical component manufacturers, and by the dental restoration industry (Dubiella-Jackowska et al., 2009; Krebs, 2006; Johnson Matthey, 2013). Rhodium is used to make thermocouple elements, electrodes and electric contacts, laboratory crucible, silverware and jewelry, and optical instruments and glass products (including LCD TV screens, mirrors, and other optical devices) (Dubiella-Jackowska et al., 2009; Johnson Matthey, 2013; Krebs, 2006). Ruthenium is used to create alloys with other PGE metals, as a hardening agent, in the creation of electrical contacts, to create jewelry, in the creation of solar cell material (Krebs, 2006), as a catalyst in the chemical industry, and for the creation of computer parts (including hard disk drives and circuit boards) (Johnson Matthey, 2013). Iridium is used to create electrical contacts, crucibles, and to form alloys that are used in situations that require rigid materials (Lide, 2006; Johnson Matthey, 2013). Iridium, palladium, and ruthenium/rhodium radioisotopes are used in the treatment of certain forms of cancer (Michalski et al., 2003; Isager et al., 2006). Osmium is used as a hardening agent for the creation of alloys with other PGE metals (Lide, 2006). It has also been used for phonograph needles and electrical contacts (Lide, 2006). Osmium tetroxide is used as a fixative agent in transmission electron microscopy (Makarovskiy et al., 2007) and has been used for fingerprint detection.

PHYSICAL AND CHEMICAL PROPERTIES

Members of the PGE share similar physical and chemical properties with each other, including their ability to resist corrosion, ability to produce a harder material when in alloy with other PGE members, and their ability to serve as catalysts for various reactions in the chemical industry.

Palladium (CASRN 7440-05-3) is steel-white in color, with a boiling point (BP) of 2963 °C and is the least dense of all the PGE (Lide, 2006). Palladium use has increased with its inclusion in automobile catalytic converters. Palladium can be used as a catalyst (it is the most reactive of all the PGE) in cracking petroleum products, in hydrogenation of liquid oils into a solid fat (Krebs, 2006), for the purification of hydrogen gas (palladium can absorb up to 900 times its own volume of hydrogen) (Lide, 2006), and for the formation of hydrogen peroxide and nitric acid (Johnson Matthey, 2013). Palladium can be added to

gold to create the alloy most commonly referred to as white gold (Lide, 2006). Its inert state and ability to resist corrosion make it an attractive dental restorative agent.

Iridium (CASRN 7439-88-5) is a hard, brittle, yellowish-white metal that can withstand high temperatures and has a BP of 4428 °C (Lide, 2006). It is the most corrosion-resistant metal known (Lide, 2006). Its resistance to high temperatures makes it attractive for making crucibles and other apparatuses that must withstand extreme temperatures. Iridium may be the densest element discovered (Lide, 2006).

Osmium (CASRN 7440-04-02) is a hard, brittle, bluish-white metal with a BP of 5012 °C (Lide, 2006). It has the distinction of being the element in the PGE, which has the highest BP and lowest vapor pressure (Lide, 2006). Its physical characteristics make it difficult to manipulate; therefore, osmium is primarily used in the creation of alloys with other PGE, notably platinum and palladium.

Rhodium (CASRN 7440-16-6) is a silvery-white metal with a BP of 3695 °C (Krebs, 2006). Similar to osmium, it can be used to create a hardened alloy with platinum and palladium (Lide, 2006). The alloys of rhodium can also be used in high temperature conditions (i.e., thermocouples and crucibles). It also can be used in electroplating glass products due to its reflective properties.

Ruthenium (CASRN 7440-18-8) is a hard, white-colored member of the PGE with a BP of 4150 °C (Lide, 2006). Like osmium, it can be used to create a hardened alloy with platinum or palladium. The addition of a small quantity of ruthenium to titanium makes an alloy with increased corrosion resistance (Lide, 2006). Ruthenium is also a versatile catalyst.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Platinum group elements are found in the environment from both natural and anthropogenic sources. Average PGE concentrations in the lithosphere are estimated for each group member: 0.015 mg/kg for palladium, 0.0001 mg/kg for rhodium, 0.0001 mg/kg for ruthenium, 0.005 mg/kg for osmium, and 0.001 mg/kg for iridium (Ravindra et al., 2004). The increase in demand for the elements has resulted in additional mining activities, which have also contributed to environmental accumulation via waste stream deposits.

The increase in mining for these elements, and their subsequent use in automobile emission control systems, has increased the amount of palladium and rhodium in the environment, both as waste from mining activities and in road side dusts from vehicle exhausts. The rate of emissions from catalytic converters may depend on a variety of factors, including driving speed, age and composition of the catalytic converter, and engine type (Wiseman and

Zereini, 2009; Artelt et al., 1999). Concentrations of PGE in road dust have been found in the pg/m^3 range in both particulate matter (PM) PM₁₀ and PM_{2.5} ranges (Wiseman and Zereini, 2009). In high traffic areas, the concentrations of PGE in soils, plants, and dusts have been found to exceed natural background concentrations (Ravindra et al., 2004). Rain and subsequent erosion may wash these dust deposits into local waterways. Some studies suggest that not all PGE road dusts are in metallic form and that they may actually be soluble under certain conditions. Platinum group element's mobility and solubility in soil may depend upon pH, chloride and nitrate content, and the individual PGE (Ek et al., 2004).

Road dust has been studied to evaluate the impact of PGE on the terrestrial biosphere. Of the PGE, palladium has been the most evaluated element (next to platinum) due to its use in vehicle catalytic converters. Some studies have indicated that palladium is the most bioavailable (next to platinum and rhodium) to some aquatic organisms (Ravindra et al., 2004), and PGE have been shown to accumulate in roadside soils and dusts (Dubiella-Jackowska et al., 2009). Platinum group elements may not be in metallic form from exhaust emissions or may be rapidly altered once deposited in the environment (Ravindra et al., 2004). While studies have indicated that anthropogenic PGE can bioaccumulate in aquatic organisms, the deleterious effects associated with the accumulation have not yet been established (Ravindra et al., 2004).

ECOTOXICOLOGY

The recent rise in the use of PGE in vehicle catalytic converters has brought scrutiny towards the deposition of anthropogenic PGE in the environment. Original research into the impact of PGE on the environment suggested that the PM being emitted from vehicle exhaust was inert (Hooda et al., 2008) and would not negatively impact the biota. Recent investigations have suggested that the PM may be more soluble than originally thought and may negatively impact environmental receptors.

Acute Effects

The toxic effects of PGE on ecological receptors have yet to be elucidated. Recent studies have suggested that sensitive receptors can absorb PGE deposited from anthropogenic sources (Ravindra et al., 2004). While uptake of soluble PGE particulates has been observed, the deleterious effects of this uptake, if any, are still being determined.

Chronic Effects

Not enough information has been published to evaluate the chronic effects of anthropogenic PGE on environmental

receptors. Studies are ongoing that are attempting to determine the extent and effects of the bioaccumulation of PGE on the ecosystem.

MAMMALIAN TOXICOLOGY

Metallic forms of PGE are biologically inert (Moldovan, 2007); however, PGE salts have the potential to act as sensitizers. Individual PGE salts or radioisotopes of PGE may have specific deleterious effects. Research in recent years has indicated that PGE particles released in automotive exhaust may be more soluble than initially assumed. This may have an impact on the overall toxicity of the PGE.

Acute Effects

While rare in the literature, occurrences of apparent immune-mediated reactions following overexposures to PGE have been reported, including occupational asthma and contact dermatitis (Ravindra et al., 2004).

A case report by Daenen et al. (1999) indicated that an isolated case of occupational asthma developed in a worker following an exposure to palladium fumes from an electroplating bath. Skin prick testing was positive for one palladium salt ($\text{Pd}(\text{NH}_3)\text{Cl}_2$) but not a second ($(\text{NH}_4)\text{PdCl}_4$), and the exposed worker was skin prick test negative for the corresponding platinum salt (Daenen et al., 1999). Specific bronchial provocation testing resulted in an approximately 35% reduction of forced expiratory volume (FEV₁).

A study on 306 South African refinery workers by Murdoch et al. (1986) found that of the 38 workers who had a positive platinum skin prick test, one worker had a positive test for palladium salts, and six workers had a positive test for rhodium salts. In this study, no independent positive skin prick results were discovered for PGE salts (Murdoch et al., 1986).

A case report detailed an incident involving three individuals that were exposed to a radioactive isotopes of iridium (¹⁹²Ir) which was the reported cause of individual cases of acute radiation sickness. The source of their exposure was linked to a leaking industrial radiograph machine that was being used in pipeline service and repair (Sevan'kaev et al., 2002).

Osmium tetroxide (OsO_4) is an oxidizer and acutely toxic to those who are overexposed. While osmium, in the metallic form, is considered inert, osmium tetroxide can form upon exposure to air under specific circumstances (spongy metal or powdered osmium metal) (Makarovskiy et al., 2007; McLaughlin et al., 1946). Health effects from acute overexposures can lead to irritation of the eyes, respiratory tract, gastrointestinal tract, and skin (McLaughlin et al., 1946). Headaches and dizziness may also present following an acute overexposure (Makarovskiy et al., 2007). Irreversible blindness has been observed from overexposure to OsO_4 . Its high

vapor pressure leads to exposures via inhalation. The symptoms of overexposure may not present immediately and may be delayed for several hours. There have been reports that ruthenium tetroxide has similar health effects from acute overexposures; however, little toxicity information is available in the literature.

Chronic Effects

The chronic effects from exposure to PGE and their salts mainly manifest as an immune response via sensitization. Much like platinum, PGE have the potential to sensitize exposed individuals, with degree of toxicity depending on the exact metal and solubility (Wiseman and Zereini, 2009). Individuals who have nickel allergy also tend to display sensitization effects when exposed to palladium (Kielhorn et al., 2002), including a study that indicated that approximately 90% of the individuals reacting for nickel allergy also displayed palladium sensitivity (Ravindra et al., 2004).

A study by Cristaudo et al. (2005) investigated the hypersensitivity to PGE salts in employees of a catalyst-manufacturing and recycling facility, including platinum, iridium, and rhodium salts. While the majority of those testing skin prick positive were reacting to platinum salts, two workers had positive skin prick reactions to iridium trichloride and rhodium trichloride (Cristaudo et al., 2005).

Chemical Pathology

It is believed that PGE acts in a similar manner to platinum, in which exposure results in sensitization. The World Health Organization (2002) reported that palladium ions target the immune system. Immune responses to platinum have been shown to illicit an immunoglobulin E (IgE) response in those that have a sensitization following an exposure (Calverley et al., 1999; Merget et al., 1999). So far, no clear immune-mediated mechanism has been elucidated for PGE. Detection of PGE sensitivity will need to be conducted with a skin prick test for the specific PGE compound.

Mode of Action(s)

The pathology of PGE is not well studied due to the inert status of their metallic form. However, due to the potential for PGE PM to exist in a soluble form, there has been an increased focus on the mechanism of PGE toxicity. While studies have suggested that PGE can bioaccumulate in certain aquatic organisms, the potential for PGE biomagnification up the food chain and the toxicity associated with its detection in body tissue has not yet been determined.

A target of palladium (and possibly other PGE) is the immune system, as some palladium compounds have been found to be potent sensitizers (WHO, 2002). Overexposures

to palladium salts may result in skin and eye irritation (WHO, 2002). Isolated case reports indicate that inhalation of PGE may result in occupational asthma. The immune response following sensitization to PGE has not been fully elucidated.

The effects that PGE will have following an overexposure will depend on the route of exposure and chemical composition of the PGE (i.e., metal versus salt). Uptake of palladium ions can occur from ingestion or dermal contact (WHO, 2002). However, palladium compounds have a low to moderate acute oral toxicity (i.e., 220 to >4,000 mg/kg body weight in rats) and the toxicity will depend on their solubility (Ravindra et al., 2004).

One case report indicated that urticaria and respiratory issues were observed following an exposure to iridium chloride at the subject's place of employment (Bergman et al., 1995). These occasional case reports of immune response following exposures to iridium salts have also indicated that contact dermatitis is possible.

Iridium, palladium, and ruthenium/rhodium radioisotopes are used in brachytherapy to treat certain forms of cancer, including prostate, breast, and ocular (Michalski et al., 2003; Hammer et al., 1994; Isager et al., 2006). The specific PGE radioisotope used will depend on tumor location. The implantation and focused nature of this therapy ensures that the energy from treatment is directed toward the neoplasm.

SOURCES OF EXPOSURE

Occupational

Since the PGE are rare elements, individuals who are occupationally exposed to PGE are limited to only a few select industries. Miners that are involved in the process of extracting these elements from the earth may be exposed during the mining, recycling, and/or refining process (WHO, 2002). Platinum group elements and their compounds (including PGE salts) are used in the chemical industry as catalysts in reactions, resulting in employees in the chemical-manufacturing industry may be exposed to PGE. Dental technicians may be exposed to palladium through the creation of dental restorations. Jewelers may be exposed to palladium during jewelry manufacture.

Employees of electronic, glass, electrochemical, and other similar industries utilizing PGE for technological purposes may also be exposed, either during the creation of these consumer goods or during the assembly process.

The use of ruthenium/rhodium, iridium, and palladium radioisotopes in certain industries may increase the opportunity for exposure to radiation. This could apply to oil and gas pipeline employees using radioisotopes to identify weaknesses in welds of pipes or in a healthcare facility using PGE radioisotopes for brachytherapy in patients.

Osmium tetroxide exposures may take place in pathology laboratories that use the chemical as a staining and/or fixative

for electron microscopy. Osmium tetroxide stains and allows the localization of unsaturated lipid bonds and nerves within a tissue (McLaughlin et al., 1946), and allows the microscopist to more easily identify these structures.

Environmental

On a global scale, exposures in the general population are expected to remain low due to the rarity of the elements. While individuals may be exposed via direct contact with palladium-containing jewelry and dental restorations, the metallic form is expected to be biologically inert and not contribute to overall body burden.

Recent studies suggest that the use of PGE in catalytic converters has increased the amount of PGE in deposited road dust. There is also evidence that the PM from vehicle exhaust is in a more soluble form than originally thought. While studies do indicate that concentrations of PGE-containing dust have increased, it still remains unknown what biologically significant contribution this road dust makes to overall human health or how bioavailable the material is for uptake by the exposed flora or fauna.

The use of PGE for the treatment of certain cancers will also be an exposure point for some members of the general population. These implanted therapies have the ability to focus the energy on the neoplasm. This makes the chance of exposure to anyone but the individual undergoing brachytherapy low. Michalski et al. (2003) reported that exposures to family members of patients undergoing brachytherapy with iridium and palladium for prostate cancer were low and were below the U.S. Nuclear Regulatory Commission's recommended threshold of 3.60 millisieverts per year (mSv/year).

INDUSTRIAL HYGIENE

The Occupational Safety and Health Administration's (OSHA) permissible exposure limits (PEL) (NIOSH, 2005), the National Institute for Occupational Safety and Health's (NIOSH) recommended exposure limits (REL) (NIOSH, 2005), and the American Conference of Governmental Industrial Hygienists' (ACGIH) threshold limit values (TLV) (ACGIH, 2012) for PGE are summarized below:

Palladium: No PEL, REL, or TLV established

Iridium: No PEL, REL, or TLV established

Osmium: As osmium tetroxide:

TLV time-weighted average (TWA) = 0.0002 parts per million (ppm); STEL = 0.0006 ppm

REL: TWA = 0.002 mg/m³; ST = 0.006 mg/m³

PEL: TWA = 0.002 mg/m³

Immediately Dangerous to Life or Health (IDLH) = 1 mg/m³

Rhodium:

Soluble compounds: PEL = 0.001 mg/m³; REL = 0.001 mg/m³; TLV = 0.01 mg/m³; IDLH = 2 mg/m³

Metal and insoluble compounds: PEL = 0.1 mg/m³; REL = 0.1 mg/m³; TLV = 1 mg/m³; IDLH = 100 mg/m³

Ruthenium: No PEL, REL, or TLV established

Respiratory protection should be used when working around potential sensitizers, like PGE. Claims of sensitizations from PGE should be investigated and the individual should be removed from exposure. The symptoms of sensitization may persist for several months. Further exposures to PGE following sensitization should be prevented.

RISK ASSESSMENTS

There is a paucity of information relating to the risks from exposures to any of the PGE. No reference dose or reference concentration information is available in the U.S. Environmental Protection Agency's Integrated Risk Information System (EPA IRIS) database for any of the PGE Metals (USEPA, IRIS). The Agency for Toxic Substances and Disease Registry (ATSDR) does not currently have a toxicological profile for any PGE.

An interim Acute Exposure Guideline Level (AEGL) for osmium tetroxide was found in the AEGL database and is listed in the summary section (USEPA AEGL, 2008).

PLATINUM

ALEX LEBEAU

First aid: Eyes: Irrigate

Dermal: Soap wash (platinum); water flush immediately (platinum salts)

Inhalation: Respiratory support

Ingestion: Medical attention

Target organ(s): Respiratory system, eyes, and skin

Occupational exposure limits: Platinum:

REL and TLV TWA = 1 mg/m³

Platinum salts: PEL, REL, and TLV TWA = 0.002 mg/m³

IDLH = 4 mg/m³(as Pt)

Reference values: None established

Risk/safety phrases:

Platinum: Powder may be flammable and/or explosive

Platinum Compounds: Ensure proper ventilation.

BACKGROUND AND USES

Platinum is primarily used in industry as a catalyst, predominately for the production of vehicle catalytic converters (Johnson Matthey, 2012). Platinum is also used in the chemical, electrical, glass, dental, healthcare, pharmaceutical, petroleum, and jewelry fields (Cristaldo et al., 2005; Dubiella-Jackowska et al., 2009; Platinum Applications, 2013). In addition to its catalytic properties, platinum, in combination with cobalt, has powerful magnetic properties (Weast, 1988). Original recognition of occupational illness associated with platinum exposure dates back to 1911 when platinum-treated photographic paper was used in photography studios in Chicago (Karasek and Karasek, 1911; Niezborala and Garnier, 1996).

PHYSICAL AND CHEMICAL PROPERTIES

Platinum (symbol Pt; CASRN 7440-06-4) is a silvery to whitish-gray metal, that is malleable and ductile (Weast, 1988; Krebs, 2006). It is estimated that the average platinum concentration in the earth's lithosphere ranges from 0.001 to 0.005 mg/kg (WHO, 1991). It has a vapor pressure of approximately 0 mmHg (NIOSH, 2005). Platinum, depending on mining location, is found in sperrylite, cooperite, braggite, and copper–nickel sulfide ores, and in alloys with other members of the platinum group elements (PGE; iridium, osmium, palladium, ruthenium, and rhodium) (Dubiella-Jackowska et al., 2009; Weast, 1988; WHO, 1991). Both elemental platinum and platinum salts are used in industry. Elemental platinum is insoluble in water whereas many of the platinum salts are water soluble to varying degrees, depending on their specific chemical properties (WHO, 1991). Platinum metal is inert and resists corrosion (Krebs, 2006). However, platinum halide salts are considered potent allergens that have a high risk of causing sensitization (Linnett, 2005). Platinum bonds with halogens in its +2 and +4 oxidation state (Krebs, 2006). The charge of the salt and the presence and number of halides, especially chloride, in a complex platinum salt may affect the degree of mammalian sensitivity to a specific salt (Cleare et al., 1976; Mapp et al., 1999; Merget et al., 2000; Ravindra et al., 2004; Pepys, 1980).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Platinum is found in the environment naturally and from anthropogenic sources. Beginning in the mid-1970s, platinum

was used for catalytic converters in vehicle across the United States and Japan, with Europe utilizing catalytic converters beginning in the mid-1980s (Dubiella-Jackowska et al., 2009; Ravindra et al., 2004). Particulate exhaust from reactions with platinum-containing catalytic converters results in the release of platinum into the environment, often times depositing as road dust (Kümmerer et al., 1999; Ravindra et al., 2004). Particles $>10.2\text{ }\mu\text{m}$ have been shown to make up the majority of the total emitted particles in the exhaust from catalytic converters (62–67%), and the particles larger than $10\text{ }\mu\text{m}$ contain the highest concentration of platinum (Artelt et al., 1999; Dubiella-Jackowska et al., 2009). Initial studies on platinum-containing exhaust particulates suggested that the majority of platinum that is released from a catalytic converter is in metallic form. One recent investigation into vehicle exhaust particulate emissions suggested that the platinum found in tunnel road dust was mobile and may be biologically available (Friegel et al., 2004; Dubiella-Jackowska et al., 2009).

Platinum is used in certain antineoplastics as a treatment for cancer. Platinum can enter hospital wastewater from the urinary excretions of patients receiving treatment with these chemotherapeutics (Kümmerer et al., 1999; Dubiella-Jackowska et al., 2009). However, studies have indicated that hospital effluent is secondary to other environmental sources of platinum, such as those of vehicle catalytic converter emissions (Kümmerer et al., 1999). Industrial use of platinum may also contribute to the presence of anthropogenic platinum compounds in the environment (Dubiella-Jackowska et al., 2009).

Recent investigations into bioavailability suggest that metallic or oxidized platinum may become soluble when deposited as road dust from vehicle exhaust, contaminating soil and water, and ultimately ending up in the food chain (Dubiella-Jackowska et al., 2009). A study investigating the effects of road dust and homogenized catalytic converter material on zebra mussels showed that humic water from a bog lake enhanced the biological availability of particle-bound platinum (Zimmermann et al., 2005). Other similar studies have indicated that bioaccumulation of platinum is possible. Many of these studies have evaluated platinum in combination with other PGE. While it has been shown that anthropogenic platinum is present and can bioaccumulate in the environment, platinum toxicity from this bioaccumulation is not clear (Ravindra et al., 2004).

ECOTOXICOLOGY

Acute Effects

Acute effects on plants or wildlife have not been determined. Recent studies have attempted to evaluate the bioavailability of anthropogenic platinum levels in biota near urbanized

areas. One theory is that metallic or oxidized platinum in road dust may transform into a soluble form and enter the food chain (Dubiella-Jackowska et al., 2009). While detectable levels of platinum have been found in plants and animals in urban areas, no deleterious effects have yet been associated with these concentrations.

Chronic Effects

Not enough information has been published to evaluate the chronic effects of anthropogenic platinum on the environment. Ongoing studies are attempting to determine the extent and effects of the bioaccumulation of platinum on the ecosystem.

MAMMALIAN TOXICOLOGY

Acute Effects

Occupational exposure to platinum can occur from inhalation and ingestion. The most common health effects associated with overexposure to platinum salts include asthma, rhinitis, conjunctivitis, urticarial, dermatitis, and nonspecific airway hyperresponsiveness (Brooks et al., 1990; Calverley et al., 1995; Cristaldo et al., 2005; Merget et al., 2000). While the exposure to platinum salts elicits a Type 1 hypersensitivity reaction involving immunoglobulin E (IgE), the sensitization and allergic response to the exposure may not be immediate. The onset of symptom development following exposure may range from a few months to 6 years (Ravindra et al., 2004). This delay in the development of hypersensitivity has also been observed in patients receiving platinum-containing antineoplastics (Makrilia et al., 2010).

Chronic Effects

Chronic effects from exposure are related to the continued sensitivity to platinum salts, even after an individual has been removed from the exposure. One study indicated that asthma symptoms, airway obstruction, elevated serum IgE, positive skin prick tests, and positive cold air challenge persisted for an average of 5 years following removal from the exposure (Brooks et al., 1990). Similar results were observed in other studies, including bronchial hyperresponsiveness and skin sensitization (Merget et al., 1994; Merget et al., 1999).

A historical prospective cohort study by Nizebora and Garnier (1996) examined 77 refinery workers and found that 23 had developed symptoms of platinum salt sensitivity, with the highest incidence within the first 2 years of work. Another study of refinery workers reported that 41% of 78 new workers became sensitized after 2 years of exposure (Calverley et al., 1995).

Healthcare employees working with platinum-containing antineoplastics and patients receiving treatment have the opportunity for chronic exposure. The International Agency for Research on Cancer (IARC) has classified cisplatin as a Class 2A probable human carcinogen (IARC, 1987). Nephrotoxicity, ototoxicity, nausea, and myelotoxicity caused by cisplatin have been observed in both laboratory animals and patients (WHO, 1991). Type 1 hypersensitivity has been reported in patients receiving platinum-containing chemotherapeutics. Hypersensitivity in patients was reported after multiple treatments and the delay in onset of symptoms depended on the type of platinum antineoplastic administered (Makrilia et al., 2010).

Chemical Pathology

Platinum halide salts are potent sensitizers (Pepys, 1980). The common platinum salts used in industry include hexachloroplatinic acid, ammonium hexachloroplatinate (IV), potassium hexachloroplatinate (IV), sodium tetrachloroplatinate (II), and potassium tetrachloroplatinate (II) (Cristaudo et al., 2005; Dubiella-Jackowska et al., 2009). The immune response from the exposure to platinum salts can elicit a Type 1 hypersensitivity reaction and can increase the total serum IgE. The immune response to platinum salts increased total and platinum-specific IgE in one study; but increased histamine release was not observed (Bolm-Audorff et al., 1992). Sodium tetrachloroplatinate was shown to liberate histamine in another study (Saindelle and Ruff, 1969). Increased total IgE was observed in a study comparing a “high” exposed group to the remainder of the sample groups (Merget et al., 1999).

Mode of Action(s)

The respiratory system, the eyes, and skin are the primary targets following exposure to platinum salts. The degree of allergic response to platinum salts may increase as the number of chlorine atoms bound to the platinum increases (Cleare et al., 1976; Pepys, 1980; Ravindra et al., 2004).

SOURCES OF EXPOSURE

Occupational

The most common occupational exposures to platinum and platinum salts are in refineries and catalyst production facilities (Cristaudo et al., 2005). Current occupational exposures to platinum include employees of the following: platinum-mining facilities and refineries, catalyst manufacturers and recyclers, jewelers, chemical manufacturers, electronic manufacturers, the pharmaceutical industry, dental offices, and hospitals and healthcare facilities (Calverley et al., 1999;

Cristaudo et al., 2005; Dubiella-Jackowska et al., 2009; Merget et al., 1991; Pethran et al., 2003; Platinum Applications, 2013).

Healthcare personnel may be exposed to platinum through the mixing, handling, administration, or cleanup of the platinum-containing antineoplastics cisplatin, carboplatin, and oxaliplatin, which are used to treat a variety of cancers (NTP, 2011; Pethran et al., 2003). Studies have indicated that exposures in healthcare settings may occur via contact with surfaces and drug vials contaminated with platinum-based antineoplastics (Mason et al., 2005; Naito et al., 2012; Nygren et al., 2002). These studies suggest that drug vial contamination may have occurred during the manufacturing and packaging of the antineoplastics.

Environmental

Patients receiving antineoplastics for the treatment of cancer will be exposed if their therapy involves the administration of platinum-containing chemotherapeutics. Biota may be exposed to platinum from road dust emitted by vehicle catalytic converters and from effluent from hospitals whose patients were administered platinum-containing antineoplastics. It has been estimated that approximately 70% of the platinum dose received by cancer patients is excreted in urine (Dubiella-Jackowska et al., 2009). Industrial sources of platinum may also contribute to environmental exposure. Taking into account the increased concentration of anthropogenic platinum in the environment, the amount found has not been sufficient to elicit an outbreak of allergic reactions in the population (Cristaudo et al., 2005).

INDUSTRIAL HYGIENE

As an important protective measure, prompt removal of sensitized individuals from a platinum salt exposure is highly recommended (Brooks et al., 1990; Niezborala and Garnier, 1996). Skin prick testing with platinum salts can be used to detect sensitization at early stages (Linnett, 2005). Platinum salt exposure and sensitivity have been associated with an increase in total serum IgE levels (Calverley et al., 1999; Merget et al., 1999). Positive skin prick tests have been associated with higher levels of total serum IgE in comparison to workers that were skin prick test negative (Mapp et al., 1999).

Skin prick testing and evaluating an employee’s symptoms for platinum salt exposure are better diagnostic tools than evaluating bronchial hyperresponsiveness for determining sensitization for both platinum salt sensitization and for occupational asthma due to exposure (Merget et al., 1995). One study indicated that a positive skin prick result had a 100% positive predictive value for the signs and symptoms of sensitization to platinum salts (Calverley et al., 1995).

Historically, atopic individuals have been excluded from exposure to platinum salts. However, recent studies have indicated that excluding atopic individuals may not necessarily result in a decreased incidence of platinum salt sensitivity and that atopy may not be a viable metric for evaluating a predisposition for platinum salt sensitivity (Merget et al., 2000; Niezborala and Garnier, 1996). Periodic monitoring of employees working with platinum salts is highly recommended as part of a workplace health surveillance program.

The National Institute for Occupational Safety and Health (NIOSH) and the American Conference of Governmental Industrial Hygienists (ACGIH) have set the time-weighted average (TWA) recommended for platinum at 1 mg/m^3 (NIOSH, 2005; ACGIH, 2012). The Occupational Safety and Health Administration (OSHA), NIOSH, and the ACGIH have set the permissible exposure limit (PEL), the REL, and the TLV, respectively, for platinum salts at 0.002 mg/m^3 (NIOSH, 2005). The Immediately Dangerous to Life and Health (IDLH) concentration for platinum salts is 4 mg/m^3 (as Pt) (NIOSH, 2005).

RISK ASSESSMENTS

No information is available for a reference dose or reference concentration relating to the exposure to platinum or platinum salts. New research indicates that anthropogenic platinum in the environment may be bioavailable and may bioaccumulate in the food chain. No study was identified that evaluated risk from environmental exposure.

Cisplatin is classified as *reasonably anticipated to be a human carcinogen* (NTP, 2011). Animal studies have indicated that cisplatin administration has resulted in lung adenomas and leukemia. Human studies have not been conclusive.

Smoking is considered a predictor/risk factor for the development of platinum salt sensitivity. Venables et al. (1989) discovered that smoking was a predictor of a positive skin prick test for platinum salts. Niezborala and Garnier (1996) used smoking status of refinery employees to positively predict a positive skin prick test and the development of symptoms from exposure. Calverley et al. (1995) found an almost eight times increased risk of sensitization from exposure to platinum salts in smokers as compared to non-smokers. Merget et al. (2000) identified smoking status of an employee as a predictor for skin prick test conversion in highly exposed individuals from a catalyst-production facility (relative risk = 3.9).

RARE EARTH METALS

RAYMOND D. HARBISON AND DAVID R. JOHNSON

First aid: Remove from exposure. Give fresh air. Immediately irrigate eyes, irrigate skin with water; wash skin with soap. Provide respiratory support. If ingested by swallowing, seek immediate medical attention.

Target organs: Skin, liver, skeleton

Risk/safety Phrases: Potent contact irritants; anticoagulant effects; GI and respiratory tract absorption; dusts may present and explosion hazard.

Element	CASRN	Atomic Number	Industrial and Commercial Uses
Scandium (Sc)	10361-84-9	21	High strength aluminum alloys; electron beam tubes; carbon arc rods; electronics; radiopharmaceutical agents; halide lamps; dental lasers
Scandium chloride			
Yttrium (Y)	7440-65-5	39	Capacitors; phosphors; microwave filters; optical glass and ceramics; oxygen sensors; radars; superconductors; color television tubes; magnesium and aluminum alloys; dental lasers; visual displays that give off different colors such as televisions; computer screens; visual displays; fiber optics
Lanthanum (La)	7439-91-0	57	Carbon arc rods; glass; ceramics; phosphor for fluorescent lamps; catalyst for cracking crude petroleum; pigments; accumulators; flint; battery electrodes; camera lenses and telescope lenses; studio lighting and cinema projection; exhaust purification system; water purification
Cerium (Ce)	7440-45-1	58	Optical glasses, polishing abrasives, ceramics, pigments; UV filters; carbon arc rods; alloys with magnesium and iron; phosphors; catalyst for cracking crude petroleum; catalytic converters in cars; ferrocereum flint; oxidizing agent; flatten screen display; exhaust purification system; water purification
Praseodymium (Pr)	7440-10-0	59	Glass colorant, ceramics; pigments; carbon arc rods, alloys; catalyst for cracking crude petroleum; ferrocereum flint; rare earth magnets; lasers; cell phones; portable wireless installation; flatten screen display; MRI and X-ray imaging; hybrid and plug-in electric vehicles; computer disc drive, wireless power tools, integrated starter, wind and hydroelectric power generation
Neodymium (Nd)	7440-00-8	60	Glass colorant; lasers; IR filters; carbon arc rods; catalyst for cracking crude petroleum; high performance magnets such as in loudspeakers, computers; hybrid cars; plug-in electric vehicles; lasers; ceramics; capacitors; flint; cell phones; portable wireless installation; MRI and X-ray imaging; computer disc drive, wireless power tools, integrated starter, wind and hydroelectric power generation
Promethium (Pm)		61	Luminescent and phosphorescent coatings; nuclear batteries; radioactive properties used in luminous paint; other radioactive applications

(continued)

(Continued)

Element	CASRN	Atomic Number	Industrial and Commercial Uses
Samarium (Sm)	10361-82-7	62	Infrared-absorbing glass, lasers; color television phosphors; magnets; microwave filters; catalyst for cracking crude petroleum; alloy with cobalt for magnets; neutron capture; masers; nuclear industry applications
Samarium chloride			
Europium (Eu)	10025-76-0	63	Lasers; phosphor for special X-ray film; mercury vapor lamps; phosphors for fluorescent lamps; NMR relaxation agent; control rods in nuclear reactors, visual displays that give off different colors such as televisions; computer screens; visual displays; cell phones; portable wireless installation; fiber optics; flatten screen display
Europium chloride			
Gadolinium (Gd)	7440-54-2	64	Reactor control rods; alloys with iron and chromium; glasses; ceramics; crystal scintillators; contrast for magnetic resonance imaging; NMR relaxation agent; X-ray tubes; computer memories; neutron capture; magneto-restrictive alloys; television screens
Terbium (Tb)	10042-88-3	65	Fluorescent phosphors; lasers; fluorescent lamps; magneto-restrictive alloys; visual displays that give off different colors such as televisions; computer screens; visual displays; cell phones; portable wireless installation; fiber optics; MRI and X-ray imaging; hybrid and plug-in electric vehicles; computer disc drive, wireless power tools, integrated starter, wind and hydroelectric power generation
Terbium chloride			
Dysprosium (Dy)		66	Control rods for nuclear reactors; ceramics; phosphors; magnets; lasers; magneto-restrictive alloys; cell phones; portable wireless installation; MRI and X-ray imaging; hybrid and plug-in electric vehicles; computer disc drive, wireless power tools, integrated starter, wind and hydroelectric power generation
Holmium (Ho)	10138-62-2	67	Ceramics; lasers; nuclear industry; paramagnetic; research application; calibration for optical spectrophotometers
Holmium chloride			
Erbium (Er)	10138-41-7	68	Colorant for glass, ceramics; metallurgy; lasers; fiber-optic technology; vanadium steel
Erbium chloride			
Thulium (Tm)	13537-18-3	69	Radiation source; electron beam tubes; X-ray machines; 16 useful isotopes; lasers; metal-halide lamps
Thulium chloride			
Ytterbium (Yb)	7440-64-4	70	Lasers; metallurgy; radiation source in X-ray/radiation devices; superconductors; chemical reducing agent; nuclear medicine applications; decoy flares; doping material stainless steel; stress gauges; emits gamma rays; flatten screen display
Lutetium (Lu)	10099-66-8	71	Single crystal scintillators; carbon arc rods; positron emission tomography (PET scan detectors); high refractive index glass
Lutetium chloride

BACKGROUND AND USES

The rare earth metals (REM) include a group of 17 sequential lanthanide elements beginning with lanthanum (La) and ending with lutetium (Lu), to which scandium (Sc) and yttrium (Y) are added. The REMs incorporate the vertical group IIIB of the periodic table, scandium, yttrium, and lanthanum; and the elements that follow lanthanum in the special horizontal subset of the periodic table because they share some similar physical, chemical, and biological properties (Hirano and Suzuki, 1996). Their unique physical and chemical properties have made them critical to a growing number of modern technologies. In reality these elements are not rare, with the exception of promethium that does not exist in a natural state but is produced by fission, usually from

neodymium. By convention, the elements are designated the REMs, and their oxides, rare earths.

Rare earth elements are present in many minerals, principally monazite and bastnasite (cerium and other lanthanides), gadolinite (yttrium, cerium, chromium, beryllium, and iron), euxenite (vanadium, cerium, europium, niobium, titanium, and uranium), and xenotime (yttrium, thulium, cerium, and other lanthanides). Mineral types include halides, carbonates, oxides, phosphates, and silicates. Although relatively abundant in the earth’s crust, they rarely occur in concentrated forms, making them economically challenging to obtain. The metals are extracted from fluorides or oxides by electrolysis, chemical reduction, or precipitation and then purified by ion exchange chromatography. While the United States used to be a world leader in mining and extracting REMs, China now

leads in this arena creating a dependency and vulnerability for other countries that need the metals for critical modern applications. New mining opportunities and extraction techniques are being explored and developed.

The value and use of the REMs and their compounds, the rare earths, have been increasing due to their uses in many modern technologies and everyday electronics. The rare earth market has been rising rapidly. From 1964 to 1997, it increased by a factor of 17 and, from 1997 to 2007, it increased by a factor of 20.5 (Naumov, 2008; Savel'eva, 2011). Examples of REM applications include catalytic filter neutralizers of exhaust gases of cars, fiber optics, oxygen sensors, phosphors, superconductors, in lighting, in metallurgy, in glass and ceramic manufacture, in crystallizing synthetic gemstones for lasers and jewelry, and for making long-lasting and special application magnets. The physical properties of the lanthanide series give rise to phosphorescence and luminescence; almost all of the rare earths are used to make television screens, special fluorescent light bulbs, and diagnostic radiographic materials. The rare earths are widely used to impart special colors and properties to glass. For example, didymium, a mixture of praseodymium and neodymium, is used for glass blowers' goggles because it absorbs the intense yellow light of flaming sodium.

Many of the REMs, especially scandium and cerium, produce intense white light when heated or ignited and are used to make the cored carbon arc rods for motion picture projection and other intense lighting equipment. Cerium is pyrophoric and is alloyed with neodymium and lanthanum to make misch metal, which is used in tracer bullets and in lighter flints as an alloy with iron and magnesium. Scandium, yttrium, lanthanum, and cerium are radiopaque, and gadolinium complexes are used extensively as a contrast media in magnetic resonance imaging (MRI).

Other critical applications involve the manufacture of components of cell phones, digital music players, microphones, hard disc drives in computers, hybrid cars and electric vehicles, GPS systems, radar, sonar, and water treatment systems.

Historically, samarium-153 was injected locally to ease the pain caused by skeletal metastases (Turner et al., 1989) and nonradioactive samarium has been used in dental alloys with silver. However, the side effects of the rare metal exposure have limited its therapeutic applications.

PHYSICAL AND CHEMICAL PROPERTIES

The lanthanum series has a similar nuclear structure; each metal has two outer electrons and eight or nine electrons in the next inside electron shell. Each element after lanthanum has an additional electron in the third electron shell from the outside. As the atomic number and weight increase, the

primary physical and chemical properties of each metal are conserved. Scandium and yttrium share some properties but do not participate in the unique lanthanide chemistry.

MAMMALIAN TOXICOLOGY

Acute Effects

The rare earths are potent contact irritants and can have significant metabolic effects (Beaser et al., 1942; Chan et al., 1989; Funakoshi et al., 1992; Graca et al., 1957, 1962; Haley et al., 1961, 1965a, 1966; Hirano and Suzuki, 1996; Rim et al., 2013). They are not absorbed from the skin and are slowly absorbed from the gastrointestinal (GI) and respiratory tract. After absorption they concentrate in the liver and the skeleton.

Skin contact produces irritation that progresses to ulceration, delayed healing, and the formation of granulomas. Ocular exposure can cause conjunctivitis, corneal injury, and, ultimately, corneal scarring and opacity. Inhalation of large amounts of rare earth dusts can produce acute irritative bronchitis and pneumonitis. Most REMs are considered to be mild to moderately toxic. Promethium is radioactive, and appropriate exposure precautions should be followed. The free ion form of gadolinium is highly toxic; however, gadolinium used in MRI contrast agents is chelated and considered safe for most persons. Ytterbium compounds are considered highly toxic as they cause irritation to the skin and eye and there is the possibility that some compounds may be teratogenic. Animal studies have shown yttrium to cause lung and liver damage. Yttrium citrate caused pulmonary edema, and while yttrium chloride exposure resulted in liver edema, pleural effusions, and pulmonary hyperemia, and it is thought that exposure to yttrium compounds in humans may cause lung disease (Rim et al., 2013).

Chronic Effects

Repetitive inhalation of large amount of rare earth dusts can cause irritative bronchitis and pneumonitis and can lead to granulomatous disease (Ball, 1966; Rim et al., 2013; Schepers, 1955). There are a number of known case reports of pulmonary fibrosis and pneumoconiosis caused by the rare earths (Rim et al., 2013; Sabbioni et al., 1982; Sulotto et al., 1986; Waring and Watling, 1990). Several of these cases were related to chronic repetitive exposure to the fumes or smoke from rare earth-containing carbon arc lights used in photoengraving, projection, and searchlight operations.

Carcinogenicity The REMs have not been classified as carcinogens. The EPA has found "inadequate information to assess carcinogenic potential" (EPA, 2012).

Mechanism of Action(s) and Chemical Pathology

The REMs all have hepatotoxic and anticoagulant properties (Beaser et al., 1942; Chan et al., 1989; Funakoshi et al., 1992; Graca et al., 1964; Haley et al., 1963, 1964; Kryker and Cress, 1957). Lanthanum, cerium, neodymium, samarium, terbium, dysprosium, erbium, and ytterbium all caused a dose-dependent prolongation of the clotting time of normal human plasma (Beaser et al., 1942). Their presence interferes with activated factor X and thrombin (Hirano and Suzuki, 1996), and they can suppress lymphocyte proliferation and cytokine production (Das et al., 1988; Evans and Ridella, 1985; Palmer et al., 1987; Sedmak and Grossberg, 1981; Yamage and Evans, 1989). Attempts to use rare earth compounds as anticoagulants were unsuccessful because researchers were unable to establish a safe dose and avoid hemorrhage. Similarly, although cerium compounds were historically effective in treating hyperemesis gravidarum and peripheral infection, side effects made their use impractical and dangerous.

Intraperitoneal injection of rare earth chlorides into experimental animals produces peritonitis and hemorrhage ascites (Haley et al., 1961, 1965a, 1965b). With increased doses or absorption, pulmonary edema and liver necrosis occur. The bleeding time and prothrombin time are increased. Recovery is followed by the formation of granulomas of the affected tissues, namely, lung, liver, and peritoneum. The median lethal dose (LD_{50}) for mice, which were given an intraperitoneal injection of chloride salts, ranges from 88 mg/kg for yttrium to 755 mg/kg for scandium (Haley et al., 1961, 1965, 1966). The lanthanide LD_{50} ranges from 315 mg/kg for lutetium to 600 mg/kg for neodymium.

Intravenous injection of neodymium salts (Haley et al., 1961, 1965a, 1966), lanthanum, and cerium in humans resulted in incoagulability of the blood for up to 8 h and unacceptable side effects of rigors, fever, muscle cramps, abdominal pain, hemoglobinuria, and hemoglobinemia.

Chen and Zhu (2008) reported that the long-term intake of low dose rare earth elements may lead to their accumulation in the bone structure, leading to changes in the bone tissue and increased bone marrow micronucleus rate and further to generation of genetic toxicity in bone marrow cells.

SOURCES OF EXPOSURE

Occupational

The growing use of rare earths in a variety of manufacturing processes has increased the potential for industrial or accidental exposure to the rare earths; to mineral contaminants; or to chemicals used in the refining process (Hirano and Suzuki, 1996; Rim et al., 2013; Vennart, 1967). The rarity, in the past, of reports of occupational illness caused by the rare earths has obscured documentation of their toxicity in the medical

literature. Nevertheless, potential exposure to REMs and contaminants encountered in production and decommissioning is increasing and occurs in mining, refining processes, manufacturing, transportation, and waste disposal. Some of the risks include exposure to the tailings of rare earth mining; the creation of radioactive dusts and water emissions arising from contaminants during mining processes; dusty environments; poor ventilation; and lack of proper use of protective equipment. While animal studies have shown rare earth exposure to be associated with acute pneumonitis and pulmonary neutrophil infiltration, reports of long-term occupational exposure being associated with pneumoconiosis are limited.

Environmental

Cerium is the 25th most abundant element in the earth's crust. Almost all of the rare earth elements are found in the earth's crust in amounts larger than that of silver, and the four most widespread rare earth elements (yttrium, lanthanum, cerium, and neodymium) are found in amounts greater than that of lead (Naumov, 2008). In nature the REMs are found to be complexed with a variety of minerals and are therefore not a risk for typical exposure via the lungs, skin, or GI tract.

Potential environmental exposures that have been considered involve persons living in close proximity to mining and refining processes; the risk of diesel emissions created by additives; and contamination via radioactive and other chemical wastes of the mining and refining processes.

In some tropical regions, there appears to be an association between a high cerium concentration in vegetables and tubers and an increased prevalence of endomyocardial fibrosis (Valiathan et al., 1989). Postmortem studies have found a high concentration of cerium in the myocardium.

INDUSTRIAL HYGIENE

The REMs in general are considered to have mild to moderate toxicity potential; however, no occupational health standards have been set for the REMs except for yttrium (NIOSH, 1981). Exposure to airborne yttrium has been associated with coughing, shortness of breath, chest pain, and cyanosis. The permissible exposure limit for yttrium was established in 1981 and remains at 1 mg/m^3 as an 8-h time-weighted average. Some common sense guidelines are clearly indicated for occupations involving exposure to the dust and fumes of the rare earths (Vennart, 1967):

1. Skin contact should be avoided.
2. Individuals with skin lesions, contact lenses, and conjunctivitis must protect themselves from contamination of the eyes and skin.

3. Individuals with lung disease and smokers must have respiratory protection.
4. Individuals receiving therapeutic anticoagulation treatment must avoid respiratory and GI exposure.

Rim et al. (2013) recommend control of the level of yttrium, terbium, and lutetium fluorides in workplace air, through maximal admissible concentrations (MACs) for the fluorides of 2.5 mg/m³ (maximal single concentration) and 0.5 mg/m³ (average shift concentration), and the level of ytterbium fluoride as moderate fibrogenic dust of 6 mg/m³.

Promethium has radioactive properties requiring those working with it to wear gloves, foot wear covers, safety glasses, and an outer layer of protective clothing. Further study will be necessary to establish occupational health standards for the REMs.

MEDICAL MANAGEMENT

Medical literature regarding the treatment of acute toxicity from REMs is sparse due to the low number of reported cases of human toxicity. If acute or chronic exposure is suspected, it is important to remove or mitigate human exposure and confirm that the illness is truly due to rare earth exposure. This involves determining that other more common etiologies are not the actual cause of the symptoms. Treatment of acute skin or conjunctival exposure should involve immediate irrigation with water and cleansing the skin with soap and water. If conjunctivitis or corneal injury is apparent, immediate irrigation should be performed in conjunction with ophthalmology consultation. Inhalation exposure should be avoided. If high level or chronic respiratory exposure has occurred or suspected, a CXR should be obtained along with standard treatment for irritative bronchitis and pneumonitis. Chronic exposure has been associated with pneumococcosis, and bronchoalveolar lavage might be useful in confirming this diagnosis.

If significant absorption is suspected via inhalation or the GI tract, laboratory evaluation should include serum chemistries, liver function test, complete blood count, and coagulation studies (bleeding time, prothrombin time, and clotting time). Significant exposure should be observed in the hospital followed by close outpatient follow-up to assess resolution of any adverse effects and to assure ongoing avoidance of exposure. As with any situation involving exposure toxicity, the local poison control center should be contacted to assist with treatment and for tracking of cases for public health purposes.

SELENIUM AND ITS COMPOUNDS

ANNA M. FAN AND MARCO VINCETI

First Aid: Elemental selenium (Se), Se alloy

Eye: Irrigate immediately

Skin: Soap wash immediately

Breathing: Respiratory support

Swallow: Medical attention immediately

Target organ(s):

Elemental Se, Se alloy: Eyes, skin, respiratory system, liver, kidneys, blood, spleen (OSHA)

Se and compounds: Inhalation—lung as primary; also cardiovascular, hepatic, nervous system, renal involvement. Oral—gastrointestinal, cardiovascular effects; selenosis (dermal and neurological) from chronic exposure.

Occupational exposure limits:

OSHA PEL: TWA 0.2 mg/m³ (elemental Se and other Se compounds, except Se hexafluoride)

NIOSH REL: TWA 0.2 mg/m³ (elemental Se and other Se compounds, except Se hexafluoride)

ACGIH TWA 0.2 mg/m³ (elemental Se).

Reference values (see text for references):

U.S. EPA oral RfD, 5 µg/kg/day

Cal/EPA oral ADD, 5 µg/kg/day

ATSDR chronic oral MRL, 5 µg/kg/day

Dietary reference values (vary for different age groups [six age groups between age 0 and 18], and they include special groups such as pregnant and lactating women):

NRC EAR: Age 0–18, 15–45 µg/day; adults, 45 µg/day; pregnant women, 49 µg/day; lactating women, 59 µg/day

NRC RDA: Age 0–18, 15–55 µg/day; adults, 55 µg/day; pregnant women, 60 µg/day; lactating women, 70 µg/day

NRC UL: Age 0–18, 45–400 µg/day; adults, pregnant women, lactating women, 400 µg/day

NRC AI: 0–6 months, 15 µg/day; 7–12 months, 20 µg/day

Risk/safety phrases: Elemental selenium (Se), Se alloy

Health risk: Potential hazard: Depends on the chemical form and exposure; industrial exposure can be highly toxic, dietary exposure can be beneficial, excess can be toxic (but rare)

Safety: Avoid skin contact. Do not use mouth-to-mouth method if victim ingested or inhaled the substance. Isolate leak or spill area. IDLH: 1 mg Se/m³. The revised IDLH (Immediately Dangerous to Life or Health) for selenium compounds is 1 mg Se/m³ based on acute toxicity data on sodium selenite in animals. It is “an atmosphere that poses an immediate threat to life, would cause irreversible adverse health effects, or would impair an individual’s ability to escape from a dangerous atmosphere (OSHA regulation 1910.134(b)).” Relevant acute toxicity data for workers are lacking (CDC, 1994; Transport Canada, 2008).

BACKGROUND AND USES

Selenium is found ubiquitously in the environment, being released from both natural and anthropogenic sources. Natural sources include the weathering of selenium-containing rocks and soils and volcanic eruptions. The principal anthropogenic source is coal combustion, petroleum mining or refining, fly-ash from coal-burning power plants, and irrigation of high selenium arid farmland soils. It occurs naturally at low concentrations in surface waters and groundwaters of the United States.

Selenium can exist as an inorganic species that includes elemental selenium, selenium salts (selenite, selenate), selenious acid, selenic acid, selenium dioxide, selenium disulfide, selenium hexafluoride, selenium monochloride, selenium monosulfide, selenium oxychloride, and selenium tetrachloride (IPCS, 2001). It can be found in various commercial products, including electronics (photoelectric cells, semiconductors, low voltage rectifiers), ceramics and glass (pigments and dyes), steel (alloy with copper), gun-bluing solutions (selenious acid and copper nitrate and nitric acid), rubber vulcanizing, chemistry (catalyst), photocopy (xerographic properties), and medicine (selenium sulfide for treatment of pityriasis versicolor and palmar plantar mycosis, dandruff and seborrheic dermatitis of the scalp). The gamma-emitting isotope ^{75}Se has been used in diagnostic applications of medicine. Metal industry workers, health service professionals, mechanics, and painters may be exposed to higher levels of selenium than the general population or workers employed in other trades.

Selenium can also exist as an organic species such as methylated selenium compounds, selenoamino acids, selenoproteins, and their derivatives (Pyrzyńska, 2002). The general population is exposed to selenium primarily by dietary intake, mainly as the amino acid selenomethionine in grains, cereals, and forage crops; as selenocysteine in meats and dairy products to a lesser extent; and as the inorganic selenate and selenite, which are the main soluble forms in aqueous media. Although selenium dioxide, selenium trioxide, selenious acid, and selenic acid are soluble in water, they have not been detected in drinking water because each becomes the corresponding selenite or selenate once it dissolves in water (Pyrzyńska, 2002; ATSDR, 2003). Selenium is an essential micronutrient for humans and animals, obtained as part of daily dietary intakes and from some dietary supplements. It is also used as a nutritional feed additive for poultry and livestock.

PHYSICAL AND CHEMICAL PROPERTIES

Selenium is a nonmetal (or semimetallic) element (also referred to as a metalloid) with an atomic number of 34 and an atomic mass of 78.96. It belongs to Group 16 (Group VIA)

of the periodic table, located between sulfur and tellurium. Six stable isotopes of selenium occur naturally. It exists in several allotrophic forms. The stable form at ordinary room temperatures is the gray or hexagonal form; the other two important forms are red (monoclinic) and amorphous selenium. Black amorphous selenium is vitreous and is formed by the rapid cooling of liquid selenium; red amorphous selenium is colloidal and is formed in reduction reactions (Hoffman and King, 1997; CRC, 2000; ATSDR, 2003).

The chemical properties of selenium are similar to sulfur. Selenium combines with metals and many nonmetals directly or in aqueous solution. It does not react directly with hydrogen fluoride or hydrogen chloride but decomposes hydrogen iodide to liberate iodine and yield hydrogen selenide. The selenides resemble sulfides in appearance, composition, and properties. It may form halides by reacting vigorously with fluorine and chlorine, but the reactions with bromine and iodine are not as rapid. It reacts with oxygen to form a number of oxides, the most stable of which is selenium dioxide (Hoffman and King, 1997; ATSDR, 2003).

The important selenium oxidation states are -2, 0, +4, and +6. The commonly occurring selenium species in these oxidation states are: (1) -2: hydrogen selenide, sodium selenide, dimethyl selenide, dimethyl diselenide, selenomethionine, selenocysteine, selenohomocysteine, selenocystine; (2) 0: elemental selenium, selenenic acid, sodium selenate; (3) +4: selenium dioxide, selenious acid, sodium selenite; and (4) +6: selenium trioxide, selenic acid, sodium selenate. Some physical and chemical properties for elemental selenium, sodium selenate, and sodium selenite are shown in Table 30.1. Additional information for these and other chemical forms of selenium can be found in OEHHA (2010; ATSDR, 2003).

ENVIRONMENTAL FATE AND BIOACCUMULATION

The behavior of selenium in the environment is influenced by its oxidation state and the properties of the different chemical compounds (NAS, 1976). The oxidation state of selenium in the environment is dependent on ambient conditions, particularly on pH and microbial activity (Maier et al., 1988).

Selenium, found in nature, can complex with multiple compounds. It can be oxidized to form selenium dioxide, which may be expected at the soil surface. Selenates and selenites are water soluble and can be found in water. Because of their high solubility and low tendency to adsorb onto soil particles, the selenates (especially sodium selenate) are very mobile and are readily taken up by biological systems or leached through the soil. Most selenites are less soluble in water than the corresponding selenates (NAS, 1980). Organic selenium—selenomethionine, selenocysteine, and dimethyl selenides—can be found in plants.

TABLE 30.1 Physical and Chemical Properties of Elemental Selenium, Sodium Selenate, and Sodium Selenite

	Selenium	Sodium Selenate	Sodium Selenite
Synonyms	Elemental selenium, selenium homopolymer, selenium dust, colloidal selenium	Disodium selenate	Disodium selenite, disodium selenium trioxide, selenious acid disodium salt, sodium selenium oxide
CAS number (No.)	7782-49-2	13410-01-0	10102-18-8
Formula	Se	Na ₂ SeO ₄	Na ₂ SeO ₃
Molecular weight	78.96	188.94	172.95
Color	Metallic gray to black; hexagonal crystals	Colorless rhombic crystals	White tetragonal crystals
Physical state	Solid	Solid	Solid
Melting point	144 °C; 221 °C	No data	No data
Boiling point	685 °C	No data	No data
Density (g/cm ³)	4.81 (20 °C)	3.213 (17.4 °C)	No data
Water solubility	Insoluble	84 g/100 ml at 35 °C	Soluble

Selenium sulfides are not very water soluble and are therefore relatively immobile.

Transport and Partitioning. The volatile selenium compounds that partition into the atmosphere include the inorganic compounds, selenium dioxide and hydrogen selenide, and the organic compounds, dimethyl selenide and dimethyl diselenide. Hydrogen selenide is highly reactive in air and is rapidly oxidized to elemental selenium and water (NAS, 1976); other compounds can persist in air. Selenium compounds in the atmosphere can be removed by dry or wet deposition on soils or on surface water where the salts of selenic and selenious acids are the expected forms. Selenic acid (H₂SeO₄) is a strong acid and the soluble selenate salts of this acid are expected to occur in alkaline waters. Selenious acid (H₂SeO₃) is a weak acid, and the diselenite ion predominates in waters between pH 3.5 and 9.

In soils, pH and Eh are determining factors in the transport and partitioning of selenium. Elemental selenium is essentially insoluble and may represent a major inert “sink” for selenium introduced into the environment under anaerobic conditions (NAS, 1977). Heavy metal selenides and selenium sulfides, which are also insoluble, predominate in acidic (low pH) soils and in soils with high amounts of organic matter. They are immobile and will remain in the soil. The selenides of other metals such as copper and cadmium are of low solubility. Sodium and potassium selenites dominate in neutral, well-drained mineral soils. In alkaline (pH > 7.5), well-oxidized soil environments, selenates are the major selenium species.

Transformation and Degradation. Selenium dioxide released into the air from the combustion of fossil fuels is anticipated to be largely reduced to elemental selenium by sulfur dioxide formed during the combustion (NAS, 1977). Hydrogen selenide is unstable in air and is oxidized to elemental selenium and water (NAS, 1976). Hazards from hydrogen selenide are expected to be confined to occupational settings where the gas might build up to hazardous

levels despite oxidative losses. Dimethyl selenide and methyl selenide are volatile organic compounds that can partition into and persist in the atmosphere. In water, in general, the more soluble and mobile forms of selenium (e.g., selenite and selenate) dominate under aerobic (high oxygen concentrations) and alkaline (high pH) conditions.

Data from a simulated laboratory pond showed that bacteria and cyanobacteria have two possible mechanisms for the uptake and transformation of selenate (Bender et al., 1991). The uptake mechanism involves the reduction of selenate to elemental selenium that will be physically held within the biological mat. The microorganisms also caused the transformation of soluble selenium into volatile alkyl selenium compounds.

In soils, elemental selenium and inorganic selenium compounds such as sodium selenite can be methylated by microorganisms and subsequently volatilized into the atmosphere. In general, microorganisms appear to methylate organic selenium compounds more readily than either selenite or selenate (Maier et al., 1988). Demethylation of the trimethylselenonium ion can also occur in soil and microorganisms are evidently required for this reaction (Yamada et al., 1994).

Terrestrial plants take up soluble selenate and selenite and biosynthesize organic selenium compounds, predominantly selenomethionine and, to a lesser extent, selenocysteine. Selenates tend to be taken up by plants from soils more readily than selenites, in part because selenites tend to adsorb more strongly to soils (Dimes et al., 1988; Zhang et al., 1988). These compounds can be released to the soils once the plants die and decay. Water-soluble organic selenium compounds are also probably readily taken up by plants.

Bioaccumulation

Uptake by plants is influenced by factors such as soil type, pH, colloidal content, concentration of organic material, oxidation-reduction potentials in the root-soil environment,

and total level of selenium in the soil (Fishbein, 1983). Alkaline and oxidizing conditions favor the plant uptake of soluble forms of selenium and selenate is preferred over selenite (Banuelos and Meek, 1990). In acidic soils (pH 4.5–6.5), and under high moisture conditions, selenium is in the form of selenite bound to colloids as iron hydroxide selenium complexes, which are insoluble and generally not bioavailable to plants (Galgan and Frank, 1995). In basic soils (pH 7.5–8.5), selenium is present as soluble selenate (principally sodium selenate). Although much of the total selenium in soil may be present in other forms, sodium selenate appears to be responsible for most of the naturally occurring accumulation of high levels of selenium by plants (NAS, 1976). The use of lime and plant ash as fertilizers raises soil pH and favors selenate formation.

Selenium in an aquatic environment is bioaccumulated and bioconcentrated by aquatic organisms (Lemly, 1985; Ohlendorf et al., 1986a; Saiki and Lowe, 1987; Maier et al., 1988). Bioconcentration factors (BCFs) of 150–1850 and bioaccumulation factors (BAFs) of 1746–3975 for selenium in freshwater have been reported. Biomagnification is also evidenced by progressively higher concentrations of selenium in organisms at successively higher trophic levels.

ECOTOXICOLOGY

Anthropogenic activities, such as coal combustion, mining, petroleum refining, and irrigation of agricultural lands, have resulted in increased levels of selenium in some aquatic ecosystems. Selenium in the aquatic environment can accumulate in biota. In fish and wildlife, adverse effects from high exposure to selenium have been observed, including reduced reproduction, offspring deformities, mortality, and reduced populations (Lemly, 1998).

In California, accumulation of selenium in agricultural drainage waters led to high levels in evaporation ponds of the Kesterson National Wildlife Refuge in the San Joaquin Valley. More than 50% of that contained in sediments occurred in organic forms (Maier et al., 1988) resulting from the synthesis and bioaccumulation of organic selenium before the plants die and decay. Elevated levels of selenium were measured (dry weight) in algae (average 35 mg/kg), midge larvae (139 mg/kg), dragonfly and damselfly nymphs (average 122 and 175 mg/kg, respectively), and mosquito fish (170 mg/kg) (Ohlendorf et al., 1986b).

Acute Effects

Toxicity of selenium to aquatic organisms can be acute through water column exposure. Excessive selenium has resulted in deformities, reproductive impairment, death, and decreased populations in fish and waterfowl (Lemly, 1993). A dietary concentration of 4 µg/g dry wt. can adversely affect fish reproduction whereas a level below

about 0.1–0.5 µg/g dry wt. can cause nutritional deficiencies. Selenium concentration in fish eggs was found to be correlated with the incidence of deformities in larvae and magnitude of reproductive failure. Teratogenic effects included spinal deformities such as lordosis, kyphosis, and scoliosis, and head, mouth, and fin deformities; edema, exophthalmus and cataracts were also observed. Biologic effect thresholds for the health and reproductive success of freshwater and anadromous fish have been suggested for the whole body at 4 µg/g; skeletal muscle at 8 µg/g; ovaries and eggs at 10 µg/g; and liver at 12 µg/g.

Chronic Effects

Selenium toxicity can be chronic via food chain exposure. Often habitats that accumulate selenium best are eutrophic, with shallow slow-moving waters with low flushing rates, such as wetland or reservoirs (Simmons and Wallschlager, 2005). Toxic effects of selenium in the lentic (standing water) environment have been extensively studied in Belews Lake, North Carolina; Hyco Reservoir, North Carline; Martin Reservoir, Texas; Tulare Lake Basin, California; Sweitzer Lake, Colorado; and Kesterson Reservoir in California. In all of these cases, adverse effects resulting in reduced fish and avian populations were observed when waterborne concentrations of selenium exceeded 2–5 µg/l. The acceptable level is believed to be <1 µg/l (Lemly, 1996). In waterfowl, deformities were seen in hair, beak, feathers, and nails (O'Toole and Raisbeck, 1998).

Simmons and Wallschlager (2005) compared the selenium concentrations found in the water and diets of fish in lentic and lotic systems (flowing waters), and the biologic effects observed in fish in these locations. They found that low waterborne exposures in lentic environments often resulted in very high bioaccumulation in tissues, whereas comparable exposures in lotic environments tended to result in lower selenium accumulation. Diet appears to be a more reliable predictor of tissue concentration rather than waterborne exposures, indicating the importance of the transfer of organic selenium through trophic interactions but not bioconcentration from environmental compartments. There is no conclusive evidence that any other dissolved selenium species besides selenite and selenate exist in freshwater. Organic species, such as dimethylselenide, have been reported in natural waters, but they usually constitute a very small fraction of the total selenium and their volatility would suggest that they would escape the water column rapidly.

MAMMALIAN TOXICOLOGY

Acute Effects

In humans and animals, the respiratory tract is the primary site of injury following inhalation exposure to selenium.

Human data are mostly obtained from occupational exposures, and only acute exposure studies were found in animals. Inhalation data are available for elemental selenium, selenium dioxide, selenium oxychloride, hydrogen selenide, and dimethyl selenide but most are on multiple chemical exposures (ATSDR, 2003).

The chemical forms of selenium most likely encountered in air in occupational settings are elemental selenium dusts, selenium dioxide, and hydrogen selenide. Following occupational exposures, in addition to respiratory tract effects, gastrointestinal and cardiovascular effects, and skin and eye irritation also occurred. Acute inhalation of selenium dusts resulted in irritated mucous membranes in the nose and throat and produced coughing, nosebleed, loss of olfaction; high exposures produced dyspnea, bronchial spasm, bronchitis, and chemical pneumonia. Selenium dioxide is formed when selenium is heated in air. Selenium forms selenious acid on contact with water, including respiration, causing severe irritation if inhaled. Acute high level exposure to selenium dioxide powder can produce pulmonary edema (following irritation to alveoli), bronchial spasms, asphyxiation symptoms, and bronchitis. Hydrogen selenide and selenium oxychloride are highly toxic. Hydrogen selenide is a gas at room temperature. Selenium oxychloride hydrolyzes to hydrogen chloride, which can then form hydrochloric acid in humid air and in the respiratory tract where it can be very irritating and corrosive.

Workers acutely exposed to selenium dioxide fumes from a fire for, at most, 20 min reported symptoms of shock, including lower blood pressure and elevated pulse rates, which were normalized in 3 h after treatment with oxygen and inhalation of ammonia vapor. Vomiting and nausea were also reported. Stomach pain was reported by workers, in a selenium rectifier plant, exposed to elemental selenium and selenium dioxide. Minimal information was found in the literature on neurological effects, but it included reports of frontal headache by workers exposed to high concentration of selenium of unknown identity for about 2 min.

In experimental animals (rats, rabbits, guinea pigs), acute exposure to selenium fumes or dust (33 mg/m^3) resulted in respiratory effects, including hemorrhage and edema of the lungs, interstitial pneumonitis, congestion, and emphysema. Death was also reported. Acute inhalation of guinea pigs to hydrogen selenide (8 mg/m^3 , 8 h) produced diffuse bronchopneumonia and pneumonitis. Dimethyl selenide at much higher concentrations ($25,958 \text{ mg/m}^3$) produced minor effects (increased lung and liver weight) in rats after 1 day of exposure. Hepatotoxicity observed as slight liver congestion and mild centrilobular atrophy were reported in rats exposed to elemental selenium dust for 8 h, and in guinea pigs exposed to elemental selenium dust for 4 h/day, for 8 days, both at 33 mg/m^3 .

Dermal exposure to selenium dioxide or selenium oxychloride may produce skin burns (IPCS, 2001). Selenium

dioxide is a primary irritant and it causes extremely painful burns on the skin, which always heal without a scar. Although, theoretically, the selenium dioxide powder itself does not burn the skin (and if dropped on the skin, it should be immediately brushed off dry), in practice, in the industrial environment, there is sufficient moisture on the skin from sweating to be taken up by this white solid to form a sticky solution of selenious acid within seconds, or at the most, minutes of coming into contact with the skin. After skin exposure to a 50% solution of selenious acid, signs such as unremitting intense pain, red and swollen skin, blisters develop within several hours, which may be followed by ulcerations. Dermal exposure to selenium oxychloride causes vesicles. Nasal discharge, loss of smell, epistaxis have been described after dermal exposure to selenium dust.

Data on oral exposures to selenium in humans and animals have been compiled for elemental selenium dust, selenium dioxide dissolved in water (selenious acid), sodium selenate, sodium selenite, potassium selenate, and dietary selenium compounds, including selenoamino acids (ATSDR, 2003). Most of the available toxicity information reviewed for oral exposures to selenium compounds comes from domestic or experimental animal studies with exposures to selenite, selenate, selenium sulfides (mixed), and organic forms (selenocystine, selenomethionine). Few acute studies were identified, as the majority of the studies reported were intermediate (weeks to months) and long-term studies.

In animal studies, oral LD₅₀s in the range of 1–12 mg/kg were reported for sodium selenite in rats, mice, guinea pigs, and rabbits (ATSDR, 2003). The minimum oral fatal dose in rats was 6700 mg/kg for elemental selenium. Rats administered selenium sulfide by gavage at the lethal level were reported to have diarrhea and anorexia. Single gavage doses of selenium monosulfide to rats produced death and widespread hepatic necrosis at 75–100 mg/kg.

For acute oral exposures in animals (14 days or shorter), systemic effects have been reported following exposure to selenium (ATSDR, 2003). These include the following: mouse: hematological, hepatic, renal, dermal, immuno/lympho, neurological, death; rat: body weight, death; pig: body weight, neurological; hamster: developmental; guinea pig, rabbit: death.

In humans, acute poisoning with selenium and its compounds is rare, especially fatal poisonings; however, death has occurred following accidental (including errors in manufacturing) or suicidal overdoses. The approximate selenium intake resulting in acute toxicity is reported to be up to 250 mg selenium as a single dose or 27–31 mg as multiple doses (SCF, 2000). Typical chronic selenosis symptoms such as hair and nail changes and loss were noted in some (e.g., U.S. supplements cases) but not all cases.

In 2008, an episode of selenium toxicity caused by a misformulated commercially distributed dietary supplement

resulted in the recall by U.S. Food and Drug Administration (FDA) and the manufacturer of 1000 bottles of the supplements that the FDA found to contain selenium at levels up to 200 times greater than the amount stated on the label or up to 40,800 µg per recommended serving (Sutter et al., 2008; U.S. FDA, 2008; MacFarquhar et al., 2010). Ten of the 16 states that received distributions reported cases of selenium toxicity. Symptoms of selenium poisoning can include significant hair loss, muscle cramps, nausea, vomiting, diarrhea, joint pain, fatigue, fingernail changes, and blistering skin. Patients reported that symptoms typically occur within 5–10 days after daily ingestion of these supplements begins. After discontinuing use of the product, the symptoms of selenium toxicity may last for several weeks but improve eventually without treatment for the poisoning. There is no proven antidote or curative treatment for selenium poisoning. A case definition would involve two or more of the following symptoms, such as hair loss, muscle or joint pains, fingernail discoloration or changes, headache, foul breath, weakness, gastrointestinal symptoms (such as nausea, vomiting, diarrhea, or abdominal pain), rash, oliguria/anuria or abnormal renal function tests, jaundice or abnormal liver function tests, anemia or hematological changes, that occurred within 2 weeks of ingesting a dietary supplement manufactured in the United States exclusively for the specific manufacturer. It was noteworthy that there was an array of nonspecific symptoms making the diagnosis difficult as selenium toxicity is rare. For example, 23% of the patients reported fever, a symptom not previously associated with selenium toxicity, and it could not be conclusively determined that selenium toxicity was the cause. Patients often continued to experience symptoms for 90 days for hair and nail changes, and constitutional symptoms such as memory loss, mood swings, fatigue, musculoskeletal complaints, and garlic breath. Selenium is sequestered in different organ tissues, and its slow metabolism accounts for the persistence of symptoms. An earlier report suggested that forced vomiting soon after ingestion of selenate may be helpful as in the case of survival of a patient in New Zealand (Civil and McDonald, 1978).

Chronic Effects

Animals For intermediate oral exposures in animals (15–364 days), systemic effects have been reported following exposure to selenium (ATSDR, 2003). These include the following: rat: hematological, cardiovascular, hepatic, renal, endocrine, metabolic, immune/lympho, developmental, body weight, death; mouse: cardiovascular, hepatic, renal, reproductive, developmental, body weight, death; pig: cardiovascular, musculoskeletal, hepatic, dermal, body weight, neurological, reproductive; rabbit: cardiovascular; monkey: gastrointestinal; cow: dermal; monkey: body weight, neurological, reproductive.

For chronic oral exposures in animals (365 days or longer) (ATSDR, 2003), most of the data on systemic effects have been conducted in mice; effects reported include respiratory, cardiovascular, hepatic, renal, endocrine, and dermal. Hepatic effects and death were reported in rats.

Hepatic The liver has long been recognized as a primary target of selenium toxicity in the pioneering studies carried out in the seleniferous areas of the United States, where intoxicated individuals showed signs such as icteroid discoloration of the skin and a history of jaundice and frank hepatitis (Smith and Westfall, 1936; Smith and Westfall, 1937) and of cirrhosis (Lemley and Merryman, 1941) though the latter observations were less clearly related to selenium intoxication. Subsequent studies carried out in the seleniferous regions of China and the United States have shown biochemical abnormalities of uncertain clinical significance apparently related to liver function, i.e., an increased prothrombin time (Yang et al., 1989a) and serum level of alanine aminotransferase (Longnecker et al., 1991), an observation of interest due to the increased activity of this enzyme observed in selenite-exposed rats (Coudray et al., 1996). The direct correlation between alanine aminotransferase and dietary selenium intake found in the former study carried out in South Dakota and western Wyoming, in particular, was not associated with enzyme levels exceeding the “normal range” (Longnecker et al., 1991). In the study in China, increased prothrombin time was clearly detected in subjects having blood selenium concentrations exceeding 1000 µg/l, corresponding to a daily intake of around 850 µg, but a correlation between prothrombin time and selenium blood levels was not reported by the authors at lower selenium exposures. In a study carried out in adults with prostate cancer supplemented for 12 or more months with 1600 or 3200 µg/day of organic selenium, increased blood total bilirubin and alkaline phosphatase levels in subjects receiving the highest dose were observed, while glutamic pyruvic and glutamic oxaloacetic transaminases were not increased; all blood analytical determinations were within the “normal range” (Reid et al., 2004). In this study, however, there were no comparisons with individuals receiving placebo, and no measurements of prothrombin time or alanine aminotransferase were made. In an investigation carried out in U.S. communities with different levels of exposure to selenium (likely in an inorganic form) through drinking water, no excess prevalence of “liver disease” was found (Valentine et al., 1987). On the other hand, no analysis of liver function and disease in individuals occupationally exposed to selenium has been reported, with the exception of the observation of acute hepatitis with pathologic signs of steatosis, localized liver necrosis, sinusoidal hyperplasia, and elevations of serum transaminases following acute intoxication with selenious acid (Pisati et al., 1988). Overall, epidemiologic and clinical evidence points to the occurrence of hepatotoxicity following

selenium overexposure, but available data that would clearly substantiate this association are limited.

Dermatological The effects on skin and related annexes were considered among the first “markers” of selenium toxicity when the pioneering studies on toxicity of environmental selenium were carried out in U.S. adults (Smith and Westfall, 1936; Smith and Westfall, 1937; Manville, 1939; Lemley, 1940) and in Venezuelan children (Jaffe et al., 1972). Among these effects were dermatitis, skin eruptions and depigmentation, diseased fingernails, and hair loss (Jaffe et al., 1972). Nails of intoxicated subjects, in particular, were atrophic, brittle, and irregular, with frequent occurrence of ridging. Interestingly, Lemley and Merryman (1941) were able to treat the signs and symptoms of selenium intoxication by administering bromobenzene to an affected patient to increase selenium clearance from the body, with immediate relief and recovery of the patient (Lemley and Merryman, 1941). In the seleniferous areas of Venezuela, high intake of selenium through consumption of “Coco de Mono” nuts (*Lecythis ollaria*) has long been shown to be accompanied by gastrointestinal and neurological signs and, in particular, extensive hair loss from several body components (scalp, axillae, chest, abdomen, pubic), loss of eyebrows and eyelashes, and nail streaking and breaking (Kerdel-Vegas, 1966). In studies carried out in the seleniferous areas of Enshi County, Hubei province in central China, a wide spectrum of hair, nail, and skin abnormalities related to selenium exposure was observed (Yang et al., 1983; Yang et al., 1989a; Fordyce, 1995). The hair of selenium-intoxicated individuals was dry and brittle and easily fell from the scalp and other body parts (Yang et al., 1983), making alopecia an extremely common sign in affected individuals (Fordyce, 1995). Nails tended to be brittle, fragile, irregular, and atrophic, with white spots on their surfaces and a clear tendency to drop off. These dermatological abnormalities were ascribed to daily selenium intake ranging from 1500 to 5000 µg/day though nail brittleness was detected in a subsequent study following supplementation with 600 µg/day of selenium (Yang et al., 1989a). Selenium-induced dermatological alterations have also been documented in some seleniferous area of rural Punjab, where consumption on an average of over 600 µg/day of selenium was associated with hair and nail loss and a wide pattern of nail abnormalities such as blackening, breaking, and streaking (Hira et al., 2004). In contrast, no relation between dermatological signs and selenium exposure was detected in seleniferous areas of South Dakota and Wyoming (Longnecker et al., 1991).

The dermatologic toxicity of selenium was actually demonstrated in a U.S. trial, named “SELECT,” that was carried out to test possible beneficial effects of selenium on reducing the risk of prostate and other cancers. The trial was terminated before completion due to the lack of efficacy on primary end points and an increased diabetes incidence

among supplemented subjects (Lippman et al., 2009). In that study, dietary supplementation of 200 µg/day selenomethionine in free-living individuals, with an attributable average “background” dietary selenium intake of around 100 µg/day, induced dermatitis and alopecia, with an increased incidence of 17–74% in comparison with placebo-receiving subjects. This study was not only a “controlled” demonstration that long-term administration of selenium induced dermatological effects, but, more importantly, it showed that such effects occurred at doses previously considered to have no adverse effects by some investigators (Yang et al., 1983; Longnecker et al., 1991), i.e., around 300 µg/day (for organic selenium, considered less toxic than the inorganic forms of the element). This dermal effect level of exposure can easily be achieved by subjects living in seleniferous areas, working in an occupationally exposed environment, or self-supplementing with high doses of selenium compounds.

Investigations carried out in workers exposed to high levels of environmental selenium also showed an excess prevalence of dermatological abnormalities such as skin eruptions, redness and burns, generalized allergic body rash, nail pain (Glover, 1970; Rajotte et al., 1996), hair loss, and deformed nails (Srivastava et al., 1995), although not all studies have consistent findings (Holness et al., 1989). Also, acute and subacute selenium intoxications have been characterized by dermatological signs and symptoms such as extensive onycholysis, Mees lines and discoloration in nails, extensive hair loss and discoloration (Schuh and Jappe, 2007; Sutter et al., 2008; Lopez et al., 2010; MacFarquhar et al., 2010; Muller and Desel, 2010; Fitzgerald et al., 1997), and erythema of the hands (Pisati et al., 1988).

Overall, the epidemiologic evidence strongly indicates that selenium exposure in humans induces adverse effects on skin and its annexes, hair and nails, and that such signs and symptoms represent early and in some cases rather selective indicators of selenium toxicity. Evidence from the recent large trial carried out in the United States described above also demonstrated that the amount of selenium required to exert such effects is much lower than previously considered.

Caries The possibility that exposure to environmental selenium may enhance the risk of dental caries has been suggested by early field studies carried out in the seleniferous areas of the United States. These include earlier investigations (Smith and Westfall, 1936) and subsequent investigations specifically carried out to test this association in Oregon and Wyoming (Hadjimarkos, 1965; Hadjimarkos, 1968), plus those in the eastern United States (Ludwig and Bibby, 1969). The results of these studies have confirmed an association between dental caries and environmental selenium in children, possibly indicating a direct effect of the metalloid in increasing susceptibility of children to caries. These observations are corroborated by studies carried out in the seleniferous regions in India (Gauba et al., 1993) but not in

Venezuela (Jaffe et al., 1972) or occupationally exposed individuals (Rajotte et al., 1996), while findings in selenium-intoxicated individuals in China were equivocal (Yang et al., 1983). Overall, the association between selenium and caries is suggestive, but not established, and it needs to be further investigated. It is worth noting that animal studies have provided biological plausibility of an association between selenium overexposure and dental caries (Buttner, 1963; Shearer, 1975).

Neurological The first association between selenium exposure and neurological effects was seen in the early observations in animals in the seleniferous areas of the United States, which documented in livestock a wide spectrum of signs such as wandering, stumbling, blindness, ataxia, disorientation, generalized paralysis, and eventually death due to respiratory failure (Rosenfeld and Beath, 1964; Fan and Kizer, 1990). In humans, chronic selenium exposure has been subsequently linked to a wide spectrum of neurological signs and symptoms, mainly on the basis of studies carried out in selenium-intoxicated individuals living in the seleniferous areas of China (Yang et al., 1983; Fordyce, 1995). Observations in heavily selenium-intoxicated individuals from the seleniferous Enshi region in China showed the occurrence of several neurological signs and symptoms such as peripheral anesthesia, acroparaesthesia, pain to the extremities, tendon hyperreflexia, numbness, convulsions, motor disturbances, and hemiplegia (Yang et al., 1983). These observations, however, were confined only to residents in one heavily contaminated community, with a prevalence of clinically recognized selenosis exceeding 80% (Yang et al., 1983). Unfortunately, Yang et al. (1983) did not mention details of key epidemiologic relevance such as the overall extent of villages and individuals investigated in the survey and the prevalence of signs and symptoms ascribed to selenium exposure in unaffected (control) communities, thus hampering the estimation of the health risks actually attributable to the exposure to environmental selenium. Fordyce (1995), a British geologist who visited the Enshi seleniferous areas in 1995, reported that, on the basis of investigations by local public health officials, the occurrence of various symptoms (paralysis, lack of strength in limbs, and tingling limbs) ranged from 2 to 5% of the 180 individuals sampled from selenium-intoxicated communities in the Enshi area.

The key association between selenium exposure and neurological diseases is related to a rare but extremely severe, neurodegenerative disease involving motor neurons, amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease or motor neuron disease. The first indication of such an association dated back to a 1977 report in JAMA by a physician in private practice and a Harvard neurologist who described the occurrence of a cluster of ALS cases in a sparsely populated South Dakota region, known to be characterized by naturally occurring selenium intoxication in

livestock (Kilness and Hochberg, 1977). The etiological significance of this finding was strongly debated for some time (Kurland, 1977; Norris and U, 1978), and limited attention was given to this observation, despite the detection in some studies of higher selenium levels in body tissues of ALS patients (Mitchell et al., 1991; Ince et al., 1994). Interest in the potential relationship was renewed when an excess ALS incidence was detected in an Italian cohort of consumers of drinking water with a selenium content of 8 µg/l (Vinceti et al., 1996), an observation recently confirmed by a case-control study carried out in the same area in a subsequent period (Vinceti et al., 2010).

Besides these epidemiological studies, the plausibility of a selenium-ALS causal relationship found suggestive support in animal studies, particularly those showing that selenium compounds induce selective degeneration of motor neurons in swine (Panter et al., 1996; Nathues et al., 2010; Raber et al., 2010) and possibly cattle (Maag et al., 1960) and horses (Polack et al., 2000). Under this perspective, selenium appears to be the only substance so far identified with a toxicity highly specific for the motor neurons, an observation of strong interest since the human disease ALS is characterized by a selective degeneration of the motor neurons. Furthermore, selenium compounds have been shown to induce *in vitro* selective biochemical abnormalities in neurons such as increased production of inducible nitric oxide synthase, reactive oxygen species (ROS) and 3-nitrotyrosine, as well as type-1 superoxide dismutase translocation into mitochondria; these effects may occur at a concentration as low as 8 µg/l of Se as selenite (Maraldi et al., 2011). Thus, selenium, particularly in its inorganic form, remains under strict scrutiny as a potential risk factor for induction of ALS. Paradoxically (but not unexpectedly due to the extremely controversial "history" of this metalloid in the health fields), selenium has also been proposed in the therapy of this disease as a putative "antioxidant" agent, with null results (Orrell et al., 2008).

Selenium has also been reported to be associated with Parkinson's disease though data are still sparse and unconvincing. In a case-control study, much higher selenium levels in both serum and cerebrospinal fluid were detected in Parkinson's patients compared with controls, irrespective of the clinical response to L-dopa therapy (Qureshi et al., 2006). In a cohort study examining mortality patterns in individuals with long-term consumption of drinking water containing an unusually high content of inorganic hexavalent selenium, mortality from Parkinson's disease was strongly increased in men, but not in women, though the risk estimates were statistically very unstable due to the limited size of the population under study (Vinceti et al., 2000b).

In workers exposed to selenium, the incidence of dizziness and particularly paresthesia was found to be considerably increased compared with controls (Holness et al., 1989), and an association between occupational exposure to selenium and headache was suggested by one study (Srivastava

et al., 1995), but not by a subsequent one (Rajotte et al., 1996). In a survey among U.S. consumers of drinking water with selenium content ranging from 194 to 494 µg/l compared with control subjects consuming drinking water with Se content around 2–3 µg/l, Valentine et al. found higher rates (6% vs. 1%) of diseases that were grouped in the general category of “diseases of nerves, paralysis or numbness, etc.,” as well as a higher prevalence of depression (18% vs. 11%) and dizziness (22% vs. 10%) (Valentine et al., 1987).

Overall, available epidemiological data indicate that selenium may actually induce neurological abnormalities consisting of different signs and symptoms, with suggestive evidence linking selenium intake to a specific neurological disease, ALS. Since selenium neurotoxicity has been demonstrated in animal and *in vitro* studies (Nehru and Iyer, 1994; Panter et al., 1996; Nehru et al., 1997; Gupta and Porter, 2002; Casteignau et al., 2006; Xiao et al., 2006; Morgan et al., 2010; Maraldi et al., 2011), the possibility of a link between selenium and neurotoxicity in humans appears plausible. Under this perspective, inorganic selenium compounds appear to exert a much stronger neurotoxicity than the organic forms, as shown in experimental studies (Ammar and Couri, 1981; Tsunoda et al., 2000; Nogueira et al., 2003).

Reproductive/Developmental Toxicity The possibility that selenium increases the risk of birth defects in humans has long been suspected, mainly on the basis of observations in livestock in the seleniferous areas and of experimental studies (Willhite, 1993; Usami and Ohno, 1996), but studies in humans on this topic are limited and such evidence has not been substantiated in humans. The first observations on this issue were anecdotal reports of birth defects in a seleniferous area from Colombia (Jaffé and Vélez, 1973) and in female workers occupationally exposed to selenite (Robertson, 1970).

More recently, a few studies have examined, among other outcomes, the teratogenic effects of exposure to selenium. Fan et al. (1988) investigated exposure and health effects in a population potentially exposed to high levels of environmental selenium in the Kesterson National Wildlife Refuge area in northern California (where waterfowl deformities from high selenium exposure were found) and did not observe adverse outcomes, including birth defects. Vinceti et al. (2000) investigated the risk of birth defects, reduced fetal growth, and miscarriage among women exposed and unexposed to drinking water with a selenium content of 8 µg/l (Vinceti et al., 2000a). In that investigation, no evidence of alterations in body weight and length was apparent in 18 newborns to women consuming the high selenium drinking water, neither an excess prevalence of birth defects emerged among 353 newborns in exposed women during a 9-year period, compared with 14,481 control births. A statistically imprecise excess of clubfoot, however, was detected (2 observed cases vs. 0.51 expected), suggesting the need to further investigate this issue, also considering the

previous observation in an occupational environment (Robertson, 1970). The risk of miscarriage among exposed women, which was examined only for 1 year, increased compared to that experienced by unexposed women, though its estimate was statistically very unstable (relative risk 1.73, 95% confidence interval (CI) 0.62–4.80). Overall, the limited study size precluded an accurate estimation of the reproductive effects of such selenium exposure though no major changes in risk of birth defects were evident, and an indication of excess risk of miscarriage emerged. Two case-control studies were carried out in Massachusetts that aimed at identifying the possible association between drinking water chemical composition and adverse pregnancy outcomes (Zierler et al., 1988; Aschengrau et al., 1993). In one study, selenium levels in drinking water were strongly associated with excess risk of integument defects and to a reduced risk of nervous system defects (Aschengrau et al., 1993). In the other investigation, Zierler et al. detected an inverse relation between the drinking water selenium concentrations and risk of congenital heart defects (Zierler et al., 1988).

A possible influence of selenium on semen quality has also been the subject of scientific interest though the observational and intervention studies carried out on this subject yielded conflicting results. Hawkes et al. found that the supplementation with 297 µg/day selenium for 99 days was associated with a reduction in sperm motility of 18%, along with adverse effects of selenium supplementation on thyroid status (decreased serum triiodothyronine and increased thyroid-stimulating hormone levels), two findings of concern also due to the low amounts of additional exposure implicated (Hawkes and Turek, 2001). However, a subsequent study was unable to replicate the occurrence of adverse effects of selenium supplementation on sperm motility, and more generally semen quality, after long-term selenium supplementation (Hawkes et al., 2009). Other experimental and observational human studies have yielded mixed results though no clear pattern of adverse effects emerged (Keskes-Ammar et al., 2003; Akinloye et al., 2005; Wirth et al., 2007; Safarinejad and Safarinejad, 2009).

Overall, the epidemiologic evidence suggesting a relation between selenium and the reproductive health remains elusive and uncertain, and large studies on this issue, focusing among other outcomes on the risk of miscarriage, are clearly needed.

Diabetes The possibility that overexposure to selenium may favor the development of diabetes was first suggested in 1948 following the observation that a chemist acutely intoxicated with hydrogen selenide developed diabetes (Gouffaute, 1948), and the subsequent demonstration in rabbits of a strong diabetogenic effect of selenite (Danon et al., 1963). However, this association was overlooked for several years until the report by Stranges and coworkers published in 2007, which examined diabetes risk as a

secondary end point of a trial in nonmelanoma skin cancer patients carried out in the United States. During nearly 7 years of follow-up of 1202 patients, 58 subjects supplemented with 200 µg/day of organic selenium and 39 placebo-treated subjects were newly diagnosed with type 2 diabetes, yielding a relative risk of 1.55 (95% CI 1.03–2.33) in the treated group. A direct association between baseline selenium plasma levels and excess diabetes risk associated with selenium supplementation also emerged. Such observations immediately led to a strong concern about the possibility that supplementation with 200 µg/selenium, within a population likely characterized by a dietary intake of around 100 µg/day, could be dangerous (Bleys et al., 2007a, 2007b; Marcason, 2008), contrary to what was previously expected on the basis of some earlier studies and expert committees (Yang et al., 1989a; Yang and Zhou, 1994; NAS, 2000; Norden, 2004). This report was accompanied or followed by large cross-sectional and cohort studies aimed at clarifying the possible relation between selenium and the risk of diabetes and/or related metabolic abnormalities, the results of which supported in all cases such an association (Czernichow et al., 2006; Bleys et al., 2007a, 2007b; Gao et al., 2007; Laclaustra et al., 2009; Lippman et al., 2009; Arnaud et al., 2012; Stranges et al., 2010; Yang et al., 2010), except for one case (Akbaraly et al., 2010). The support of a diabetogenic effect of selenium came, in particular, from an additional experimental investigation carried out in the United States, the *Selenium and Vitamin E Cancer Prevention* (SELECT) trial (Lippman et al., 2009). SELECT was a randomized, placebo-controlled intervention study that aimed at evaluating a possible activity of selenium in preventing cancer and other chronic diseases. It was terminated due to the lack of any activity against prostate cancer or other diseases under investigation, as well as due to an excess risk from diabetes in supplemented individuals (relative risk 1.07, 99% CI 0.94–1.22) (Lippman et al., 2009). Thus, both the selenium trials so far carried out have shown an enhanced risk of diabetes among U.S. residents who received long-term supplementation of a daily dose of 200 µg of organic selenium, providing evidence that such an association was causal. The observational prospective studies also indicated that the amounts of selenium intake enhancing diabetes risk may be considerably lower than those implicated in the above trials that started at around 50 µg/day, thus providing evidence to decrease the allowed highest “safe” dose of dietary selenium (Stranges et al., 2010) and raising a great concern on the toxicity of this metalloid. Interestingly, a cohort study carried out in Rotterdam showed an excess diabetes risk among high consumers of fish, which is an excellent source of dietary selenium (van Woudenberg et al., 2009). The authors stated that higher selenium intake could have been a cause of such excess diabetes risk, also considering that the adjustment for selenium intake in multivariate analysis decreased the association between fish intake and subsequent

diabetes risk. Selenium intake has also been linked to increased concentrations of total and LDL cholesterol in the U.S. adult population (Bleys et al., 2008; Laclaustra et al., 2010), further suggesting a deleterious effect of even low amounts of this metalloid on the metabolic profile in humans.

These observations arising from epidemiologic studies have led to a careful scrutiny of the biological plausibility of such an association, recently reviewed and currently under active investigation (Steinbrenner et al., 2011). First, selenium compounds have been shown to induce several derangements of glucose homeostasis and metabolism (Rasekh et al., 1991; Potmis et al., 1993; Furnsinn et al., 1996) though not all studies have been consistent (Gronbaek et al., 1995; Sheng et al., 2005). Furthermore, studies conducted in plants (Malik et al., 2011) and in fish (Miller et al., 2009) have demonstrated that selenium exposure increases glucose concentrations and production under different experimental conditions. In addition, recent animal studies suggested that overexpression of selenium-dependent glutathione peroxidase represents a potential trigger of insulin resistance, hyperinsulinemia, and obesity, thus providing additional biological plausibility to a relation between selenium exposure and the risk of diabetes (McClung et al., 2004; Wang et al., 2008; Pepper et al., 2011).

Overall, evidence from both epidemiologic and laboratory studies indicates that selenium exposure, even at levels considerably lower than the approximate intake of 300 µg/day, which characterizes overall intake in the two randomized trials carried out in the United States, is associated with derangements of glucose homeostasis and an excess diabetes risk, supporting the conclusion that glucose metabolism may be a major target of selenium toxicity in humans.

Endocrine The possibility that selenium has deleterious effects on the endocrine system, apart from the above-mentioned possible effects on sperm quality and on the increased diabetes risk in particular, has been suggested by some studies originally performed in the seleniferous areas. In a pioneering study carried out in Venezuela, Brägger and Negretti de Brägger observed an inverse association between serum triiodothyronine and two indicators of selenium exposure, dietary intake and serum levels, defined as “significant” at amounts of dietary selenium of about 350 µg/day. More recently, a number of human studies have suggested deleterious effects on thyroid hormone status of both acute (Hofbauer et al., 1997) and chronic selenium exposure (Contempre et al., 1992; Thilly et al., 1992; Ramaekers et al., 1994; Calomme et al., 1995; Duffield et al., 1999). Supplementation of selenium to children with iodine deficiency and to phenylketonuria patients decreased thyroxine levels (Contempre et al., 1992; Thilly et al., 1992; Ramaekers et al., 1994; Calomme et al., 1995), and similar effects were observed in studies carried out in Italy (Olivieri et al., 1995) and New Zealand (Duffield et al., 1999; Thomson

et al., 2005). On the contrary, other studies failed to show any association between administration of 100 µg of selenomethionine for 60 days (Roti et al., 1993) or 90 days (Thomson et al., 2009) and changes of thyroid hormones status in euthyroid individuals. Overall, though conflicting results of the epidemiologic studies preclude definitive conclusions on the relation between selenium and thyroid hormones, it appears that overexposure even to low doses of selenium may adversely affect circulating levels of triiodothyronine and thyroxine in particular, and this might occur only in susceptible populations.

Selenium administration has also been associated with reversible inhibition of growth hormone secretion and irreversible suppression of insulin-like growth factor-1 by Danish investigators on the basis of some animal studies (Thorlacius-Ussing et al., 1987; Thorlacius-Ussing et al., 1988) and following the results of an experimental human study (Thorlacius-Ussing et al., 1989), in which patients with rheumatic disease were randomized to receive 256 µg/day of organic selenium or placebo for 6 months. Such observations raised a concern about the safety of the metalloid, but two subsequent observational studies (Salbe et al., 1993; Maggio et al., 2010) and one additional trial in humans (Meltzer and Haug, 1995) had been unable to confirm an association between organic selenium and growth hormone or insulin-like growth factor-1 inhibition. Such potential relations remain therefore elusive, and additional human studies are clearly needed to elucidate the possible induction of growth retardation by selenium by interfering with growth hormone secretion and activity (Vinceti et al., 2001).

Carcinogenicity The relation between selenium intake/exposure and cancer risk has been the subject of a large body of controversial, promising, and ultimately disappointing literature, with evidence from both epidemiologic and clinical studies ranging from the cancer-enhancing effect to preventive or therapeutic activities of the metalloid (Fan and Kizer, 1990; Clark and Alberts, 1995; Vinceti et al., 2000c; Letavayova et al., 2006; Brozmanova et al., 2010; Dennert et al., 2011). Though the occurrence of controversies on this issue is by no means unexpected due to the usual intriguing and conflicting results of selenium research on most health outcomes, the relation between this metalloid and cancer has generated an enormous body of interest during recent decades, followed by strong disappointment due to the negative results of a large intervention study carried out in the United States, the SELECT trial (Gann, 2009; Lippman et al., 2009).

Presently, the carcinogenicity of selenium compounds is still uncertain, since no substantial reassessment of this issue has been made in most recent years, despite the very large number of human and animal studies published on this topic in the latest two decades (Vinceti et al., 2000c; Lippman et al., 2009). According to major regulatory agencies or scientific bodies, selenium compounds are classifiable as members of

Group 3 by IARC (“Not classifiable as to its carcinogenicity to humans) and, in the form of selenium sulfide and selenium disulfide, as probable human carcinogens by the U.S. Environmental Protection Agency (EPA). Further substantial update of this topic by major regulatory agencies appear to be warranted by recent animal studies that have demonstrated the potential carcinogenicity of selenium compounds (Birt et al., 1989; Woutersen et al., 1999; Chen et al., 2000; Su et al., 2005) and by the substantial advancement of our knowledge of the biological activities of selenium.

The hypothesis of a cancer-preventing effect of selenium on human cancer has been substantially generated by ecologic investigations documenting inverse correlations between average soil selenium content and cancer death rates (Shamberger and Frost, 1969; Clark et al., 1991) and by a randomized trial carried out in the United States (Clark et al., 1996), coupled with laboratory data showing the ability of the metalloid to counteract cancer growth (Jackson and Combs, 2008). The clinical trial, in particular, randomized from 1983 through 1991 a group of 1312 patients in the eastern United States with a history of nonmelanoma skin cancer to receive either 200 µg/day of organic selenium or placebo until the end of the blinded period of treatment February 2, 1996, thus accumulating 9301 person-years of follow-up (Clark et al., 1996; Duffield-Lillico et al., 2002; Duffield-Lillico et al., 2003). This study did not document any beneficial effect of selenium supplementation on the primary end points, i.e., incidence of basal and squamous cell carcinomas of the skin, and it was even eventually associated with an increase in the latter skin cancer type and in overall skin cancer incidence (Duffield-Lillico et al., 2003). However, analysis of secondary end points showed among selenium-supplemented individuals a strong decrease in risk of all cancers and some site-specific cancers such as prostate and colon cancer (Clark et al., 1996; Duffield-Lillico et al., 2002). These findings, along with the new biochemical observations documenting the nutritional importance of selenium and the associated claims of its “antioxidant” properties, generated enormous interest on the metalloid and favored consumption by the general population of selenium-containing supplements, as well as implementation of several observational and experimental epidemiologic studies and laboratory investigations (Vinceti et al., 2000c; Lippman et al., 2009).

The previously mentioned SELECT trial, in particular, followed nearly 35,000 individuals from the United States, Canada, and Puerto Rico to assess if daily supplementation with 200 µg organic selenium in the form of *L*-selenomethionine could decrease the risk of prostate cancer as well as of other cancers. The study, started in July 2001, was unexpectedly discontinued in October 2008 long before its anticipated end date (2013) due to the lack of any effect in preventing cancer, as well as the excess incidence of diabetes in the 8752 supplemented subjects. Its findings have demonstrated that no

positive effect in cancer prevention can be ascribed to selenium (Allen and Key, 2009), causing large disappointment in the public and the scientific world (Gann, 2009). Actually the relative risk of prostate cancer in the supplemented individuals was 1.04 (95% CI 0.90–1.18), and slight increases in risk were seen also for colorectal cancer (1.05, 99% CI 0.66–1.67) and lung cancer (1.12, 99% CI 0.73–1.72). In 2014, the SELECT investigators also reported that selenium supplementation increased the risk of high-grade prostate cancer, yielding a relative risk of 1.91 (95% CI 1.20–3.05) for individuals treated with selenium or selenium plus vitamin E supplements compared with placebo (Kristal et al., 2014). Attempts to attribute these null results to the chemical form of selenium or to the selenium status of the supplemented subjects have been subsequently made, but such objections appear to have little basis since the species of selenium used was the same (and in the same amount) as previously used in the trial showing strongly beneficial effects in skin cancer patients (Clark et al., 1996), and also the population was drawn from the same country, the United States.

Moreover, results of the SELECT trial are consistent with the lack of apparent beneficial effects on cancer risk in the Finnish population compared with other Nordic populations, despite the implementation of a nationwide program in Finland aiming at increasing selenium content of locally produced foodstuffs (Vinceti et al., 2000c). In a recent case-control study on vitamin and mineral use and the risk of prostate cancer, an increased risk was seen in long-term (≥ 10 years) consumers of selenium-containing supplements (relative risk 1.7, 95% CI 0.6–4.3) (Zhang et al., 2009), while no such association was found in two U.S. prospective studies (Lawson et al., 2007; Peters et al., 2008). Finally, a few studies have investigated the cancer risk of an Italian community where drinking water with hexavalent selenium (around 8 µg/l) was distributed (Vinceti et al., 1998; Vinceti et al., 2000b). These investigations have shown an excess risk of site-specific cancers in that community, particularly lymphoid malignancies, melanoma, colorectal cancer, and kidney cancer, raising concerns about the long-term safety of inorganic selenium through drinking water. Finally, the epidemiologic literature has been recently reviewed within a Cochrane Collaboration study group, and the results of this analysis have confirmed that selenium intake does not appear to have effects in cancer prevention (Vinceti et al., 2014).

Overall, the epidemiologic literature indicates that increasing selenium intake over the average daily human consumption in the United States and in Europe (where intake is usually lower) does not lower cancer risk, suggesting that the claim of “chemopreventive” effects of the metalloid were unwarranted, and that unmeasured confounders were likely responsible for the different results of the observational studies (Vinceti et al., 2000c), as well as of the secondary end points noted in the skin cancer patients trial of Clark et al. (1996). On the contrary, a suggestion of potential deleterious effects on cancer risk,

though only through evaluation of biochemical indicators of toxicity, has been provided by a small trial carried out in a Danish county, Funen, by supplementing subjects aged 60–74 with 100–300 µg/day of organic selenium (Ravn-Haren et al., 2008). In that cohort, selenium treatment induced a down-regulation of genes carrying electrophile response elements in the promoter regions, an effect potentially associated with increased cancer risk (Ravn-Haren et al., 2008). Laboratory studies yielded additional support to a potential toxic effect of even very low doses of selenium, particularly in its inorganic forms, due to its genotoxic (Bronzetti et al., 2001; Cemeli et al., 2006) and immunotoxic properties (Nair and Schwartz, 1990; Methenitou et al., 2001), the former effect possibly occurring also in humans (Chandra et al., 1993; Atasever et al., 2006). Finally, the enhanced incidence of skin cancer among selenium-supplemented individuals in the skin cancer trial by Clark et al. (1996) should not be underestimated also considering that this was the primary end point of that investigation, and data on this outcome from the SELECT trial would be of strong importance to evaluate the validity of this finding.

The hypothesis that selenium compounds can counteract cancer growth, acting as pharmacological agents, has also been suggested, on the basis of a number of laboratory studies, though it has not been tested to date in randomized clinical trials. The ability of the metalloid to inhibit cancer cell proliferation through its toxic properties is currently under active investigation (Nilsonne et al., 2009; Olm et al., 2009), as more generally the possibility to use the toxic properties of Se for pharmacological purposes.

In conclusion, the relation between selenium and human cancer remains elusive and unclear despite the enormous number of studies devoted to this issue. Based on the results of the recent SELECT trial, at least one hypothesis has been invalidated, i.e., the possibility that a moderate increase in dietary selenium in free-living individuals in a Western country may reduce cancer risk. On the other hand, open issues in research and public health include the possibility that extreme changes in the intake of the metalloid, i.e., very low and very high exposures, may increase cancer risk, that selenium may influence cancer risk according to its chemical species or only in susceptible or high risk individuals, and that selenium may be able to be used as a therapeutic agent in cancer therapy, calling for further research on these topics (Vinceti et al., 2000c; Letavayova et al., 2006; Brozmanova et al., 2010).

Glaucoma Additional diseases have been associated with excess selenium exposure both in occupational settings and in the general population though frequently on the basis of limited and unconvincing epidemiologic evidence. Among these associations, preliminary data from the first trial with selenium carried out among skin cancer patients (Clark et al., 1996) showed an excess risk of glaucoma among supplemented individuals, particularly in females, thus suggesting that excess selenium may represent a risk factor for glaucoma (Conley et al.,

2004). A study carried out to investigate this issue in a group of hospital-referred patients in Tucson, Arizona, showed a strongly increased relative risk of glaucoma (11.3, *P*-value 0.03) among subjects in the highest tertile of plasma selenium, and a dose-response relation between plasma selenium category and risk, thus confirming the hypothesis tested in the study of a glaucoma-enhancing effect of the metalloid (Bruhn et al., 2009). Surprisingly, subjects in the middle tertile of aqueous humor selenium exhibited a lower risk compared with subjects in the bottom tertile, while risk was not reduced in the highest category. The investigators expressed their concern about the possibility that high selenium may enhance glaucoma risk though they were aware of the study limitations, among which were the study size and the potential for referral bias. The need to further assess this potential end point of selenium toxicity (Bruhn et al., 2009) was also expressed (van Woudenberg et al., 2009; Sogbesan and Damji, 2010). Biological plausibility supporting a relation between excess selenium exposure and glaucoma has been provided by an *in vitro* study, which showed that even very low doses of selenium decrease the secretion of metalloproteinases in human trabecular meshwork cells, suggesting the capacity of the metalloid to increase intraocular pressure and eventually to cause glaucoma (Conley et al., 2004).

Chemical Pathology

The toxicology of selenium that forms the basis of the chemical's pathology described herein is discussed above and in the derivation of the RfD below. The two principal clinical conditions that characterize selenosis are dermal and neurological effects observed in humans following chronic ingestion of high levels of selenium in food grown in seleniferous soil in China. The dermal manifestations of selenosis include hair loss and nail loss and deformity, while neurological effects include numbness, paralysis, and occasional hemiplegia. Nervous system abnormalities such as hemiplegia, peripheral anesthesia, acroparesthesia, and pain in extremities were observed in some cases. Nail and hair change and loss have also been observed in individuals in the United States, following ingestion of supplements with very high selenium content due to formulation error, and in cases of acute intoxication among residents of a seleniferous area of Venezuela who consumed the high selenium nuts of *L. ollaria*, known as "Coco de Mono."

Hair loss and hoof malformation in pigs, horses, and cattle, and poliomyelomalacia in pigs have been reported to occur following long-term exposure to excessive amounts of the organic selenium compounds found in seleniferous plants. Histologically, swines with selenium-induced neurological signs exhibit bilateral macroscopic lesions of the ventral horn of the spinal cord. Myocardial degeneration has been experimentally produced in cattle, sheep, and swine (as well as in laboratory mammals) by acute and longer-term exposures to inorganic salts of selenium, but it is unclear

whether seleniferous grains or forages, or other natural sources of selenium, caused the same cardiomyopathy.

Some effects observed earlier in cattle, sheep, and horses that grazed on plants in areas of high selenium in soil in South Dakota, United States were believed to be associated with selenium. However, these neurological signs and histopathology have not been recorded in laboratory animals. The conditions include "blind staggers" and alkali disease. For blind staggers, the actual involvement of selenium or other compounds is unknown because the effects have not been replicated in experimentally exposed cattles receiving doses of selenium sufficient to induce hoof lesions. Alkali disease is a chronic disease in which the animals become emaciated, stiff, and lame; lose long hair from the mane and the tail; and the hooves become deformed. It is also associated with atrophy of the heart and liver. Congestion and focal necrosis of the liver are more prominent in "blind staggers." No studies were identified regarding definitive hepatic effects in humans after intermediate or long-term exposure to selenium compounds.

In fish, lordosis, kyphosis, scoliosis, and deformities of the head, mouth, and fin were observed. In waterfowl and mammals, abnormalities were observed in keratin-forming cells, which produce hard tissues such as hair, horn, beak, feathers, and nails.

Mode of Action(s)

Selenium in the body can be grouped into three main categories, namely, selenium in proteins, nonprotein selenium species, and selenoamino acids (Lobinski et al., 2000). Selenium functions largely through an association with proteins, known as selenoproteins. Selenoproteins refer only to selenocysteine-containing proteins and do not include selenium-binding proteins or selenomethionine-containing proteins. These proteins are required for health and development, playing a diverse role in various biochemical and physiological processes, including the biosynthesis of coenzyme Q (a component of the mitochondrial electron transport system), regulation of iron flux across membranes, maintenance of the integrity of keratins, and stimulation of antibody synthesis. The molecular basis for the essential role of selenium in higher vertebrates is being a component, in the form of the amino acid residue selenocysteine, of some major redox-regulating enzymes such as the selenium-dependent glutathione peroxidases (GPx) and thioredoxin reductase. The known biological functions include defense against oxidative stress, regulation of thyroid hormone action (selenium-dependent iodothyronine deiodinases), and regulation of the redox status of vitamin C and other molecules.

The possible mechanisms of selenium toxicity include substitution of selenium for sulfur in protein synthesis, inhibition of methylation metabolism resulting in selenide accumulation, or membrane and protein damage from selenium-generated ROS (Spallholz et al., 2004). Substitution of

Se for sulfur may damage sulfhydryl-containing enzymes involved in cellular respiration, affect mitochondrial and microsomal electron transport, and favor apoptotic and free radical formation (Kamble et al., 2009).

The specific biochemical mechanism(s) by which selenium and its compounds exert their acute toxicity is not known. In cases of chronic selenium overexposure, the major clinical manifestations are dermal/integumentary effects such as skin, hair, and nail damage. The mechanism causing these changes is unclear, but it has been postulated to be related to the high selenium concentrations in these tissues as a consequence of the substitution of selenium for sulfur in certain amino acids, including the disulfide bridges that provide tertiary structure and function to proteins. The nails and hair are considered to be routes for excretion of excess selenium (Yang et al., 1989a), and substitution of selenium for sulfur in keratin results in weakened physical protein structure and failure of keratinized tissues such as hair and hoof (Raisbeck, 2000). It might be possible that inactivation of the sulfhydryl enzymes necessary for oxidative reactions in cellular respiration, through effects on the mitochondrial and microsomal electron transport, contributes to selenium's acute toxicity.

Oxidative stress is the key biochemical lesion of selenium intoxication (Raisbeck, 2000; Spallholz et al., 2004). Selenium enzymes and selenoethers that do not readily form a selenide anion are not toxic. Methylation of selenium by both plants and animals serves to detoxify selenium by generating methylated selenides. Alternatively, reduction of selenium to elemental selenium as done by some bacteria and formation of heavy metal selenides such as mercuric selenide (Hg_2Se) results in a noncatalytic nontoxic form of selenium. The catalytic prooxidant attribute of some selenium compounds appears to account for their toxicity when such an activity exceeds plant and animal methylation reactions and antioxidant defenses.

SOURCES OF EXPOSURE

Occupational

Human exposures occur in occupational settings, especially in industries that extract, mine, treat, or process selenium-bearing minerals and in industries that use selenium or selenium compounds in manufacturing (ATSDR, 2003). The selenium compounds that are most likely to be encountered in air in occupational settings are dusts of elemental selenium, hydrogen selenide, and selenium dioxide. Deposits of compounds of selenium could be released off-site in dust or air. Occupational chronic exposure to selenium occurs mainly through the air and in some cases via direct dermal contact.

The National Institute for Occupational Safety and Health (NIOSH) conducted a National Occupation Hazard Survey

(NOHS) and estimated that 108,682 workers in 15,127 plants were potentially exposed to selenium in the workplace in 1970 (NIOSH, 1976). NIOSH (1983) conducted a second workplace survey from 1981 to 1983, the National Occupational Exposure Survey (NOES), which indicated that 27,208 workers in 1102 plants were potentially exposed to selenium in the workplace. The majority of these workers were employed in the health services (e.g., nursing), as janitors and cleaners, as machine operators in the metals industry, or in work involving food and kindred products (NIOSH, 1989).

Selenium dioxide, hydrogen selenide, and selenium oxychloride are highly toxic and occupational exposure hazards. Selenium dioxide is formed when selenium is heated in air. It forms selenious acid on contact with water, including perspiration, and can cause severe irritation. Acute inhalation of large quantities of selenium dioxide powder can produce pulmonary edema from local irritant effect on alveoli (Glover, 1970), bronchial spasms, symptoms of asphyxiation, and bronchitis (Kinnigkeit, 1962; Wilson, 1962). Hydrogen selenide is a gas at room temperature with a density much higher than air. Selenium oxychloride is irritating and corrosive to the human respiratory tract because the compound hydrolyzes to hydrogen chloride (HCl), which can then form hydrochloric acid in humid air and in the respiratory tract (Dudley, 1938).

Environmental

Humans are exposed to low levels of selenium daily through food, water, and air, with the majority from dietary intakes, including dietary supplements. Higher exposures may result from consumption of locally grown grains and vegetables, animal products, fish and game in areas where some soils have naturally higher levels of selenium, or working in occupations noted above.

Children are exposed to selenium by the same pathways as adults, with ingestion of food sources as the primary route (Dudley, 1938). Selenium has been identified in pasteurized milk and milk-based infant formulas in the United States and in breast milk of women at different lactation stages. Soil is a potential route of exposure, especially in areas with naturally high selenium content. Young children have a tendency to ingest soil, either through pica or hand-to-mouth activity, and they often play in fields and soils, thus leading to possible dermal exposure and inhalation of dust particles from soil surfaces. The soluble forms such as the inorganic alkali selenites and selenates are more likely to be bioavailable in soils than the relatively insoluble selenides. Children are not likely to be exposed to selenium from their parents' work clothes, skin, hair, tools, or other objects removed from the workplace. Although selenium is contained in some household products such as shampoos and preparations to treat dandruff and eczema, and in some dietary

supplements, the potential for overexposure from these products is low unless there is lack of adult supervision or if accidental poisoning occurs.

NUTRITION ESSENTIALITY

The understanding of selenium has been evolving over the last two decades. Selenium was originally known mainly for its high toxicity, then recognized as an essential trace element and studied for its protective role in human health and diseases, but more recently questions have been raised regarding its protective role and possible link to human diseases. Various aspects of toxicity and the studies of the potential role of selenium compounds in the prevention of specific cancers and antitumorigenic effects and its link to human diseases have been described above.

Selenium supplementation in animal nutrition led to the consideration of possible inadequate dietary selenium in human health. The essential functions of selenium for human and animal health are mediated through selenoproteins (discussed above). The Food and Nutrition Board of the Institute of Medicine has established human dietary reference values for selenium intakes for different age groups (NRC, 2000); these are presented above. These values include Estimated Average Requirement (EAR), Recommended Dietary Allowance (RDA), Tolerable Upper Intake Level (UL), and Adequate Intake (AI). The EAR and RDA are the lower bounds of intake compatible with health. The EAR is the intake at which the risk of inadequacy is 50% to an individual. The RDA is the intake at which the risk of inadequacy is 2–3%. The UL is the highest level of daily intake that is likely to pose no risk of adverse health effects (the risks of inadequacy and of excess are both close to zero). The AI is set instead of a RDA if the scientific evidence is not sufficient to calculate an EAR, and is applicable to young infants for whom human breast milk is the recommended sole source of food, based on the nutrient intake of apparently healthy, full-term infants who receive only human milk.

In the United States, most individuals readily meet their nutritional need for selenium. In Asia and Africa, low selenium status has been associated with human conditions such as Keshan disease (cardiomyopathy, a heart disease, responsive to selenium supplementation) and Kashin–Beck disease (osteoarthritis, a degenerative bone disease). Patients on total parenteral nutrition for prolonged periods can be at a risk of developing selenium deficiency if there is inadequate selenium in the infusion fluids. Selenium deficiency seldom causes overt illness when it occurs in isolation but can lead to biochemical changes that predisposes to illness associated with other stresses (NRC, 2000).

The benefits of selenium nutritional supplements are actively being examined because of potential health issues raised in terms of adverse effects seen in some of the

supplement trials or environmental exposures described above, plus the uncertainty about their effectiveness in cancer prevention (Kristal and Moe, 1998).

INDUSTRIAL HYGIENE

Selenium exists in various chemical forms (speciation) and oxidation states that can affect its occurrence, properties, use, and toxicity. Human exposures occur in the workplace, and via food and drinking water, through dermal, inhalation, or ingestion routes involving organic or inorganic forms. Ingestion of the organic form from food, including dietary supplements, is the main source of exposure for the general population. Evaluation of exposure and health effects of selenium has to consider both essentiality and toxicity. The occupational and environmental limits and reference values that are established are associated with the specific route of exposure and the chemical form, where data exist, as shown below.

Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL): Time-weighted average (TWA) 0.2 mg/m³ (elemental Se and other Se compounds, except Se hexafluoride)

NIOSH recommended exposure limit (REL): TWA 0.2 mg/m³ (elemental Se and other Se compounds, except Se hexafluoride)

American Conference of Industrial Hygienists (ACGIH) TWA 0.2 mg/m³ (elemental Se).

RISK ASSESSMENTS

Reference Dose (RfD) (U.S. EPA, 2011)

An oral reference dose (RfD) is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. An oral RfD of 5 µg/kg/day has been established by the U.S. EPA and presented above. It is based on clinical selenosis in the study of Yang et al. (1989a) at a no-observed-effect level, NOEL, of 15 µg/kg/day and an uncertainty factor (UF) of 3. The no-observed-adverse-effect level (NOAEL) of 0.853 mg/day and lowest-observed-adverse-effect level (LOAEL) of 1.261 mg/day were calculated from regression analysis ($\log Y = 0.767 \log X - 2.248$, where Y = blood selenium and X = selenium intake) (Yang et al., 1989b) based upon the correlation ($r = 0.962$) between dietary selenium intake and blood selenium level for data showing incidence of clinical selenosis in adults with an average adult body weight of 55 kg (Yang et al., 1989a).

The study population included approximately 400 individuals living in an area of China with unusually high environmental concentrations of selenium. Three geographical areas with low, medium, and high selenium levels in the soil and food supply were chosen for comparison. The 1989 studies were a follow-up to an earlier study (Yang et al., 1983) conducted in response to endemic selenium intoxication but with a small sample size in the study area. The 1989 study individuals were evaluated for clinical and biochemical signs of selenium intoxication and tissue selenium levels. Selenium levels in soil and approximately 30 typical food types commonly eaten by the exposed population showed a positive correlation with blood and tissue selenium levels. The daily average selenium intakes, based on lifetime exposure, were 70, 195, and 1438 µg for adult males and 62, 198, and 1238 µg for adult females in the low, medium, and high selenium areas, respectively. To estimate a marginal safe level of daily intake, significant correlations demonstrated between selenium concentrations of various tissues were used to estimate the minimal daily intake values, which elicited various alterations in biochemical parameters indicative of possible selenium-induced liver dysfunction (i.e., prolongation of clotting time and serum glutathione titer) and clinical signs of selenosis (i.e., hair or nail loss, morphological changes of the nails, etc.). Persistent clinical signs of selenosis were observed only in 5/349 adults, a potentially sensitive subpopulation. The blood selenium concentration in this group ranged from 1.054 to 1.854 mg/l with a mean of 1.346 mg/l. Clinical signs observed included the characteristic "garlic odor" of excess selenium excretion in the breath and urine, thickened and brittle nails, hair and nail loss, lowered hemoglobin levels, mottled teeth, skin lesions, and CNS abnormalities (peripheral anesthesia, acroparesthesia, and pain in the extremities). Alterations in the measured biochemical parameters occurred at dietary intake levels of 750–850 µg/day, described as a delay in prothrombin time, i.e., increase in blood coagulation time and reduction in blood glutathione concentration. However, these indicators were poorly characterized and are not typically used as an index for clinical selenosis resulting from chronic exposure to selenium (NAS, 1989). Using the blood selenium levels to reflect clinical signs of selenium intoxication, a whole blood selenium concentration of 1.35 mg/corresponding to 1.261 mg of daily selenium intake is the LOAEL for overt signs of selenosis. The NOAEL with no clinical signs of selenosis is 1.0 mg/l, corresponding to 0.853 mg selenium/day.

Minimal Risk Level (MRL) (ATSDR, 2003)

A Minimal Risk level (MRL) represents a daily intake that Agency for Toxic Substances and Disease Registry (ATSDR) considers to be safe for all populations, not a threshold for toxicity. The exact point above the MRL at

which effects might occur in sensitive individuals is uncertain. An MRL of 5 µg/kg/day was derived for chronic oral exposure (>365 days) to selenium. This MRL is based on a study (Yang and Zhou, 1994) that examined a group of five individuals recovering from selenosis and who were drawn from a larger population in an area of China where selenosis occurred (Yang et al., 1989a; Yang et al., 1989b). The 1994 study was a follow-up of the two 1989 studies, and thus the data used by ATSDR from the 1989 studies were the same as those by the U.S. EPA for deriving the RfD. Examinations were made on selenium levels in the diet, blood, nails, hair, urine, and milk of residents at three sites with low, medium, and high selenium in soil and food and the incidence of clinical symptoms of selenosis (morphological changes in fingernails) with dietary intake of selenium and selenium levels in blood. Selenium levels in blood were found to correspond to the dietary intake; symptoms of selenosis occurred at or above a selenium intake level of 910 µg/day (0.016 mg/kg/day) (Yang et al., 1989b). In 1992, Yang and Zhou (1994) reexamined five individuals from the high selenium area who were recovering (regrowing nails) from symptoms of selenosis (loss of fingernails and hair). Part of their diet from locally produced corn had been replaced with rice or cereals. The concentration of selenium in the blood of these individuals had lowered from 1346 µg/l (measured in 1986) to 968 µg/l (measured in 1992). Using a regression equation derived from the earlier data (Yang et al., 1989a), the dietary intake of selenium associated with selenosis in these individuals was calculated to be 1270 µg/day, while an intake of 819 µg/day was associated with recovery (Yang and Zhou, 1994). The chronic oral MRL is based on a NOAEL of 819 µg/day (0.015 mg/kg/day) for disappearance of symptoms of selenosis in recovering individuals (Yang and Zhou, 1994), an UF of 3 for human variability, and an average adult body weight of 55 kg (Yang et al., 1989a). An UF of 3 was considered appropriate because the individuals in this study were sensitive individuals drawn from a larger population and because of supporting studies.

Acceptable Daily Dose (ADD) (OEHHA, 2010)

The Office of Environmental Health Hazard Assessment, California Environmental Protection Agency, developed an acceptable daily dose (ADD) of 5 µg/kg/day (OEHHA, 2010) for selenium, which is in agreement to the RfD set by the U.S. EPA and the MRL set by the ATSDR as noted above, also based on the same studies (Yang et al., 1983; Yang et al., 1989a; Yang and Zhou, 1994). Selenosis was reported in approximately 400 adult villagers exposed to excess selenomethionine in locally grown grains and vegetables from seleniferous soils, and to a much lesser extent in the drinking water, in a remote mountainous region of China. A NOAEL of 15 µg/kg/day was derived based on measurements of selenium

intakes and whole blood concentrations, a level leading to disappearance of selenosis symptoms in recovering adults (Yang and Zhou, 1994). An UF of 3 was used to account for potentially sensitive subpopulations such as infants, pregnant women and their fetuses, the elderly, the undernourished with respect to proteins and methionine, and patients with liver diseases, resulting in an ADD of 5 µg/kg/day.

SILVER

GIFFE T. JOHNSON

Target organ(s): Skin, lungs, eyes, GI tract

Occupational exposure limits: 0.01 mg/m³ OSHA (PEL); 0.01 mg/m³ ACGIH (TLV); EU OEL 0.1 mg/m³; 0.01 mg/m³ NIOSH (REL); 10 mg/m³ NIOSH (IDLH)

Reference values: 0.005 mg/kg/day USEPA (RfD); 0.1 mg/l USEPA (Drinking Water SMCL)

BACKGROUND AND USES

Silver (symbol Ag) is one of the basic elements present in the earth's crust. Silver is rare, but occurs naturally in the environment as a soft, "silver"-colored metal or as a white powdery compound (silver nitrate). Metallic silver and silver alloys are used to make jewelry, eating utensils, electronic equipment, and dental fillings. Nanoparticles of silver have been developed into meshes, bandages, and clothing as an antibacterial.

Silver is used in photographic materials, electric and electronic products, brazing alloys and solders, electroplated and sterling ware, as a catalyst, and in coinage. Silver is alloyed with many other metals to improve strength and hardness and to achieve corrosion resistance. Small amounts of silver are released into the environment during coal gasification, municipal waste incineration, and coal combustion. It is produced in the United States, Mexico, Canada, Peru, and the former Soviet Union. It is often refined from ore containing lead, copper, and gold.

PHYSICAL AND CHEMICAL PROPERTIES

The metal silver (CASRN 7440-22-4) is described as a white, lustrous solid. In its pure form it has the highest thermal and

electrical conductivity and lowest contact resistance of all metals. With the exception of gold, silver is the most malleable metal. The melting point of silver is 961.93 °C, boiling point is 2212 °C, specific gravity is 10.50 (20 °C), and has valence states consisting of +1 and +2.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute inhalation of colloidal silver aerosols has been reported to damage exposed epithelium in rabbits (Konradova, 1968). Abdominal pain has been reported by workers exposed to silver nitrate and silver oxides from airborne exposure levels of approximately 0.039 mg silver/m³ (Rosenman et al., 1979). Death has been observed in rats following ingestion of colloidal silver and inorganic silver compounds at extremely high doses; silver nitrate has an oral LD₅₀ of 1173 mg/kg in rats and an LD₅₀ of 50 mg/kg in mice (Dequidt et al., 1974; Walker, 1971).

Chronic Effects

The most commonly encountered silver-induced toxicity is argyria, of which two distinct clinical diagnoses have been defined. The first occurs in persons exposed by inhalation or ingestion of silver nitrate, fulminate, or cyanide. This exposure may cause generalized argyria, the systemic distribution and deposition of silver-containing particles in body tissues. Characteristically, this results in a slate gray discoloration of the skin, particularly in sun-exposed areas (Lee and Lee, 1994). The color is the result of silver sulfide as well as metallic silver deposition, and ultimately is produced by

photoactivated reduction. Blond people are especially susceptible to this effect. A blue line along the gingival area of the gum may be an early sign of argyria. The second type of argyria is a localized form resulting from dermal exposure. Localized argyria is especially common among jewelry makers who may puncture their skin with a silver wire. The skin discoloration often resembles small dermal nevi (Rongioletti et al., 1992; Sarsfield et al., 1992). Although argyria is a cosmetic effect that does not threaten life or health, it is troublesome because the discoloration is permanent. A specific gray/blue pigmentation of the cornea and conjunctiva resulting from deposition of inert silver is known as argyrosis.

Inhalation of 10 µg/m³ of soluble silver for long periods or ingestion of 1–5 g of soluble silver may result in generalized argyria. A study of silver reclamation workers exposed only to insoluble silver revealed no evidence of argyria or any other adverse health effects (Pifer et al., 1989). In another report, a silver reclamation worker with a blood silver level of 49 µg/l had no signs of argyrosis (Williams and Gardner, 1995). A second worker at the same facility had a blood silver level of 74 µg/l and pronounced argyrosis but no evidence of other health effects.

Dermal exposure to silver fulminate may cause a contact dermatitis sometimes referred to as fulminate itch (White and Rycroft, 1982). Some silver salts can be irritating to the mucous membranes and skin. Silver oxide, which is used in battery manufacturing, glass polishing, and water purification and as a catalyst and germicidal ointment, is a strong oxidizer. Silver nitrate may cause conjunctivitis and blindness. Silver oxide and silver nitrate are both considered irritants. Mucosal irritation, cough, and chest tightness were reported by workers exposed to silver nitrate (Rosenman et al., 1979, 1987). Therefore, both skin contact and inhalation should be controlled. However, the same study failed to find a correlation between silver exposure and nephrotoxic effects. Personal air monitoring conducted 4 months previous to the study determined an 8 h time-weighted average (TWA) concentration range of 0.039–0.378 mg silver/m³. There is no research indicating an association between exposure to silver or silver compounds and cancer in humans.

Death has been reported in rats receiving 222.2 mg silver/kg/day as silver nitrate in drinking water beginning at 23 weeks of exposure; the surviving rats showed a decreased weight gain compared to animals receiving only water at the same time point (Matuk and McCulloch, 1981).

Mechanism of Action(s)

Argyria is thought to be the result of a complex biotransformation and deposition of ingested silver. Silver that is ingested orally is oxidized into a salt form that is absorbed by the gastrointestinal tract and distributed by the blood to the dermis. A series of biotransformations may occur in dermal cells, including the photoreduction of

thiol–silver complexes and further complexing with selenium which leads to the permanent deposition of silver in this tissue (Liu et al., 2012).

SOURCES OF EXPOSURE

Occupational

Most occupational exposures to silver occur through inhalation of silver-containing dusts or dermal exposure to colloidal silver compounds. Common forms of occupational exposure include elemental silver, silver nitrate, and silver oxide. Humans may be dermally exposed to silver through the use of silver-containing processing solutions for radiographic and photographic materials, dental amalgams, and medicines (e.g., silver sulfadiazine cream and solutions for treating burns). Due to the high electrical conductivity of silver, it is used in many technology-based industries in solders, wiring, and electronic board manufacture that may produce a fume exposure.

Environmental

People are exposed daily to very low levels of silver from food and drinking water, and to some extent, in air—most of which is naturally occurring. Other sources of exposure include the use of silver in medicines and bandages, silver dinnerware and jewelry, nanosilver laced clothing to prevent odor, and hobbies that involve soldering and photography. Exposure from everyday use of silver alloy, such as wearing jewelry or eating with silver-coated flatware, is not expected to result in silver being absorbed into the body. Exposure to fumes, colloidal compounds, or aerosolized forms may, however, result in absorption.

In the natural environment, silver levels of <0.000001 mg silver/m³ of air, 0.2–2.0 parts silver per billion parts water (ppb) in surface waters, such as lakes and rivers, and 0.20–0.30 parts silver per million parts soil (ppm) in soils are found from naturally occurring sources (Davidson et al., 1985; Boyle, 1968; Kharkar et al., 1968).

Silver compounds are also found in groundwater, and may be found at increased levels at hazardous waste sites. Sources of drinking water in the United States have been found to contain silver levels of up to 80 ppb. Several sampling surveys have been conducted, indicating that 1/10th–1/3rd of the samples taken from drinking water supplies contain silver at levels >30 ppb (Letkiewicz et al., 1984).

INDUSTRIAL HYGIENE

Overall, the risks of working with silver are low. Workers are most likely to be exposed during silver plating, silver reclamation from photographic materials, and welding. There are

minimal risks associated with pure silver; however, silver intensive industries often are hazardous. Many health effects associated with occupational exposure in silver-intensive industries are caused by associated materials, such as cyanide, lead, and cadmium. Silver reclamation workers may be exposed to excessive levels of cyanides (Blanc et al., 1985). Workers in silver soldering operations may be exposed to hazardous levels of cadmium (Vance, 1960). Silver jewelry workers may be exposed to high levels of lead (Flora et al., 1990).

Silver fulminate, an explosive compound, may be formed when silver is treated with nitric acid in the presence of ethyl alcohol. Workers may be exposed to silver during gold casting processes, more so when using an oxyacetylene flame than with electromagnetic induction.

The Occupational Safety and Health Administration (OSHA) and the National Institute for Occupational Safety and Health (NIOSH) have set both the permissible exposure limit and the recommended exposure limit for silver at 0.01 mg/m³ (NIOSH, 2012). The American Conference of Governmental Industrial Hygienists (ACGIH) has set the threshold limit value (TLV) for the metal silver at 0.1 mg/m³ and the TLV for soluble silver salts as silver at 0.01 mg/m³ (ACGIH, 1996). Workers should wear gloves, face shields, and impervious clothing when necessary to prevent contact with powdered metallic silver and soluble silver salts. Respirator use is indicated for airborne exposures that exceed the OSHA PEL (NIOSH, 2012).

MEDICAL MANAGEMENT

In the event of severe exposure to silver or silver compounds, exposure removal is a primary intervention. Symptoms of silver exposure may include the presentation of blue-gray eyes, nasal septum, throat, and skin; irritation or ulceration skin; and gastrointestinal disturbance. First aid for irritant exposure to eyes or skin is to immediately flush affected area with water. After the patient has been removed from the exposure and first aid conducted, medical treatment should be sought for unresolved symptoms. Medical management consists of supportive care for skin and eye irritation and/or acute respiratory impairment.

There is no recognized management for argyria or argyrosis that results from chronic silver exposure. Beyond the physical disfigurement associated with this condition, no further complications exist which require treatment. Removal from known exposures should be emphasized.

TELLURIUM

MAREK BANASIK

First aid: CAUTION! First aid personnel must be aware of own risk during rescue! Eyes: make sure to remove any contact lenses from the eyes before rinsing, promptly wash eyes with plenty of water while lifting the eye lids, continue to rinse for at least 15 min—get medical attention if any discomfort continues; skin: remove affected person from source of contamination, remove contaminated clothing, wash the skin immediately with soap and water—get medical attention if any discomfort continues; inhalation: move the exposed person to fresh air at once, rinse nose and mouth with water—get medical attention if any discomfort continues; ingestion: immediately rinse mouth and provide fresh air—get medical attention if any discomfort continues.

Occupational exposure limits: OSHA PEL: 0.1 mg/m³ time-weighted average (TWA) (except tellurium hexafluoride and bismuth telluride); NIOSH REL: 0.1 mg/m³ TWA (except tellurium hexafluoride and bismuth telluride); ACGIH TLV: 0.1 mg/m³ TWA (except hydrogen telluride); see NIOSH (2011)

Reference value(s): None

Hazard statements: H317: may cause an allergic skin reaction; H332: harmful if inhaled; H413: may cause long lasting harmful effects to aquatic life

Precautionary statements: P261: avoid breathing dust/fume/gas/mist/vapors/spray; P280: wear protective gloves/protective clothing/eye protection/face protection; P312: call a poison center/doctor/... if you feel unwell; P333+313: if skin irritation or rash occurs: get medical advice/attention

Risk phrases: R20: harmful by inhalation; R43: may cause sensitization by skin contact; R53: may cause long-term adverse effects in the aquatic environment

Safety phrases: S24: avoid contact with skin; S36/37: wear suitable protective clothing and gloves; S61: avoid release to the environment, refer to special instructions/safety data sheet

BACKGROUND AND USES

Tellurium [symbol Te; Chemical Abstracts Service Registry Number (CASRN): 13494-80-9] is a silvery white metal in group 16 of the periodic table. It shares chemical and clinical properties with selenium (Amdur, 1947, 1958; Schroeder et al., 1967; Shie and Deeds, 1920). Tellurium is a semiconductor and may have multiple electron states (-2, 0, +2, +4, +6). It can react with hydrogen to form hydrogen telluride and with halogens. Tellurite (+2) and teleurate (+4) compounds are water soluble. Elemental tellurium burns, producing a blue flame and tellurium dioxide (TeO₂; CASRN: 7446-07-3).

Tellurium is a common constituent of ores that contain silver, gold, lead, antimony, and bismuth, and it is often present in small amounts in coal. Tellurium is widely used in metallurgy because it improves the properties of copper, tin, lead-based alloys, steel, and cast iron. It is used in rubber manufacturing to increase heat resistance and to retard the aging of rubber hoses and cable coatings. Small amounts are used in the electronics industry for lasers and photoreceptors. Tellurium is not an essential micronutrient; therefore, it is not found in nutritional supplements.

In the United States (US), no publicly available production volume data, including manufacturing and importing, are available. Under the US Environmental Protection Agency's 2012 Chemical Data Reporting rule, one US manufacturer was identified, who claimed the production volume as confidential business information (EPA, 2012). In the European Union, the annual production volume of tellurium is between *ca.* 2.2 hundred thousand and *ca.* 2.2 million pounds (100–1,000 tonnes) per annum (ECHA, 2014).

The potential risks from tellurium are primarily limited to occupational exposures because the end uses are not in forms that consumers or the general population will be exposed. Virtually all of the toxicological testing on tellurium has been conducted in accordance with regulatory registration requirements. A summary of these data, along with historical accounts of toxicological effects in humans are provided herein.

PHYSICAL AND CHEMICAL PROPERTIES

Tellurium is a heavy metal, which is processed as a grey powder. It has hexagonal, rhombohedral structure, a low water solubility and high relative density. The particle size ranges from 52.36 to 112.98 μm .

ENVIRONMENTAL FATE AND BIOACCUMULATION

Metals are recalcitrant to degradation; therefore, no bio-degradation studies have been performed on tellurium. No aquatic bioaccumulation data exist for tellurium; however, based on its density and low water solubility, it is unlikely to present a concern for bioaccumulation in the water column. No environmental monitoring data are available on the levels of tellurium in sediment or sediment-dwelling organisms. Therefore, it is unclear whether tellurium has the potential to bioaccumulate in this compartment. In humans, tellurium accumulates in the bones. Based on this, it may be assumed that tellurium has the potential to bioaccumulate in vertebrates.

ECOTOXICOLOGY

Elemental tellurium has not been evaluated in standard aquatic or terrestrial toxicity studies. Standard toxicology studies have been performed on TeO_2 and used as a read across for assessing ecotoxicological hazards. A summary of these data is presented in Table 32.2. The following predicted no effect concentrations (PNECs) were derived for tellurium as part of regulatory submissions to the European Union: $\text{PNEC}_{\text{aquatic}} \text{ (freshwater)} = 5.79 \mu\text{g/l}$; $\text{PNEC}_{\text{aquatic}} \text{ (marine water)} = 0.579 \mu\text{g/l}$; $\text{PNEC}_{\text{aquatic}}$

TABLE 32.1 Chemical and Physical Properties of Tellurium

Characteristic	Information
Name	Tellurium
Synonyms/trade names	Aurum paradoxum, metallum problematum, telloy
CASRN	13494-80-9
Molecular weight	127.60 g/mol
Physical state	Grey powder (at 20 °C and 1,013 hPa)
Melting point	449.8 °C
Relative density	6. 232
Water solubility	20.02 $\mu\text{g/l}$ at 21.2 °C, 183.3 $\mu\text{g/l}$ at 21 °C, and 1.762 mg/l at 21 °C ($\text{pH} = 8$) ^a
Particle size	$L_{10} = 52.36 \mu\text{m}$; $L_{50} = 77.00 \mu\text{m}$; $L_{90} = 112.98 \mu\text{m}$ ^b

Source: ECHA (2014); HSDB (2009).

^aThese values were obtained after 7 days with initial loadings of 1, 10, and 100 mg/l, respectively.

^b $L_{\#}$ represents # % of the particle volume or particle mass with a lower particle diameter.

(intermittent releases) = 57.9 $\mu\text{g/l}$; and PNEC_{STP} (sewage treatment plant) = 3.2 mg/l (ECHA, 2014).

MAMMALIAN TOXICOLOGY

Animal studies performed in the 1970s or earlier reported that tellurium can cause teratogenic effects in experimental animals and the demyelination of nerves, and it crosses the blood–brain barrier (Agnew and Curry, 1972; De Meio, 1946; Lampert and Garrett, 1971; Uncini et al., 1988). Chronic ingestion of tellurium by rats results in deposition of tellurium in brain tissue, a condition known as “black brain” (Duckett and White, 1974). Inhalation or endotracheal administration of metallic tellurium or TeO_2 dust causes chronic inflammation and blue-gray discoloration of the trachea (Geary et al., 1978). These earlier reports have been evaluated in more recent guideline studies to determine tellurium’s potential to cause acute and developmental toxicity in experimental animals. A summary of the acute and developmental studies, performed in accordance with validated testing guidelines, is provided below.

Acute Studies

In a guideline 4 h inhalation study, groups of five male and female Wistar rats were exposed to a single, nose only analytical concentration of tellurium powder at 2.42 g/m³ (particle size = *ca.* 72% had an aerodynamic diameter between 1.8 and 4.2 μm) (ECHA, 2014). Immediately after exposure, all exposed rats were observed with black heads, half closed eyes, and hunched posture. From postexposure days 7–14, female rats had baldness on the head, back, and posterior body weight (bw) was decreased in all rats by 1 week postexposure,

compared to their preexposure bw. During the autopsy, a garlic-like smell was noted. In male rats, the lungs contained brownish spots. In female rats, the lungs appeared pale or contained grey to black stains. In four of the female rats, the thymus was grey. None of the rats died during the exposure or postexposure period. A 4-h LC₅₀ >2.42 g/m³ was reported.

In a guideline acute oral gavage study, five male and five female Wistar rats were administered tellurium in a maize oil vehicle at a single dose of 5,000 mg/kg bw (ECHA, 2014). No mortalities or treatment-related effects on clinical signs or gross pathology were reported after the 14-day posttreatment period. All animals gained weight during the 14-day observation period.

Skin and eye irritation have been assessed using standard guideline *in vitro* methods (ECHA, 2014). Negative results were obtained with each. In support of the *in vitro* skin irritation study, no local skin irritation was observed in mice during the performance of a guideline local lymph node assay, as discussed below. It should be noted, however, that the first-aid measures listed under the European Chemicals Agency tellurium registration state that tellurium skin contact may cause irritation, redness, pain, and discoloration. For eye contact, it states that tellurium may cause redness and pain (ECHA, 2014).

The skin sensitization potential of tellurium powder was evaluated in female CBA mice (four per dose) (ECHA, 2014). Eight animals served as the negative control. Hexyl cinnamic aldehyde was used as a positive control. Tellurium powder was suspended in propylene glycol at 0, 25, 50, or 100% and

applied to the dorsal surface of the ears (25 µl/ear) for 3 consecutive days, followed by 3 consecutive days without treatment. Negative and positive controls were treated in a similar manner with 100% propylene glycol or the positive control, respectively. Proliferation of lymphocytes within the lymph nodes was evaluated by incorporation of ³H-methyl thymidine and measured by β-scintillation counting. A stimulation index ≥3 was used for determining a positive result.

At study termination, the negative controls had normal lymph nodes. In the positive control, a stimulation index value of 13.0 was recorded, which confirmed the validity of the assay. In the treated animals, stimulation index values of 3.8, 3.2, and 3.2 were recorded for the 25, 50, and 100% groups, respectively. These results demonstrated that tellurium has skin sensitization potential.

Repeated Dose Studies

Two guideline developmental toxicity studies have been performed on tellurium in the rat and rabbit (Johnson et al., 1988). In the first study, 32–33 pregnant CrI Sprague-Dawley rats were administered tellurium in the diet at concentrations of 0, 30, 300, 3,000, or 15,000 parts per million (ppm) from gestation days (GDs) 6 through 15. The corresponding daily intake from GDs 6 through 10 was calculated to be 0, 2.2, 19.6, 165.6, or 633.4 mg/kg bw/day. From GDs 11 through 15, the daily intake was 0, 1.9, 18.0, 173.0, or 579.4 mg/kg bw/day. On GD 20, approximately two-thirds of the dams were

sacrificed and the fetuses were examined. The remaining dams were allowed to deliver. The pups were observed and sacrificed on postnatal day (PND) 7. The heads of pups sacrificed on PND 7 or that died prior to this were examined.

No treatment-related effects were reported on dam mortality, incidences of pregnancy, mean number of corpora lutea, implantations and resorptions, mean litter size, numbers of live and dead fetuses, or percentage of male fetuses. Maternal bw gain and food consumption statistically significantly decreased in the 300 and 3,000 ppm groups. Weight loss and halved food consumption were statistically significantly decreased in the high dose group.

In the fetuses, no treatment-related effects were observed in the 0, 30, or 300 ppm groups. In the 3,000 ppm group, the incidence of litters with variations was statistically significantly increased. An increased incidence of fetuses with variation (10.6%), malformed fetuses (no details provided), and fetuses with delayed ossification (no details provided) were reported. Non-statistically significant increases were reported for internal hydrocephalus with dilation of the lateral ventricles in 3 litters (14.3%) and 11 fetuses (8.3%). Moderate dilation of the renal pelvis was also reported, but details were not provided. In the 15,000 ppm group, statistically significant decreases in male and female fetal bw and increases in litter variations were reported. Increased incidences of fetuses with variation, malformed fetuses, and fetuses with delayed ossification were reported; no further details were provided. Statistically significant increases in the incidence of internal hydrocephalus with dilation of the lateral ventricles were observed in 17 litters and 67 fetuses. External hydrocephalus was reported for two fetuses; the number of litters was not specified. Moderate dilation of the renal pelvis was reported, but no further details were provided.

In the dams allowed to deliver, no treatment-related effects were reported on duration of gestation, number (percentage) of dams with stillborn, litter size, number of live pups delivered, gross anomalies, external or visceral anomalies, or mean pup weights on PND 7. In the high dose group, pup survival to PND 7 was statistically significantly decreased. A statistically significant increase in the incidence of slight to extreme dilation of the lateral ventricles was reported in pups on PND 7 from the high dose group.

In the second developmental toxicity study, 17 per dose artificially inseminated New Zealand white rabbits were administered tellurium in the diet at concentrations of 0, 17.5, 175, 1,750, or 5,250 ppm from GDs 6 to 18. The average feed intake on GDs 6 through 18 and the average maternal bw on GD 6 were used to calculate intake values of 0, 0.8, 8, 52, and 97 mg/kg bw/day. Dams were sacrificed on GD 29 and the fetuses were examined.

No treatment-related effects were observed on the incidence of abortion, mean numbers of corpora lutea, implantations, resorptions, litter size, or sex ratio (percentage of male fetuses per litter). In the 1,750 and 5,250 ppm groups, statistically

significant decreases in maternal bw and food consumption were reported. Signs of toxicity in these groups included: soft or liquid feces, alopecia, thin appearance, and/or decreased motor activity. In the high dose group, non-statistically significant decreases in mean fetal bw were reported in males (84% of controls) and females (95% of controls). A 46.2% (controls 2%) and 11.8% (controls 6.7%) increase in the incidence of litters with abnormalities and malformed fetuses was reported, respectively. Increased incidences of malformed fetuses and fetuses with delayed ossification were reported; further details were not provided.

The study authors concluded that “[s]ince maternal toxicity was observed at dosages that did not affect the developing conceptus, there were no indications of unique developmental susceptibility upon exposure of pregnant rats or rabbits to tellurium” (Johnson et al., 1988). However, the Health Council of the Netherlands’ Subcommittee on the Classification of Reproduction Toxic Substances evaluated the complete developmental toxicity database on tellurium, including the older studies and those performed by Johnson et al. (1988). It recommended that tellurium be classified category 1B (presumed human reproductive toxicant) and be labeled with H360D (may damage the unborn child) (HCN, 2013).

In humans, exposure to tellurium vapor, tellurium dioxide dust, or hydrogen telluride has caused respiratory inflammation, somnolence, and anorexia (Blackadder and Manderson, 1975; Keall et al., 1946; Steinberg et al., 1942). Hydrogen telluride is a hemolytic agent that has the same effects as hydrogen arsenide and hydrogen selenide (Webster, 1946). Fatalities, clinically characterized by cyanosis, vomiting, and stupor progressing to coma, have resulted from accidental parenteral administration of sodium tellurite (Kron et al., 1991). In cases of occupational exposure to the gaseous form of tellurium hexafluoride (CASRN 7783-80-4), patients experienced somnolence, garlic breath odor, and bluish-black patches on the skin of the neck, face, and hands (Blackadder and Manderson, 1975).

Tellurium is excreted in sweat, urine, feces, and exhaled air. In humans, a garlic odor that lasts longer than 200 days has been produced by a dose of about 15 mg of tellurium (De Meio, 1947). The garlic taste and odor are useful indicators of potentially dangerous exposure but are also a social liability. Dr. Harriet Hardy, one of the authors of the previous editions of this book, was asked to consult for the employees of an electronics company that used tellurium because their wives refused to kiss them because of their garlic odor.

SOURCES OF EXPOSURE

Occupational

Tellurium and its various compounds can be absorbed by ingestion, by inhalation, or through the skin (Cerwenka and

Cooper, 1961). Metabolism *in vivo* produces the characteristic “garlic breath” caused by methylation of tellurium to volatile dimethyl telluride (De Meio, 1947). To prevent the “garlic breath” complex, the concentrations of tellurium and its compounds must be kept at or below 0.01 mg/m³.

Environmental

Background levels in humans are 0.6 µg/ml in urine and 1 µg/ml in serum (ACGIH, 1996; Kron et al., 1991). The calculated total body burden is about 600 mg, 90% of which is found in bone (Kron et al., 1991). Tellurium is a more potent producer of garlic breath than selenium.

INDUSTRIAL HYGIENE

Workplace engineering controls (e.g., ventilation) and personal protective equipment, including suitable respiratory protection, protective gloves, and safety goggles or a face shield, are recommended to reduce respective exposures through inhalation, skin, and eye contact (ECHA, 2014).

THALLIUM

NIKOLAY M. FILIPOV

First aid: A. General measures: Immediately remove from exposure source and seek medical attention; antidote (FDA approved): Prussian blue (Radiogardase), given orally as follows: 3 g immediately, followed by 250 mg/kg/day divided into four daily doses (QID); if Prussian blue is unavailable: repeated activated charcoal administration (up to four oral doses (0.5–1.0 g/kg); one dose every 2–3 h). B. Exposure-route specific measures: 1. Ingestion: ensure unobstructed airways; induce emesis (ipecac syrup) within 30–60 min of exposure. 2. Inhalation: ensure unobstructed airways; evaluate respiratory function and pulse. 3. Dermal: decontaminate the patient/victim following standard decontamination procedures.

Target organ(s): CNS, PNS, neuromuscular, eye, cardiac, renal, gastrointestinal, skin

Occupational exposure limits: 8 h shift PEL/TLV: 0.1 mg/m³ (OSHA/ACGIH); 10 h shift REL/PEL: 0.1 mg/m³ (NIOSH/OSHA); IDLH: 15 mg/m³ (NIOSH).

Reference values: Candidate RfD for Tl/Tl salts: 3×10^{-6} mg/kg/day (alopecia), 1×10^{-5} mg/kg/day (alopecia plus hair follicle atrophy); RfC: not available (insufficient information); TDIs: 0.00007 mg/kg/day (for oral Tl), 0.00008–0.00009 mg/kg/day (for oral Tl compounds); Tl: 15.4 µg/day; MRL: 0.002 mg/l.

Risk/safety phrases: Very toxic if inhaled or swallowed; danger of cumulative effects; may cause long-term effects in the aquatic environment; keep locked up and out of the reach of children; keep away from food, drinks, and feedstuff; avoid contact with skin; in case of accidental exposure seek medical assistance immediately; avoid environmental release.

BACKGROUND AND USES

Thallium (Tl), an element sharing the same family with aluminum (Al), gallium (Ga), indium (In) and boron (B), was discovered by Sir William Crookes in 1861 (Crookes, 1861). Thallium is a rare, but widely dispersed element; it is found in nature in various earth's crust minerals (e.g., lorandite, crookesite, hutchinsonite) from North and South America to Asia (Kazantzis, 2007). Thallium is considered nonessential and its environmental concentrations, similar to Al, Ga, and In, are quite low (Kazantzis, 2007; EPA, 2009). For example, Tl's crustal abundance is approximately 1 mg/kg; in the soil, Tl's concentrations range from 0.1 to 1 mg/kg with higher concentrations occurring in close proximity to metallic ore deposits (Kazantzis, 2007). Thus, Tl concentrations of more than 100 mg/kg in soils from a mining region in China have been reported (Xiao et al., 2004a, 2004b). Detectable levels of Tl are also found in saltwater, freshwater, and air (RIVM, 2005; EPA, 2009). Thallium is taken up by vegetation, with the extent of uptake determined by soil acidity and plant species (Kazantzis, 2007).

All forms of Tl are relatively soluble and capable of causing eco- or mammalian toxicity. In fact, thallium has greater acute mammalian (human) toxicity than, for example, mercury (Hg), cadmium (Cd), or lead (Pb). As a result, Tl has been responsible for many accidental, occupational, deliberate, and therapeutic human intoxications since its discovery in 1861 (Peter and Viraraghavan, 2005).

Annual worldwide production of Tl is quite low: approximately 15 tons, but various industrial processes mobilize approximately 2000–5000 tons per year (Kazantzis, 2007; EPA, 2009; Rodriguez-Mercado and Altamirano-Lozano, 2013). Current uses of Tl are numerous and broad ranging.

For example, the isotope ^{201}Tl is used for tumor and myocardium imaging (Yildirim et al., 2005). Thallium is also used in medicines and health products, as a pigment and depilatory agent in cosmetics, in specialty alloys and in various electrical and electronic equipment or instrumentation (e.g., semiconductors, fiber optic cables, infrared instruments, laser equipment, ozone meters, and low temperature thermometers). Other uses of Tl include in pyrotechnics (green color), as a catalyst in organic synthesis, and in the production of pesticides and certain phosphate fertilizers (ATSDR, 1992; Kazantzis, 2007; EPA, 2009; Rodriguez-Mercado and Altamirano-Lozano, 2013). Due to favorable physicochemical and toxic properties, Tl salts have been used in war-like preparations (Lawrence and Kirk, 2007) and, either alone or in combination with cocaine or other toxic agents, such as arsenic, for malicious, deliberate intoxications (Rusyniak et al., 2002). Historically, Tl has been used for the treatment of diseases of the scalp, syphilis, tuberculosis, and malaria (Leonard and Gerber, 1997); these treatments have been discontinued due to the high toxicity of this metal. Overall, Tl's widespread use and environmental release has led to increased Tl levels in the environment and increased exposure risk to humans and other living organisms (EPA, 2009; Rodriguez-Mercado and Altamirano-Lozano, 2013).

PHYSICAL AND CHEMICAL PROPERTIES

Thallium (Tl), from the Greek word *thallos*, is a bluish-gray, shiny, ductile, malleable, heavy metal with atomic number 81 and atomic weight of 204.38. Its density is 11.85 g/cm³; other key characteristics of Tl are as follows: melting point of 303.5 °C, boiling point of 1,457 °C, a hexagonal crystalline structure, electron configuration of [Xe] 6s² 4f¹⁴ 5d¹⁰ 6p¹, and oxidation states of +1 and +3. Thallium belongs to group IIIa of the periodic table with Al, Ga, In, and B. Unlike the other metal cations in this family, which are more stable in oxidation state +3 (Al³⁺, Ga³⁺, and In³⁺), Tl is more stable in oxidation state +1 (thallous, Tl⁺) than oxidation state +3 (thallic, Tl³⁺). Thallium has electronegativity of 2.04, Van der Waals radius of 193 pm, atomic radius of 171 pm, and an ionic radius of 150 pm (Tl⁺). There are 26 artificial isotopes of Tl, but in nature 29.52% of Tl exists as ^{203}Tl and 70.48% exists as ^{205}Tl . Upon exposure to air, Tl forms brownish black oxide. Thallium is acid-soluble and highly reactive metal; it forms monovalent salts, i.e., Tl acetate, Tl carbonate, Tl sulfate, and trivalent thallic salts, i.e., Tl trichloride and Tl sesquioxide, which are less stable than the thallous salts (Fergusson, 1990; Kazantzis, 2007; EPA, 2009).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Thallium is retained in soil, with large amounts of clay, organic material, and iron and manganese oxides (WHO,

1996). As the soil pH decreases, Tl's uptake by plants increases (WHO, 1996; EPA, 2009) and it could reach up to 45 mg/kg in green kale (Kazantzis, 2007). From acidic soils, Tl can leach into ground and surface waters with the monovalent form being the one predominantly found there (WHO, 1996). Some bioconcentration, but limited biomagnification takes place for Tl. In aquatic environments, thallium's distribution and concentration is poorly defined. However, recent report suggest direct correlation between Tl aqueous concentrations and the proximity of collection sites to metal mines, i.e., water concentrations were 13 and 2640 ng/l in samples from a river with a catchment without no metal mines and from an abandoned mine shaft in England, respectively. Importantly, concentrations of Tl in rivers in the vicinity of mine-related effluents reached about 770 ng/l (Tatsi and Turner, 2014). In lakes, i.e., Lake Ontario, bioavailable concentrations of Tl in the sediments are greater than in the water, with deep-water sediments having the greatest amounts of bioavailable Tl (Borgmann et al., 1998).

In terms of bioaccumulation up the food chain, studies with the bioindicator amphipod crustacean species *Hyalella Azteca* report increased Tl uptake and body burden, but the body concentrations were below the toxic threshold (Borgmann et al., 1998). Regarding plant uptake, Tl⁺ is the dominant species, but in extracts of plants cultivated in the presence of tailing sediments about 10% is Tl³⁺. Some plants are highly tolerant to Tl and bioconcentrate it very effectively; one such example is *Sinapis alba*, which could potentially be used for bioremediation purposes as it bioconcentrates Tl much more effectively than Cd, Zn, or Pb. (Krasnodebska-Ostrega et al., 2012). Another plant, the aquatic macrophyte *Callitrichia cophocarpa*, could also be used for phytoremediation of Tl contaminated waters, but in this case the metal selectivity is not directed towards Tl, i.e., this would be a pan-metal phytoremediation approach (Augustynowicz et al., 2014). Clams and mussels also bioconcentrate Tl in aquatic environments with bioconcentration factor (BCF) values of 18.2 and 11.7, respectively, as described by Zitko and Carson (1975). Bioconcentration factors for muscle tissue of juvenile salmon range from 27 to 1430 as described by Zitko et al. (1975). Studies on Tl levels in wildlife are limited, but in wild ducks in Japan contents of Tl in kidney and liver ranged from 0.42 to 119.61 and 0.10 to 33.94 µg dry weight, respectively. Importantly, Tl levels were dependent on sampling locations with the highest mean Tl content observed in samples collected from the Ibaraki Prefecture (Mochizuki et al., 2005).

In certain geographical areas, i.e., the Lanmchang area of southwest Guizhou, China, soil concentrations of Tl are naturally much higher, i.e., 40–124 mg/kg in soils originating from mining areas, 20–28 mg/kg in slope wash materials, and 14–62 mg/kg in alluvial deposits downstream, which are levels substantially higher than the background soil concentrations of <0.2–0.5 mg/kg (Xiao et al., 2004a, 2004b). This is important from a biomagnification point of view as Tl

levels in edible plants ranging from green cabbage to rice and corn that are grown in such areas could reach up to 500 mg/kg dry weight (the highest levels are found in cabbage). This would translate to Tl ADI of the local population 50 times higher than the Tl's intake of the background population (Xiao et al., 2004a, 2004b). Ground and surface waters from these "naturally contaminated" areas also contain markedly elevated levels of Tl, further increasing the potential for human overexposure of the local population (Xiao et al., 2004a, 2004b). Preliminary findings in Europe also show Tl uptake by edible vegetables, which is dependent upon the plant type/species and the Tl soil levels (Pavlickova et al., 2006). In the United States and Canada, data on such high levels of thallium in edible plants or animals are lacking, but there may be an increased risk for Tl intoxication by consumption of fish from the Great Lakes (Lin and Nriagu, 1999; Pickard et al., 2001). Due to its interaction with potassium, greater bioaccumulation, or Tl may take place in waters with low K levels (Kazantzis, 2007).

ECOTOXICOLOGY

Acute Effects

Studies examining the acute ecotoxicological effects of Tl are limited. Nevertheless, examination of the aquatic toxicity of Tl using *Daphnia magna* demonstrated that Tl^{3+} is substantially more potent than Tl^+ and, importantly, Tl^{3+} is more toxic to daphnids than many other metals, including Cd, Ni, and Cu; Tl^{3+} toxicity was comparable to that of inorganic Hg with 48 h LC₅₀ values ranging from 24 to 204 µg/l for Tl chloride and Tl acetate, respectively (Lan and Lin, 2005). In a related study, when the acute toxicity of Tl^+ (as thallium nitrate) was evaluated in two different daphnids, *Daphnia magna* and *Ceriodaphnia dubia*, there was 2.5-fold difference in sensitivity, with *C. dubia* being more sensitive; the LC₅₀ values, 0.65 and 1.7 mg/l on average for *D. magna* and *C. dubia*, respectively, also confirmed that daphnids are more sensitive to Tl^{3+} (Lin et al., 2005). Marine microalgae, i.e., *Ulva lactuca*, are very sensitive to Tl^+ as >10 µg/l concentrations were toxic; toxicity was independent of the water's salinity and it was associated with substantial accumulation of Tl by *U. lactuca* (Turner and Furniss, 2012). To Atlantic salmon, Tl is toxic, with its incipient lethal level estimated to be around 30 µg/l. Importantly, Tl is more toxic to salmon than Zn and is of similar potency with Cd (Zitko et al., 1975). In rainbow trout, the average LC₅₀ (96 h exposure) was estimated to be 4.3 mg/l (Pickard et al., 2001).

Chronic Effects

Studies examining the chronic ecotoxicological effects of Tl are extremely limited. A study with the duckweed *Lemna*

minor determined that Tl exposure stuns plant growth, with production of smaller fronds, being the most sensitive plant response to Tl stress. Notably, curtailment of frond expansion was more sensitive than inhibition of frond multiplication; these and other toxic effects of Tl were not permanent at lower (up to EC₅₀) exposure levels (Kwan and Smith, 1988).

There are no true chronic studies with daphnids, but a comparison of *C. dubia*'s 48 h LC₅₀ of approximately 0.65 mg/l (Lin et al., 2005) with a 7-day LC₅₀ in this aquatic organism, which is 0.37 mg/l (Pickard et al., 2001) hints towards the possibility of lower Tl levels being toxic to aquatic life under chronic exposure circumstances. Overall, chronic ecotoxicity data, especially from areas with differential geochemically and/or anthropogenically driven Tl levels are needed.

MAMMALIAN TOXICOLOGY

Acute Effects

The human oral LD₅₀ for Tl is estimated to be between 6 and 40 mg/kg; serious, nonfatal intoxication occurs at lower exposure levels. This estimate is based on cases of suicidal ingestion of Tl salts or homicide attempts (ATSDR, 1992; WHO, 1996). Acute thallium intoxication is characterized with a triad of symptoms: gastrointestinal, polyneuropathy, and alopecia; if left untreated and the exposure level is not lethal, progression through these symptoms will take place (ATSDR, 1992; Hoffman, 2003; Cvjetko et al., 2010). In cases of high deliberate or accidental exposures, contemporary timely therapy may not be successful. For example, despite multiple-dose activated charcoal and Prussian blue (PB) therapy initiated <1 h after initial symptoms, the patient died 3 days post exposure; his last blood and urine Tl concentrations were extremely high: 5369 µg/l and >2000 µg/l, for blood and urine, respectively (Riyaz et al., 2013).

While deliberate intoxications with Tl involve primarily Tl salts; occupational and children exposure to Tl may take place in the form of Tl-containing ceramic superconductor material (CSM) (Mulkey and Oehme, 1998). Comparison of bioavailability of Tl from CSM to that of Tl sulfate suggests that Tl in CSM has significantly lower bioavailability than Tl sulfate implying lower health risk from this source of Tl than the risk from Tl salts such as Tl sulfate (Mulkey and Oehme, 1998).

In neonatal rodents, Tl (Tl^+ acetate) causes long-lasting neuromyopathy manifested with progressive distal axonopathy and muscle fibers myopathic alterations (Barroso-Moguel et al., 1996). Much like in the rodent, signs of polyneuropathy persisted months after acute oral exposure to Tl-contaminated water (about 3124 mg/l) in human patients; damage of sensory nerve endings was still present

after all dermatological clinical features have subsided (Lu et al., 2007). In a long-term follow-up of Tl-exposed human patients, using functional imaging with fluorodeoxyglucose positron emission tomography (^{18}FDG PET), patients exhibited decreased glucose metabolism in the cingulate gyrus, bilateral frontal, and parietal lobes 2–5 months after exposure. These alterations in brain metabolism were accompanied with deficits in executive function and memory (Liu et al., 2013). Over time, partial, but not complete, recovery was observed (Liu et al., 2013), highlighting the fact that the neurological deficits associated with acute Tl intoxications are of particular concern.

Chronic Effects

Chronic or sub-chronic mammalian toxicity data for Tl are not abundant. Review of data summarized by EPA and ATSDR indicate that (i) long-term exposure to 1.4 mg/kg/day as thallium sulfate for 40–240 days is associated with increased lethality and (ii) chronic inhalation exposure to Tl (unknown amounts) in the workplace is associated with neurological deficits (ATSDR, 1992; EPA, 2009). Chronic animal studies are also scarce. Ninety-day oral gavage exposure of male and female Sprague-Dawley rats to approximately 0, 0.008, 0.04, or 0.20 mg/kg/day Tl was associated with increased incidence of alopecia, which was statistically significant at the mid and high dose for the female rats (EPA, 2009). The biological significance of this finding is not clear. Male reproductive toxicity of Tl was examined in adult male Wistar rats given 10 parts per million (ppm) Tl (as thallium sulfate) in the drinking water for up to 60 days. Sixty, but not 30-day, Tl exposure was associated with reduced sperm motility, increased immature germ cells in the tubular lumen, and with cytoplasmic vacuolation and distension of the smooth endoplasmic reticulum of Sertoli cells (Formigli et al., 1986). These findings indicate that the male reproductive system, Sertoli cells in particular, is susceptible to chronic Tl exposure (Formigli et al., 1986).

There are no reported chronic animal studies or cancer bioassays for Tl; similarly chronic effects of inhalation exposure to Tl in animal models have not been examined (EPA, 2009). There are several studies where sub-chronic or chronic effects of Tl given by injection have been studied. Of note, chronic (up to 26 weeks) s.c. exposure to Tl resulted in liver and kidney pathology in Sprague-Dawley rats; which at the structural level was confined primarily to the mitochondria (EPA, 2009). Two chronic systemic injection studies highlight the fact that the brain is a primary Tl target in both acute and chronic exposure scenarios. Thus, increased brain lipid peroxidation, which at the lower exposure level (0.8 mg/kg) was brain region specific, was observed in Tl exposed rats (Galvan-Arzate et al., 2000); in chronically exposed cats (2.3–4.5 mg/kg Tl[acetate] per week for 4–26 weeks) the main functional disturbances hypotonia and ataxia and the

pathological changes were confined primarily to sensory neurons and were “dying back” type (Kennedy and Cavanagh, 1977).

Due to the scarcity of data and the potential for chronic effects, reliable chronic exposure studies with Tl compounds where relevant exposure routes are employed are clearly needed.

Chemical Pathology

Thallium intoxication targets primarily the nervous system, the digestive system, and the skin (Tromme et al., 1998; Hoffman, 2003; Kazantzis, 2007; Cvjetko et al., 2010; Rusyniak et al., 2010). First clinical signs are observed 1–3 days after exposure and are dominated by nausea and vomiting; if exposure levels are in the LD₅₀ range, cardiovascular collapse, coma, and death will ensue within 24 h (Tromme et al., 1998; Cvjetko et al., 2010). Unlike exposure to other metal salts, the gastrointestinal symptoms associated with Tl toxicity are relatively minor and constipation is more characteristic than diarrhea (Hoffman, 2003). Neurological deficits associated with non-lethal Tl overexposure are of greatest concern. When nonlethal exposure takes place, peripheral neuropathy develops, which initially is more severe in the lower extremities. Over time, the neurological symptoms become more wide-spread and may include autonomic neuropathy, various psychiatric symptoms, and seizures. Initial dermatological signs are not specific, i.e., scaling of palms and soles, and acne-like lesions on the face (Tromme et al., 1998), but at higher exposures a characteristic mark, a “thallium band,” may appear in the scalp hair about 4 days post exposure (Tromme et al., 1998; Hoffman, 2003; Kazantzis, 2007; Cvjetko et al., 2010; Rusyniak et al., 2010). During the second (third) week after acute exposure, sudden alopecia, which becomes diffuse, develops (Tromme et al., 1998; Hoffman, 2003; Kazantzis, 2007). Another Tl intoxication characteristic, the Mee’s lines, takes longer to appear, but are more pronounced than the lines seen in arsenic intoxications. When exposure is terminated and treatment is instituted, Tl tissue levels decline and the hair and nails usually regrow, but the neurological deficits persist and full recovery of neurological function may not take place (Hoffman, 2003; Lu et al., 2007; Liu et al., 2013).

Prussian blue is the treatment of choice for acute Tl intoxications (Hoffman, 2003), but recent studies suggest that DL-penicillamine may be useful addition to PB in combating acute thallotoxicosis (Montes et al., 2011).

Mode of Action(s)

Most thallium salts are water-soluble. Monovalent thallium (Tl^+) has ionic radius and electrical charge that are similar to potassium (K^+) and contribute to its toxic mechanism (EPA, 2009). Thallium is absorbed rapidly and distributed widely regardless of exposure route (Kazantzis, 2007). Its elimination rate, which is also exposure route independent, is rather

slow; biological half-life is estimated to be 3.3 days (Kazantzis, 2007). In part due to its slow elimination rate, Tl tends to accumulate in different organs and cellular compartments (ATSDR, 1992). The exact mechanism of Tl toxicity still remains unknown, but interference with potassium homeostasis and glutathione metabolism, as well as oxidative stress, may all play a role in Tl's toxic mechanism (Cvjetko et al., 2010). *In silico*, Tl^{3+} is slowly converted to Tl^+ , which is more stable (Harris and Messori, 2002), but the extent of this conversion in a cellular context has not been fully described (Hanzel and Verstraeten, 2006; Hanzel and Verstraeten, 2009; Cvjetko et al., 2010). Thallium (Tl^+ and Tl^{3+}) increases cellular reactive oxygen species (ROS) production (Cvjetko et al., 2010). Lipid peroxidation and interference with intracellular antioxidants are suggested as being key components of Tl's toxic mode of action (Villaverde et al., 2004; Molina and Verstraeten, 2008). Competition of Tl^+ with K^+ has been associated with interference with many cellular processes ranging from modification of important metabolic enzymes, such as pyruvate kinase and fructose-1,6-bisphosphatase, to uncoupling of mitochondrial oxidative phosphorylation (Cvjetko et al., 2010). Thallium also interferes with enzymatic activity of multiple enzymes and interacts with exposed amino-sulphydryl groups (Mulkey and Oehme, 1993; Cvjetko et al., 2010). *In vivo*, structural degenerative changes in the mitochondria and a "dying back" type of sensory neuron pathology were associated with chronic exposures of laboratory animals to Tl (Kazantzis, 2007). Of note, certain behavioral abnormalities correlate with increased lipid peroxidation in the brain of Tl-exposed rodents (Brown et al., 1985). Information regarding Tl's genotoxicity and mechanism(s) involved is scarce (Rodriguez-Mercado and Altamirano-Lozano, 2013). Scarcity of data and the lack of clearly identifiable mechanism(s) of thallium toxicity in acute and chronic exposure settings need to be addressed with further research.

SOURCES OF EXPOSURE

Occupational

Occupational exposures to Tl may occur through alloy production and machining or through the manufacturing of thallium-containing electronic components, optical lenses, and jewelry (ATSDR, 1992; WHO, 1996). Prior to its elimination, manufacturing of Tl-containing rodenticides was another source of occupational exposure to this metal (ATSDR, 1992; WHO, 1996; Kazantzis, 2007). Air concentration in the workplace of smelting operations is typically $>22\text{ }\mu\text{g}/\text{m}^3$ (WHO, 1996). Inhalation is also an important exposure route for workers engaged in the separation of industrial diamonds, manufacturing of Tl-containing optics, extraction of Tl, or roasting of pyrites (Kazantzis, 2007; EPA,

2009). The two primary routes of exposure to thallium workers that are associated with intoxications are dermal and oral (Ewers, 1988; Kazantzis, 2007).

Environmental

Food in the typical human diet contains $<1\text{ mg/kg}$ Tl and human intake is estimated to be $<5\text{ }\mu\text{g}/\text{day}$ (WHO, 1996). Absorption through inhalation in unpolluted environments is fairly low: not $>0.005\text{ }\mu\text{g}/\text{day}$ (WHO, 1996). Detectable, but low levels of Tl are also found in unpolluted saltwater and freshwater (EPA, 2009). However, Tl-polluted atmospheres from emissions from coal-burning power plants and metal smelting operations can contribute to environmental exposures greater than exposures through the diet (Kazantzis, 2007; EPA, 2009). Industrial activity can also lead to substantial increase of Tl levels in soil; i.e., concentrations of more than 100 mg/kg in soils from a mining region in China have been reported (Xiao et al., 2004a, 2004b). Some soils contain greater Tl levels from natural sources (Xiao et al., 2012). In either case, soil Tl can be mobilized by edible plants resulting in increased dietary intake of Tl and increased human and ecotoxicological risk for Tl intoxication in such areas (Kazantzis, 2007; EPA, 2009; Xiao et al., 2012). Increased Tl in metal mining effluents and its ineffective waste water removal by conventional means is another source of increased environmental Tl exposures (Peter and Viraraghavan, 2005).

INDUSTRIAL HYGIENE

Exposure Limits:

8 h shift permissible exposure level (PEL): 0.1 mg/m^3 (OHSA, 2005)

8 h shift threshold limit value (TLV): 0.1 mg/m^3 (ACGIH, 2010)

10 h shift recommended exposure limit (REL) and PEL: 0.1 mg/m^3 (NIOSH, 2005; OHSA, 2005)

Immediately Dangerous to Life and Health (IDLH): 15 mg/m^3 (NIOSH, 2005)

PPEs: NIOSH/OSHA:

0.5 mg/m^3 : DM^{^A}; 1.0 mg/m^3 : DMXSQ^{^A}/SA; 2.5 mg/m^3 : SA: CF/PAPRDM^{^A}; 5 mg/m^3 : HiEF/SAT: CF/PAPR-THiE/SCBAF/SAF DM^{^A}; 15 mg/m^3 : SAF/PD, PP; §: SCBAF:PD, PP/SAF:PD, PP:ASCBA; Escape: HiEF/SCBAE.

RISK ASSESSMENTS

Thallium is classified as an environmental and industrial pollutant, potentially dangerous to human health and wildlife

(EPA, 2009). From an ecotoxicological perspective, the ecotoxicological serious risk concentrations (SR_{ECO}) values are as follows: (i) fresh water: $6.8 \mu\text{g/l}$, ground water: $8.5 \mu\text{g/l}$, marine water: $6.5 \mu\text{g/l}$ (a serious risk addition [SRA_{ECO}] value), sediment: 11 mg/kg , and soil: 2 mg/kg (RIVM, 2005). According to EPA and ATSDR, there is inadequate information to assess the carcinogenic potential of Tl/thallium salts (ATSDR, 1992; EPA, 2009). Subsegments of the population, i.e., people with preexisting neurological disease, kidney, and liver damage may be at risk for Tl toxicosis (ATSDR, 1992). Individuals with potassium deficiency may also be at risk (ATSDR, 1992; WHO, 1996, EPA, 2009).

TIN

RAYMOND D. HARBISON AND DAVID R. JOHNSON

First aid: Remove from exposure. Give fresh air. Immediately irrigate eyes, wash the skin with soap. Provide respiratory support. If ingested by swallowing, seek immediate medical attention.

Target organs: Metallic and inorganic tin targets the eyes, skin, respiratory tract. Organic tin compounds target the central nervous system, liver, kidneys, urinary tract, and blood.

Risk/safety phrases: Irritant; inhalation risk; ingestion may be neurotoxic. The solid form is non-combustible; however, the powdered form may ignite.

Exposure limits and threshold limit values for tin compounds:

Tin Compounds	CAS Number	PEL, mg/m ³	REL, mg/m ³	TLV, mg/m ³
Tin	7440-31-5	2	2	2
Inorganic compounds, excluding oxides	7440-31-5	2	2	2
Inorganic compounds, including oxides but excluding SnH ₄	Varies	—	—	2
Organic compound	Varies	0.1	0.1; STEL: 0.2	
Tin(II) oxide (as Sn)	21651-19-4	15 (maritime shipyards)	2	2
Tin(IV) oxide (as Sn)	18282-10-5	15 (maritime shipyards)	2	2

From National Institute for Occupational Safety and Health (NIOSH, 2010): *Pocket guide to chemical hazards*, NIOSH 94–116, Washington, DC, 2010, US Department of Health and Human Services; American Conference of Governmental Industrial Hygienists (ACGIH, 2003): *Threshold limit values (TLVs) for chemical substances and physical agents and biological exposure indexs (BEIs)*, Cincinnati, 2003, American Conference of Governmental Industrial Hygienists.

CAS, Chemical Abstract Service; PEL, permissible exposure limit, set by the Occupational Safety and Health Administration (OSHA); REL, recommended exposure limit, set by the NIOSH; TLV, threshold limit value, set by the ACGIH; STEL, short-term exposure limit, set by the ACGIH.

BACKGROUND AND USES

Tin is primarily produced from the ore cassiterite (SnO₂). It has a variety of industrial and domestic uses; its usefulness stems from its pliability and ability to readily form compounds and alloys with other metals, inorganic compounds, and organic compounds. Tin metal is used to line cans for storing and transporting food, beverages, and aerosols. Bronze is an alloy of tin and copper; pewter is an alloy of tin with various amounts of antimony, copper, bismuth, and sometimes lead. Soldering compounds are made with tin alloys. Inorganic tin is used in making toothpaste, perfumes, soaps, coloring agents, food additives, dyes, and in the glass industry (ATSDR, 2005). Artificial organotin compounds are used to make plastics, food packages, as a stabilizer for PVC (pipes), agrochemicals (such as pesticides), paints, wood

preservatives, surface disinfectants (including hospital and veterinary disinfectants), bacteriostats, antimicrobials and slimicides, biocides such as rodent repellants, laundry sanitizers, mildewcides, industrial catalysts, scintillation detectors for gamma and X-rays, ballistic additives for solid-rocket engine fuels, and ionophores in liquid membrane ion-selective electrodes (Nath, 2008; Cao et al., 2008; Kotake, 2012). Organotin compounds have been used extensively in boat paints due to their excellent antifouling properties (Okoro et al., 2011; Graceli et al., 2013).

Tributyltin is used as a slime control in paper mills, for disinfection of circulating industrial cooling waters, as anti-fouling agents, and in the preservation of wood (Antizar-Ladislao, 2008; Nakanishi, 2008). Tributyltin, triphenyltin, and tricyclohexyltin are used in agriculture as fungicides, anti-helminthics, miticides, herbicides, nematocides, ovicides, molluscicides, ascaricides, pesticides, in industry as biocides, and as antifouling agents for large ship bottoms and fishery farm nets (as industrial catalysts). In the past, several organometallic metallocene complexes of tin have been identified as having antitumor activity (Köpf-Maier et al., 1988; Winship, 1988). Tin protoporphyrin has been used to treat acute hepatic porphyria (Dover et al., 1993). Niobium-tin compounds are used to build superconducting magnets (Gaballe, 1993). Zirconium-tin alloys are used for cladding nuclear fuel (Campbell, 2008). Tin is used in advanced Li-ion batteries as the negative electrode (Lucas et al., 2011). Large amounts of organotins are used in the plastics industry, and large amounts of tin are also recycled.

PHYSICAL AND CHEMICAL PROPERTIES

Tin is a ductile, malleable, lustrous solid with a gray to almost silver-white color. It has: atomic number 50; molecular weight 118.7; melting point 449 °F (232 °C); boiling point 4118 °F (2270 °C); and specific gravity 7.28. Tin forms covalent bonds with carbon forming a variety of organometallic or organotin compounds, and the physical and chemical properties differ for various compounds such as Tin II (SnO) and Tin IV (SnO_2), organotins, and inorganic tin compounds. Tin compounds are generally insoluble in water and have vapor pressures of approximately 0 mm Hg. Tin is not easily oxidized and resists corrosion; however, powdered tin has a tendency to oxidize, especially at high humidity.

MAMMALIAN TOXICOLOGY

While tin in its inorganic form is generally considered nontoxic, various organotin compounds have shown significant toxicity in animals and humans.

Acute Effects

Metallic and inorganic tin is of low oral toxicity to humans because of its poor gastrointestinal (GI) absorption and rapid excretion in the feces. About 5% is absorbed from the GI tract, widely distributed throughout the body and then excreted by the kidneys (Winship, 1988). Doses of 100 mg can cause acute GI effects resembling food poisoning. Some reports suggest that the concentration of tin may be more important than the dose in causing acute GI symptoms. Urinary tin levels of 625–1600 µg/l have been associated with illness. There are reports of acute health effects as a result of consumption of highly contaminated fruit juices. As far back as 1890, there were case reports of tin poisoning affecting four individuals who ate cherries from the same large tinned can. Analysis of the juice found it to be strongly acidic due to the presence of malic acid with an estimated “1.9 grains of the oxide of tin or 3.2 grains of the malate of tin per fluid ounce” (1 grain = 65 mg). The authors estimated doses of 4–10 grains of the malate of tin (260–650 mg). The symptoms included nausea, abdominal pain, vomiting, diarrhea, drowsiness, feeble weak irregular pulse, and unconsciousness in one patient. One patient had cramps in the legs and two had a trace of albumin in the urine. Although treatment was unconventional by today’s standards, all four patients were practically well by the next morning. The authors concluded that tin salts act as an irritant and cardiac poison. They warned about the dangers of eating fruits preserved in acid juices in tin cans (Luff and Metcalfe, 1890). In 2005 the World Health Organization (WHO) reported that human poisoning from consumption of food and drink contaminated with inorganic tin have resulted in abdominal distension and pain, vomiting, diarrhea, and headache. The symptoms occurred when the food or beverage was found to contain tin at concentrations varying from 250 to 2000 mg/kg. They concluded from available information that the GI irritation was more closely related to the concentration and nature of tin in the product rather than the dose of tin ingested on a body-weight basis. In 2003, Blunden and Wallace suggested that there is little evidence for an association between the consumption of food containing tin at concentrations up to 200 parts per million (ppm) and acute GI effects, noting that further studies needed to be done (Blunden and Wallace, 2003). Food and beverages should not be stored in opened tin-plated cans. The lacquering of tin-plated cans prevents the migration of inorganic tin into food and beverages (WHO, 2005a).

Inorganic tin compounds (excluding oxides) may be skin irritants. Contact with them may cause intense itching and erythematous lesions. People with skin diseases may be particularly susceptible to this irritation. Signs and symptoms typically resolve after exposure has ceased. One case-control study linked occupational exposure to tin with chronic renal failure (Nuyts et al., 1995). Human and animal studies have shown that the ingestion of large amounts of inorganic tin compounds can cause stomach ache, anemia, and liver and

kidney problems. Gunay et al (2006) studied the effect of long-term exposure to tin fumes in tinsmiths and concluded that the occupational exposure to heavy tin fumes was associated with left ventricular dysfunction and sclerosis of the aortic valve.

Organotin compounds such as tributyltin, trimethyltin, and triethyltin are more toxic than inorganic tin compounds. The ethyl derivative of organotins is the most toxic, and triethyltin and trimethyltin are known to be neurotoxic (Winship, 1988). As the number of attached alkyl groups increases, the toxicity of organotins compounds also increases (Nath, 2008). Trialkyltin is more toxic than dialkyltin or monoalkyltin. Various organotins are absorbed through the GI tract and skin and may cause irritation of the mucous membranes, eyes and skin, respiratory irritation, GI effects, nausea, vomiting, diarrhea, neurological problems, headache, fatigue, muscular weakness, and paralysis followed by respiratory failure after acute exposure to high amounts (Okoro et al., 2011). Some organotin compounds can cause cerebral edema and produce central nervous system and cardiovascular effects while others may cause hepatic necrosis. Organotins can be highly lipophilic and therefore can easily penetrate the blood-brain barrier ((Nath, 2008; Kotake, 2012). Dermatitis has been reported after exposure to tributyltin phthalate (Hamanaka et al., 1992). Acute burns of skin and eyes have been reported from tributyltin and dibutyltin compounds after brief contact (Lyle, 1958). Lethal cases have been reported due to ingestion of very high amounts of organotins (ATSDR, 2005).

Chronic Effects

Inhalation of tin dust or tin oxides may produce benign pneumoconiosis called *stannosis* (Robertson et al., 1961). Stannosis is *not* associated with symptoms or significant pulmonary impairment; however, there are distinctive chest X-ray findings. The chest X-rays of this condition resemble those of siderosis, showing dense bilateral nodular infiltrates. The opacities are unusually dense because of the high radiopacity of tin. This should facilitate early diagnosis. Blackish or gray macules consisting of dust-laden macrophages are present in the lungs (Morgan and Seaton, 1984). Stannosis has not been associated with morbidity or decreased life expectancy.

Organotin compounds have recently gained research interest due to concerns about their potential for bioaccumulation and biomagnification in food chains coupled with the potential adverse effects on human health and environment. Organotin compounds such as tributyltin are suspected as endocrine disruptors in mammals (Kotake, 2012).

Animal studies have shown that some organotins such as dibutyltins, tributyltins, and triphenyltins can affect the reproductive system (ATSDR, 2005). Other organotins have been associated with neurotoxicity or immunotoxicity in animal studies (Nath, 2008).

Carcinogenicity Tin has not been established as a human carcinogen. Animal studies have not shown associations between exposure to inorganic tin compounds and the development of cancer. Organotin compounds have been associated with cancer in animals in a limited number of studies. A study in rats and another in mice found triphenyltin hydroxide to be associated with the development of cancer after long-term oral administration (ATSDR, 2005). Based on animal studies, Nagano et al. (2011) recently reported an association between the inhalation of indium-tin oxide and the development of benign and malignant lung tumors, preneoplastic lesions of bronchioloalveolar hyperplasia, fibrosis of alveolar walls, and thickening of pleural walls.

Tin Mining and Lung Cancer Extensive research has attempted to explain the high incidence of lung cancer among Chinese tin miners (Wu et al., 1989). Miners and smelter workers over 40 years old with at least 10 years of work experience have annual lung cancer incidence rates >1% (Taylor, 1994). Factors such as smoking, radon, arsenic, and silica exposure may all contribute to these high rates of lung cancer. Qiao et al. (1989) reported that miners in the highest quartile of radon exposure had an odds ratio of 9.5 for lung cancer when controlled for arsenic exposure. In a much larger cohort study, Xuan et al. (1993) reported an increased risk of 0.2% per working month exposed to radon while controlling for arsenic exposure. Pathohistogenetic examination of 100 lung cancer cases also implicated radon rather than ore dust as having a greater role in cancer etiology (Sun et al., 1989). Taylor et al. (1989) reported that tin miners in the highest quartile of arsenic exposure had a relative risk of 22.6 when the variables of radon and smoking were controlled. Silicosis may also be responsible for lung cancer in tin miners (Fu et al., 1994).

One case-control study indicated that the increased fruit and vegetable intake among some tin miners might have a protective effect against the development of lung cancer (Forman et al., 1992)

Mechanism of Action(s)

Animal studies have shown that ingestion of stannous chloride interferes with the body's handling of copper, iron, and zinc; and limited data suggest a possible neurotoxic effect involving calcium channel neuromuscular transmission. Patch testing has shown people to be allergic to tin (WHO, 2005b).

Rabbits treated intraperitoneally with tin were reportedly anemic, but rabbits exposed to tin orally had only transient anemia (Chmielnick et al., 1993).

Some tin compounds, stannic chloride in particular, have been reported to induce chromosomal abnormalities in human peripheral lymphocytes (Ganguly et al., 1992).

Regarding organotins, various mechanisms of action have been described depending on the organotin compound and type of animal being studied. Proposed mechanisms include induction of apoptosis, uncoupling of mitochondrial energy transduction and ion exchange, inhibition of membrane functions, interference with ATPase activity, decreases in functional activity of intestinal cytochrome-450, and inhibition of intracellular phospholipid transport affecting the immune systems. Organotins mainly favor fat accumulation and have been associated with endocrine and lipid disruption. They have been reported to affect the heme metabolism, the cardiovascular and central nervous system, and cause a fall in blood pressure due to depression of the vascular smooth muscle (Nath, 2008; Pagliarani et al., 2013; ATSDR, 2005).

Animals dosed with trialkyl tin did not suffer permanent brain damage or demyelination of the spinal cord found with exposure to some other alkyl metals (i.e., mercury). However, postmortem studies confirmed organotin-induced hepatic necrosis and cerebral edema with irreversible cell damage in the area of the nucleus amygdaloideus of humans. These changes correlated with the clinical manifestations observed in organotin-intoxicated workers.

Kotake (2012) reported on the potential mechanisms of organotin toxicity in mammals, including ATP synthase inhibition; disruption of steroid homeostasis; agonistic activities toward nuclear receptors; obesogenic effect and immunotoxicity; neurotoxicity; and GluR2 decrease by endogenous levels of organotins. Nakanishi (2008) describes organotins as endocrine-disrupting chemicals possibly acting as nanomolar agonists for retinoid X receptor and peroxisome proliferator-activated receptors. The critical target molecules for the toxicity of organotin compounds remain unclear and further studies are needed (Kotake, 2012; Pagliarani et al., 2013).

SOURCES OF EXPOSURE

All forms of tin can be found in soil, water, and air in various environmental settings, including areas of natural deposits, near mining operations, manufacturing, or where tin products are being used. However, eating food contaminated with tin is considered the main route of exposure.

Occupational

Reports of oral occupational exposure are lacking. Exposure to tin dust may occur during tin ore extraction, bagging, smelting, and refining operations. As indicated in the preceding discussion regarding cancer, tin miners may be exposed to other potentially toxic substances such as silica, arsenic, radon, thorium, uranium, lead, as well as to bismuth

and antimony in the roasting and smelting process. Exposure to these toxic metals may also occur during the preparation and use of tin alloys and solders (Taylor et al., 1989; Dosemeci et al., 1993; WHO, 2005b). Tinsmiths can be exposed to heavy fumes of tin; such exposure should be minimized and workers monitored for heart disease (Gunay et al., 2006). It has been shown that workers involved in electric cable splicing may contaminate their homes with lead and tin (Rinehart and Yanagisawa, 1993).

Workers involved with the use or manufacture of inorganic tin compounds or organotins may be exposed. Potential occupational exposure to organotins is increasing due to the manufacturing of many new organotins with a variety of applications; however, current data on the frequency, concentration, and duration of worker exposure are lacking (ATSDR, 2005).

Environmental

Canned foods make the biggest contribution to the dietary intake of tin. Tin exposure to the general public has been reduced greatly in the past few decades, primarily as a result of improvements in the canning process such as tinning cans with an enamel or lacquered overcoat and crimping lids. Prior to these improvements, tin-canned food could contain tin concentrations of 100 ppm.

Human exposure to organotins can potentially occur via contaminated dietary sources such as seafood, shellfish, and food crops (Nakanishi, 2008). The potential for water contamination with organotins exists due to their use in the manufacture of plastics and PVC pipes.

The daily intake of tin from food is <1 mg. Concentrations of tin in soil range from 5 to 200 ppm. Rural air concentrations are below 10 ng/m³.

Pewter dinnerware contains >90% tin as an alloy. Stannous fluoride is also used as a toothpaste additive.

Tributyl tin has been reported as one of the most toxic chemicals released into the marine environment by an anthropometric source (Cao et al., 2008), and there are concerns about the increased use of organotins in general resulting in marine contamination via leaching and runoff (Antizar-Ladislao, 2008). Exposure to organotin-contaminated water and sediments induce accumulation of organotins in mollusks and biological effects such as endocrine disruption and impossex (female masculinization). Health effects could potentially result from human consumption of contaminated seafoods (Cao et al., 2008; Nakanishi, 2008; Graceli et al., 2013).

Because of the many increasing applications, organic and inorganic tin has been considered to be the third most important elemental pollutant in the ecosystem (Nath, 2008).

Drinking water is not currently considered a significant source of tin exposure and inhaled environmental air represents very low exposure (WHO, 2005b).

INDUSTRIAL HYGIENE

It is necessary to monitor air concentrations in occupational settings where tin dust exposure is a risk, keeping concentrations within the REL, TLV, and PEL. See the table in the introduction to this chapter. Monitoring methods are available in OSHA and NIOSH publications and websites.

Wet processes can minimize exposures during tin ore extraction; however, dust and fumes may still escape during bagging, smelting, and refining operations. Due to the increasing manufacture and use of alloys and organotins, employers need to be educated about the risk of organotin exposure and implement strategies to minimize exposure to the skin, lungs, and GI tract. Periodic sampling of the worker's environment may be useful in assessing and mitigating risks. Tin mining might involve exposure to radon, thorium, uranium, silica, lead, arsenic, bismuth, and antimony; and industrial hygiene measures should be implemented for these substances as well.

Ultrasensitive analytical techniques have been developed for the measurement of tin in tissues and urine; however, relationships between tin dose and biological indicators have not yet been established (WHO, 2005b). De Azevedo et al. (2013) reported the validation of a procedure for the determination of tin in whole blood and urine utilizing graphite furnace atomic absorption spectrometry.

MEDICAL MANAGEMENT

Because most forms of metallic and inorganic tin are poorly absorbed and acute intoxication is rare, treatment guidelines for acute tin intoxication are sparse or nonexistent in the medical literature. Antidotes are not published. Acute tin intoxication has on rare occasion occurred after ingestion of tin-contaminated food stored in tin cans; most cases have rapidly recovered with removal of exposure. Persons suspected of acute intoxication should be provided close observation and supportive care for symptoms of fever, headache, nausea, vomiting, diarrhea, abdominal cramps, and bloating, which should be short lived. Monitor cardiac function and rhythm. Gastric lavage might be considered in a few specific situations after consulting the local poison control center. A complete workup for other forms of intoxication, including medications and illicit drugs should be included until tin intoxication is proven. A thorough exposure history is imperative to confirm the diagnosis and to identify the source of tin exposure in order to prevent further exposure of the intoxicated individual or others. Contacting the local poison control center may be helpful in the management of the case and is an important reporting responsibility allowing public health authorities to document and track cases. Additionally, the poison control center may be helpful in identifying

laboratories that can determine tin levels in urine, blood, and environmental samples.

Although organotins are considered more toxic than inorganic tin compounds and more likely to adversely affect the nervous system and liver, similar medical management principles should be followed as for tin and inorganic tin compounds, including observation, supportive care, confirmation of exposure, confirmation of intoxication, and reporting of the case.

Identifying and eliminating exposure to tin compounds is a must for both acute and chronic intoxication.

Occupational exposure limits	OSHA PEL ^a : 15 mg/m ³ as titanium dioxide (TiO ₂ , total dust) ACGIH TLV ^b : 10 mg/m ³ as TiO ₂ NIOSH REL ^c : (Ca) lowest feasible concentration NIOSH Immediately Dangerous to Life or Health Concentration(IDLH): 5000 mg/m ³
Reference values	Titanium (CAS # 7440-32-6) Oral RfD: 4.0E+00 mg/kg/day Inhalation RfD: 8.6E-03 mg/kg/day RfC: 3.0E-02 mg Ti/m ³
Risk/safety phrases	For titanium dioxide: Risk phrases: R40 limited evidence of a carcinogenic effect Safety phrases: S36/37 wear suitable protective clothing and gloves For titanium tetrachloride: Risk phrases: R-14 reacts violently with water R34 causes burns 2. Safety phrases: S26 in case of contact with eyes, rinse immediately with plenty of water and seek medical advice S36/37/39 wear suitable protective clothing, gloves, and eye/face protection S45 in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible) S7/8 keep container tightly closed and dry

^aOccupational Safety and Health Administration (OSHA PELs (permissible exposure limits) are 8-h TWA (time-weighted average) concentrations

^bAmerican Conference of Governmental Industrial Hygienists (ACGIH TLVs (time limit threshold values) are 8-h TWA concentrations established by ACGIH

^cNational Institute for Occupational Safety and Health (NIOSH RELs(recommended exposure limits) are 10-h TWA concentrations established by NIOSH

BACKGROUND AND USES

Titanium (Ti, CASRN 7440-32-6) was first discovered in the eighteenth century and named after the Titan, a god of strength from the Greek mythology. It is the ninth most

abundant element in the earth's crust and is known as a space-aged metal. Its enormous strength, low density, and light weight make it the foremost choice for aircraft, space vehicle, and missile programs. Titanium is commonly used in surgical prosthetics and instruments because of its ability to form high

strength alloys with other metals. Its versatile properties are used in the manufacturing of jewelry, automobiles, bicycles, firearms, and other merchandise. Its anticorrosive and heat-resistant properties make it useful in marine equipment and wall paints (Gambogi, 1995).

PHYSICAL AND CHEMICAL PROPERTIES

Titanium dioxide (TiO_2 , CAS # 13463-67-7) is a white pigment that is water insoluble and very stable. It has a molecular weight 79.9, boiling point (760 mmHg) <3000 °C (<5432 °F), specific gravity of 3.9–4.2, melting point of 1640 °C (2984 °F), and it is not a combustible compound. Titanium tetrachloride (TiCl_4 , CAS# 7550-45-0) is a colorless liquid with a vapor pressure of 10 mmHg at 20 °C. It has a molecular weight of 189.70, melting point –24 °C, boiling point 136.4 °C, density at 20 °C, and it is nonflammable. It is soluble in both water and alcohol with a penetrating acidic odor.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute inhalation exposure of titanium dioxide (TiO_2) shows pulmonary inflammation with cell damage and an increasing adequately high surface area deposition in rats. Greater toxicity was observed with doses of ultrafine TiO_2 at a given mass dose (Oberdörster et al., 1992; Renwick et al., 2004). Acute exposure of titanium tetrachloride (TiCl_4) in rats and dogs resulted in nasal discharge, dyspnea, severe respiratory inflammation, epithelial denudation, discrete inflammatory residue in the lungs, coarsened alveolar septa, and swollen eyelids and death due to pulmonary edema (DuPont, 1980; Kelly, 1980). Acute titanium tetrachloride toxicity causes irritation to the skin, eyes, mucus membranes, and respiratory tract in humans. Acute exposure may result in surface skin burns; marked congestion of mucous membranes of the pharynx, vocal cords, and trachea; and stenosis (constriction) of the larynx, trachea, and upper bronchi in humans. It may also damage the cornea in the eyes.

A worker accidentally exposed to a high concentration of titanium tetrachloride via inhalation later developed endobronchial polyps (Garabrant et al., 1987). Workers exposed to titanium dioxide, showing deposits of dust in the pulmonary interstitium, are associated with cell destruction and slight fibrosis, which also suggested that TiO_2 is a pulmonary irritant (Bermudez et al., 2002, 2004). Acute titanium dioxide toxicity may produce metal fume fever (Otani et al., 2008).

Chronic Effects

Chronic exposures of titanium dioxide (TiO_2) in rodents show dose-related pulmonary responses to fine or ultrafine

TiO_2 . The responses in rats include pulmonary inflammation, oxidative stress, tissue damage, fibrosis, and lung cancer (Heinrich et al., 1995; Muhle et al., 1991). Chronic exposure of titanium tetrachloride (TiCl_4) in rats resulted in tracheitis and rhinitis. Also, immunological and lymphoreticular changes in lungs, like foamy lung macrophages with increased TiCl_4 dust deposition, were observed (Lee et al., 1986; Driscoll et al., 1991). Chronic exposures to titanium tetrachloride at the workplace produce pleural thickening and decreased pulmonary function in the workers. Chronic inhalation exposure may result in upper respiratory tract irritation, chronic bronchitis, cough, bronchoconstriction, wheezing, chemical pneumonitis, or pulmonary edema in humans (Garabrant et al., 1987).

Mechanisms of Action

Titanium tetrachloride (TiCl_4) is extremely corrosive, hydrolyzing upon contact with moisture releasing heat, hydrochloric acid, and orthotitanic acids causing direct tissue damage in the lungs. Studies show that fine oxychloride intermediates generated from TiCl_4 hydrolysis can penetrate deep into the lung tissue resulting in direct contact irritation and bronchitis or pneumonia (Mezentseva et al., 1963; Kelly, 1980; Chitkara and McNeela, 1992). The mechanism of toxicity of titanium dioxide (TiO_2) is based on the inflammatory response to TiO_2 particles in the target tissue. Studies have demonstrated a neutrophil-mediated inflammatory response to TiO_2 , in addition to increased inflammatory response through particle-laden macrophages (Ferin et al., 1992; Renwick et al., 2004; Grassian et al., 2007a, 2007b).

Chemical Pathology

In vivo studies in animals have demonstrated that exposure to TiO_2 particles can induce inflammatory responses in lung tissue and cytotoxicity in lung cells; the degree of inflammatory response and cytotoxicity elicited depends on the particle size and its surface chemistry (Rehn et al., 2003; Dick et al., 2003; Renwick et al., 2004; Warheit et al., 2005; Monteiller et al., 2007). Exposure to titanium dioxide nanoparticles (<100 nm in diameter) induces genotoxicity and cytotoxicity in cultured human lymphoblastoid (WIL2-NS) cells (Wang et al., 2007).

SOURCES OF EXPOSURE

Occupational

Inhalation and dermal absorption are significant routes of occupational exposure to titanium dioxide (TiO_2). The occupations in which exposure to titanium dioxide (TiO_2) occurs are titanium mining, purification, packaging, and distribution. During the manufacturing of paints, varnishes, lacquers,

paper, photographic papers, packaging paper, and cellophane, TiO_2 is used as a coating where exposure to TiO_2 may occur. Other occupations involved in TiO_2 exposure are manufacturing of elastomers for use in tire side walls, footwear, floor mats, gloves, rainwear, wall covering and manufacturing of ceramic and glass for capacitors, electromechanical transducers, welding rod coating, and glass fibers. Titanium dioxide (TiO_2) exposure also occurs in the production of cosmetics, food color additives, synthetic diamonds, artificial leather, and printing inks (Petty, 1963; Schwartz et al., 1957). Like titanium dioxide, inhalation and dermal absorption are the significant routes of exposure to TiCl_4 (Friberg et al., 1979). Workers who are involved in the process of producing titanium metal from titanium tetrachloride receive the most exposure. Maintenance workers of these facilities are also exposed to a high level of titanium tetrachloride vapor containing its hydrolysis products, titanium dioxide, and hydrochloric acid. (Garabrant et al., 1987) Some of the workers use titanium tetrachloride to check welding machinery. Accidentally, they may be exposed to titanium tetrachloride because of an occupational spill (Ross, 1985).

Environmental

Titanium oxide is the most commonly available form of titanium, which is the ninth most abundant element in the earth. The main source of environmental exposure to titanium dioxide is dermal absorption from sunscreens, paints, enamels, and cosmetics; ingestion of these products may also be a significant route of exposure (IARC, 2010). Populations living nearby titanium mines and industries using titanium dioxide may suffer an increased risk of exposure. However, environmental exposure to titanium tetrachloride is unlikely, as it breaks down rapidly in water (Wilms et al., 1992).

INDUSTRIAL HYGENE

The Occupational Safety and Health Administration set PELs for titanium dioxide and titanium tetrachloride, which are legally enforceable in the industries involving these chemicals. Good industrial hygiene methods like general dilution ventilation and personal protective equipment have been used to keep the environmental concentration below the PELs. Though under certain conditions exposure control may not be technically possible, the workers should use a proper respirator to avoid chemical exposure at that point. During the spillage of TiO_2 , properly ventilate the area of spill. Thereafter, collect the material and dispose in a secured sanitary landfill; this is the most convenient and safe way of reclamation or disposal. Liquid containing TiO_2 should be absorbed in vermiculite, dry sand, earth, or a similar material (Raterman, 1996; Burton, 1997; Hinds, 1999).

MEDICAL MANAGEMENT

Acute exposure of titanium dioxide and titanium tetrachloride requires an immediate removal from the place of exposure and the use of appropriate first aid to the exposed person. The respiratory system is most commonly affected during inhalation exposure. During management, ensure a clear airway and maintain adequate breathing. If the patient has symptoms of bronchospasm, treat symptomatically with bronchodilators or corticosteroids. Endotracheal intubation may be required for a person with life-threatening laryngeal edema. Acute dermal exposures require the removal of the person from the place of exposure, and in case of chemical burn, it should be reviewed by a burn specialist (Bronstein and Currance, 1994).

TUNGSTEN

KAMBRIA K. HAIRE AND RAYMOND D. HARBISON

Target organ(s): Eyes, skin, lungs, and blood

Occupational exposure limits: Insoluble tungsten (8-h TWA):
5 mg/m³ (OSHA), 5 mg/m³ (NIOSH); 10 mg/m³ STEL
(NIOSH)

Risk/safety phrases: Skin irritant; eye irritant; respiratory
irritant; gastrointestinal irritant; corrosive

(Berry and Gailie, 1990; Gbaruko and Igwe, 2007). Tungsten trioxide is used as pigments in ceramics and in the coloring process for textiles and fireproofing fabrics (Berry and Gailie, 1990; Zuyagin, 1999; Gbaruko and Igwe, 2007). Tungsten carbide is used in metal, mining, and petroleum industries. (Cajal, 1982; Gbaruko and Igwe, 2007).

BACKGROUND AND USES

Tungsten (CASRN 7440-33-7), also known as wolfram, occurs as wolframite (FeWO_4). It can be found in the earth's crust but not in its pure metal form. It combines with other chemicals and compounds within the rocky earth's crust. It is a transitional hard metal with physicochemical properties and can also be manufactured commercially (Lassner and Schnubert, 1999; Gbaruko and Igwe, 2007; Stefaniak, 2010; Strigul et al., 2010).

Tungsten is most commonly used to increase the hardness of steel. It is available commercially in the form of powder, single crystal, and ultrapure granule grades. It is also used in the manufacturing of alloys, light filaments, and X-ray tubes. A recent use for tungsten is as a lead substitute during the manufacturing of ammunition and sporting good products. Another recent commercial use for tungsten is in the production of wedding bands. It is also used as a catalyst in chemical reactions (Lassner and Schnubert, 1999; Gbaruko and Igwe, 2007; Stefaniak, 2010; Strigul et al., 2010).

There are many chemical configurations for tungsten compounds. The most common compounds are sodium tungstate, tungsten trioxide, and tungsten carbide. Sodium tungstate is commonly used for fire and waterproofing fabrics

PHYSICAL AND CHEMICAL PROPERTIES

Tungsten is a steel-gray to tin-white metal. It is a heavy metal with a high density and melting point (Table 36.1) (Lassner and Schnubert, 1999; Stefaniak, 2010; Strigul et al., 2010). It is a very hard metal that is stable in dry air at ordinary temperatures. Although very difficult to work with, tungsten can be cut with a hacksaw, forged, or spun. Commercially, tungsten is obtained via the reduction of tungsten oxide with hydrogen or carbon. Due to its hardness, tungsten has the highest boiling point and highest tensile strength of all metals. Although the metal shows resistance to corrosion, it can oxidize in air with an increase in temperature (Robert and Golden, 1980; Gbaruko and Igwe, 2007).

Tungsten is a very hard metal with similar properties and functions to molybdenum and chromium. Unlike molybdenum, tungsten is not an essential trace metal. However, tungsten is a competitive inhibitor of molybdenum in bacteria, plants, and animals (Hainline and Rajagopalan, 1983; Smith, 1991).

At high temperatures, tungsten forms tungsten trioxide from sodium tungstate. Sodium tungstate is an aqueous solution with an alkaline pH (Cajal, 1982; Zuyagin, 1999; Gbaruko and Igwe, 2007). Sodium tungstate is used in the preparation of complex compounds, as a reagent for biological

TABLE 36.1 Physical and Chemical Properties of Tungsten Compounds

Name	Chemical Formula	Molecular Weight/ Molar Mass	Density	Melting Point	Boiling Point
Tungsten	W	183.89 g	19.25 g/cm ³	3422 °C	3422 °C
Sodium tungstate (dihydride)	H ₄ Na ₂ O ₆ W	329.85 g/mol	3.25 g/cm ³	698 °C	—
Tungsten trioxide	WO ₃	231.84 g/mol	7.16 g/cm ³	1473 °C	1700 °C
Tungsten carbide	WC	195.85 g/mol	15.63 g/cm ³	2870 °C	6000 °C

products, and as a precipitant for alkaloids. It is also used as a catalyst in the oxidation of maleic acid (Berry and Gailie, 1990; Gbaruko and Igwe, 2007).

MAMMALIAN TOXICOLOGY

Acute Effects

As a heavy metal, tungsten is known as an irritant where acute health effects may result in occupational workers. Acute occupational exposures can cause irritation to the skin and eyes. Skin exposures may cause reddening and itching of the skin. Irritation from eye exposures may cause watering and redness of the eye. Inhalational exposures may cause irritation of the lungs through the impairment of the function of the mucus membranes (Gbaruko and Igwe, 2007).

Chronic Effects

Many of the chronic health effects resulting from tungsten exposure impact the lungs and respiratory system. Long-term exposures may impact the cells of the respiratory tract and could lead to lung diseases. Chronic inhalational exposure to tungsten dust may cause hard metal disease or occupational asthma (Stefaniak et al., 2007).

Mechanism of Action(s)

Tungsten is not considered to be an essential nutrient for living organisms; however, some tungsten compounds impact both human and animal health adversely (Leggett, 1997; Tajima, 2001; Domingo, 2002; Lagarde and Leroy, 2002; Strigul et al., 2005). Tungsten exposures may result in the substitution of elements in different biological systems, which may impact specific enzyme processes (Stiefel, 2002; Strigul et al., 2005). Due to its close relation to molybdenum, exposures may impact some of the body's metabolic processes (Friberg et al., 1979; Gossentin et al., 1976; Gbaruko and Igwe, 2007). In the presence of cobalt, tungsten carbide generates high amounts of free radicals (Lison and Lauwers, 1995; Stefaniak, 2010).

Animal studies conducted in rats exposed to high doses (20 pellets) of heavy metal tungsten alloy (>90%) developed aggressive tumors surrounding the implantation site within

4–5 months. Rats implanted with low dose pellets (four pellets) developed rapidly metastasizing tumors along the respiratory pathways (Nyrén et al., 1995; Witten et al., 2012). Cell culture studies suggest that a combination of tungsten (91%), nickel (6%), and cobalt (3%) alloys in rat muscle cells may result in DNA damage, cell hypoxia, and cell death within 24 h of exposure (Harris et al., 2011; Witten et al., 2012).

Chemical Pathology

Tungsten toxicity depends on the chemical form of the tungsten compounds and the exposure route, with most exposures occurring via the inhalational route. These exposures not only impact the lungs but the other parts of the respiratory system as well. Tungsten is transported through the body by the blood, which can impact the liver, kidneys, spleen, and other organs (Leggett, 1997; Strigul et al., 2005).

SOURCES OF EXPOSURE

Occupational

Although tungsten is considered to be a heavy metal, it is not however considered a heavy metal exposure for industrial and occupational workers. Most occupational exposures to tungsten occur through inhalation of dust or through dermal contact during the processes of production and usage of tungsten and its compounds (Berry and Gailie, 1990; Gbaruko and Igwe, 2007). Industrial or occupational workers who may work with cemented tungsten carbide may be exposed to tungsten as well as its compounds (Kraus et al., 2001; Stefaniak, 2010). The potential for producing adverse health effects following inhalation of fiber-shaped tungsten oxide particles from occupational workers is not understood (Stefaniak, 2010).

Environmental

Exposure to tungsten is possible from the ingestion of products containing tungsten or its compounds for the general public. Beverages such as wine, mineral water, beer, brewed tea, and instant coffee have been found to contribute to the total dietary intake of tungsten (Gbaruko and Igwe, 2007). Currently, there are no environmental regulations in

place in the United States addressing tungsten pollution (Strigul et al., 2005). Tungsten may be released into the environmental systems as the result of natural or anthropogenic activities (Bourcier et al., 1980; Ondov et al., 1989; Grimes et al., 1995; Feldman and Cullen, 1997; Peltola and Wikstrom, 2006; Strigul et al., 2010).

If released into the soil, tungsten compounds will have moderate to low mobility, depending upon sorption coefficients. These compounds are not expected to volatize from dry soil surfaces. If released into the water, tungsten compounds may absorb to suspended solids and sediments (Berry and Gailie, 1990; Gbaruko and Igwe, 2007). The production and use of tungsten compounds may result in the release of tungsten into the environment through waste streams.

Industrial emissions may release tungsten in the form of tungsten trioxide into the atmosphere.

Most tungsten compounds exist in the particulate phase in the ambient atmosphere because of their low vapor pressure (Berry and Gailie, 1990; Gbaruko and Igwe, 2007). Metallic tungsten particles may cause adverse environmental effects such as soil acidification (Dermates et al., 2004; Strigul et al., 2005; Ringelberg et al., 2009; Johnson et al., 2009; Strigul et al., 2010).

INDUSTRIAL HYGIENE

Most adverse health effects that result from exposure are due to acute toxic exposures. Acute exposures affect the eyes and skin. The use of personal protective equipment during the handling and use of tungsten and its compounds is considered as safe industrial hygiene practices. Respiratory masks may also be recommended to prevent high levels of exposure when tungsten carbide dust particles combine with cobalt (Stefaniak et al., 2007; Gbaruko and Igwe, 2007).

The National Institute for Occupational Safety and Health (NIOSH) and the American Conference of Governmental Industrial Hygienists (ACGIH) have set the recommended exposure limit (REL) and the threshold limit value (TLV), respectively, for insoluble forms of tungsten at 5 mg/m³, with a 15-min short-term exposure limit (STEL) of 10 mg/m³. For soluble forms of tungsten, NIOSH and the ACGIH have set both the REL and the TLV at 1 mg/m³, with a STEL of 3 mg/m³.

MEDICAL MANAGEMENT

If tungsten or tungsten compounds come in contact with the eyes, one should immediately wash (irrigate) the eye with water, occasionally lifting the lower and upper lids. If there is contact with the skin, wash the affected skin area with soap and water. If a person inhales large amounts of tungsten or its compounds, move the person to fresh air. If one has

swallowed tungsten or its compounds or suffered a serious injury, seek medical attention immediately.

VANADIUM¹

JAMES C. BALL AND MAUREEN R. GWINN

First aid:

Eyes: Flush eyes with running water for 15 min. If irritation persists, obtain medical assistance.

Skin: Treat skin cuts and abrasions with standard first aid. Skin contamination can be removed with soap and water. If irritation persists, obtain medical assistance.

Ingestion: Obtain medical assistance at once. If conscious, give one to two glasses of milk or water and induce vomiting.

Inhalation: Removal to fresh air is usually sufficient. If breathing difficulty, give oxygen.

Target organ(s): Respiratory system; hematology; developmental effects

Occupational exposure limits: (as vanadium pentoxide):

ACGIH TLVs: TWA 0.05 mg/m³ (respirable dust or fume); STEL not established

OSHA PELs: TWA 0.05 mg/m³ ceiling (fume as vanadium); STEL 0.5 mg/m³ ceiling (respirable dust), 0.1 mg/m³ ceiling (fume)

NIOSH RELs: TWA not established; STEL 0.05 mg/m³ ceiling (15 min, total dust as vanadium)

NIOSH: Immediately Dangerous to Life or Health (IDLH) 35 mg/m³

Reference values:

EPA: RfD 9×10^{-3} mg/kg/day (vanadium pentoxide)

ATSDR-MRLs: Inhalation: Acute 0.8 µg vanadium/m³, chronic 0.1 µg vanadium/m³; oral: Acute 10 µg vanadium/kg/day

Risk phrases:

Harmful by inhalation and if swallowed

Irritating to the respiratory system

Toxic: Danger of serious damage to health by prolonged exposure through inhalation

Possible risk of harm to the unborn child

Toxic to aquatic organisms, may cause long-term adverse effects in the aquatic environment

Possible risk of irreversible effects

Safety phrases:

Wear suitable protective clothing and gloves.

In case of insufficient ventilation, wear suitable respiratory equipment.

In case of accident or if you feel unwell, seek medical advice immediately (show the label where possible).

Avoid release to the environment. Refer to special instructions/safety data sheet.

BACKGROUND AND USES

Vanadium is a naturally occurring element, and is the 22nd most abundant element found in geological formations. The

¹ Disclaimer: The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the U.S. Environmental Protection Agency.

initial discovery of vanadium occurred in 1801 by a Spanish chemist and mineralogist working as a teacher in Mexico, Andrés Manuel del Río. He described his analyses of lead ores and further chemical tests concluded that he had discovered a new element. He gave samples of his work to Alexander von Humboldt, who after consulting with a French chemist, was convinced that this new element was chromium. Del Río published a retraction of his discovery, but later regretted this action and was convinced that he had indeed discovered what later became known as vanadium. About 30 years later, a Swedish chemist, Nils G. Sefström rediscovered vanadium from iron ore and was given credit for its discovery and the origin of its name (Atomix, 2003; Cintas, 2004). In 1869, the pure metal was isolated by Sir H. E. Roscoe using dry hydrogen gas (oxygen free) to reduce vanadium dichloride (VCl_2) to metallic vanadium (Roscoe, 1869). The first application of vanadium in steel occurred in 1889 under the direction of Professor Arnold of Sheffield Firth College, England. This new vanadium steel had been used by a French luxury car manufacturer and this intrigued Henry Ford after he examined pieces of the car from a crash that occurred during racing. He recognized the potential use of this new, stronger steel to reduce weight in the Model T. Henry Ford learned the process of making vanadium steel, which was subsequently used in Model T cars. The Model T retained the advantage of higher strength steel for at least 5 years before other manufacturers adopted this new steel (Gross and Magazine, 1996).

Currently, a majority of vanadium (>90%) is used in the production of steel, where it is added in small amounts to impart additional strength to steel (Yong and Han, 2010) (Box 37.1). This is due, in part, to the inherent hardness and strength of ferrovanadium (FeV), vanadium metal nitrides (VN), and carbides (e.g., VC or V_3C_4). Much of the steel produced with vanadium as a key component are microalloyed or high strength low alloy steels (Baker, 2009). These kinds of steel also use combinations of other metals such as nickel, tungsten, molybdenum, chromium, manganese, aluminum, and carbon to synthesize unique alloys. Vanadium is present in low concentrations in these steels, typically no more than 0.1%, but these low levels impart significant strength and hardness to the steel. Specific alloys are used in specialized industries. For example, a combination of steel, chromium, molybdenum, and vanadium have been used to make high temperature steels for use in gas turbine engines (Baker, 2009).

Vanadium is also commonly used as a catalyst in the production of sulfuric acid and maleic acid anhydride—the latter compound is used in the synthesis of rubber polymers (Cheng et al., 2009). Vanadium pentoxide is used as a catalyst to oxidize sulfur dioxide (SO_2) to anhydrous sulfur trioxide (SO_3) followed by a reaction with water to generate sulfuric acid (H_2SO_4). Maleic acid anhydride is prepared by the vanadium pentoxide-catalyzed oxidation of benzene. More recently, vanadium pentoxide has been used as a

selective reducing catalyst to reduce NO and NO_2 emitted from diesel engines to nitrogen gas (N_2) (Matthey, 2010). Other uses of vanadium compounds include the development of new batteries (e.g., vanadium flow and lithium–vanadium batteries), treatment of wastewater for nitrates, and as a colorant in ceramics and enamels.

PHYSICAL AND CHEMICAL PROPERTIES

Vanadium compounds, typically, have a range of oxidation states from +3 to +5 with more exotic compounds having oxidation states from -1 to +2 (IARC, 2006). The solubility of different vanadium compounds in water between 20 and 25 °C differs among different oxidation states (Table 37.1; (Rahman and Skyllas-Kazacos, 1998; WHO, 2001; HSDB, 2008)).

The +4 oxidation state (V^{4+}) compound, vanadyl sulfate ($VOSO_4$), is highly soluble in water while vanadium compounds with a +5 oxidation state (V^{5+}) have mixed solubilities. Vanadium pentoxide (V_2O_5) and vanadium trioxide (V_2O_3) can be considered as acid anhydrides and when dissolved in water, these compounds react with water (i.e., decompose) at different rates, depending on the compound, to form mono vanadium compounds. Other V^{5+} compounds such as sodium metavanadate ($NaVO_3$), sodium orthovanadate (Na_3VO_4), and ammonium metavanadate (NH_4VO_3) are highly water soluble with solubilities of 211, 100, and 58 g/l,

TABLE 37.1 Oxidation States and Water Solubility of Various Vanadium Compounds

Vanadium Compound	Formula	CASRN	Oxidation State	Solubility (g/l) at 20–25 °C	Structure
Vanadium	V	7440-62-2	0	Insoluble	
Vanadium pentoxide	V ₂ O ₅	1314-62-1	+5	8, decomposes	
Sodium metavanadate	NaVO ₃	13718-26-8	+5	211	
Sodium orthovanadate	Na ₃ VO ₄	13721-39-6	+5	100	
Ammonium metavanadate	NH ₄ VO ₃	7803-55-6	+5	5.2 at 15 °C

Heat of fusion	21.45 J/mol
Heat of vaporization	459 kJ/mol

respectively. Furthermore, the rate of dissolution (which is distinct from solubility—an equilibrium or thermodynamic parameter) of various vanadium compounds can vary, resulting in different concentrations of specific forms of vanadium depending on how long these compounds have been in water. Additional properties for metallic vanadium are listed in Table 37.2.

ENVIRONMENTAL FATE

Natural sources of vanadium in soil come from minerals (over 50 known minerals containing vanadium; Box 37.2) and from

the atmospheric deposition of marine aerosols and particulate matter of volcanic origin. Vanadium is not typically mined for directly but is recovered while mining for other minerals. In addition, anthropogenic sources of vanadium also find their way into soil primarily from the deposition of particulate matter from fossil fuel combustion sources (e.g., coal- and oil-fueled power plants). The movement of vanadium in soil is heavily pH dependent since most vanadium minerals are not soluble in neutral water. The pH of water leaching the soil depends primarily on the alkalinity of the soil with more movement of vanadium at higher pH solutions [more alkaline] (NRC, 1974; WHO, 1988; ATSDR, 2012). Acid rain (primarily nitric and sulfuric acids) can contribute to the acidity of leaching fluids by lowering the pH of ground water. Vanadium is found in all natural sources of water. Theoretical estimates of the concentration of vanadium that could be found in sea water, due to the levels found in the earth's crust, suggest that vanadium concentrations should be fairly high, around 60 parts per million (ppm) [60 mg V/l] (NRC, 1974; WHO, 1988). However, concentrations in freshwater and seawater have been measured to be <50 µg V/l and 0.3–3.2 µg V/l, respectively (Holdway and Sprague, 1979; Ünsal, 1982). This discrepancy has been attributed to the binding of vanadium with suspended particulate matter and precipitation of vanadium-enriched silt to the ocean floor (NRC, 1974; WHO, 1988). Many marine organisms bioaccumulate vanadium compared to the surrounding sea water. Sea squirts (*Didemnum* sp.), for example, are known to achieve vanadium levels >10,000× than the concentration of sea water (ATSDR, 2012). Vanadium typically exists in two forms in fresh water depending on the presence of oxidizing or reducing agents in the water. In the presence of reducing agents, vanadium is present as vanadyl compounds (VO²⁺ and VO(OH)⁺) and in the presence of oxidizing substances vanadium is found in the pentavalent form (V⁵⁺) as vanadate compounds such as

H₂VO₄²⁻ and HVO₄²⁻ (Holdway and Sprague, 1979). Vanadium compounds also combine with particulate matter in fresh water with a particular affinity for humic acids (Ünsal, 1982).

The presence of vanadium in the atmosphere is primarily in the form of compounds bound to particulate matter as gaseous species of vanadium do not exist at ambient temperatures. Examples of vanadium compounds bound to particulate matter include vanadium pentoxide (V₂O₅), but most measurements of vanadium bound to particles is measured as elemental vanadium and is not speciated to specific compounds or minerals. Vanadium-enriched particles can dry deposit, as do particles in general, as well as be rained out with particles either acting as condensation nuclei or being absorbed directly into water droplets.

ECOTOXICOLOGY AND BIOACCUMULATION

The toxicity of vanadium to freshwater fish depends on a number of factors, two of which are dominant such as exposure time, (e.g., 96-h exposures) and water hardness, with vanadium generally being more toxic in softer water (defined as CaCO₃ equivalents) and longer exposure times. The range of toxicities found for freshwater fish (Table 37.3), depending on these two factors, ranges from 3.2 to 55 mg V/l for 96-h exposures with vanadium being more toxic at longer exposures (e.g., LC₅₀ of 48 mg V/l at 24 h compared to 12 mg V/l in the flannelmouth sucker) (Hamilton and Buhl, 1997). In the case of saltwater fish, the salinity of the water is an additional complicating factor. For two saltwater species and one freshwater species tested in 10% salinity (three-spined stickleback, Table 37.3) the LC₅₀ toxicities ranged from 0.6 to 18 mg V/l for 96-h exposures. In addition to studies on the lethal effects of vanadium on adult fish, this metal was also assessed for its impact on the growth of juvenile rainbow

TABLE 37.3 Examples of Ecotoxicological Studies of Vanadium

Common Name (Family or <i>Genus species</i>)	Comments on Toxicity, Toxicological Endpoint, or Accumulation of Vanadium	Reference
Fish		
Guppies (<i>Poecilia reticulata</i>)	LC ₅₀ : 4.4 mg V/l (7 days)	Perez-Benito, 2006
Three-spined stickleback, (<i>Gasterosteus aculeatus</i>); fathead minnow (<i>Pimephales promelas</i>); bluegill sunfish (<i>Lepomis macrochirus</i>); rainbow trout (<i>Oncorhynchus mykiss</i>); brown trout (<i>Salvelinus fontinalis</i>); goldfish (<i>Carassius auratus</i>); guppy (<i>Lebistes reticulatus</i>); American-flag fish (<i>Jordanella floridae</i>); striped gourami (<i>Colisa fasciatus</i>); mummichog (<i>Fundulus heteroclitus</i>); tigerfish (<i>Terapon jarbua</i>)	<i>G. aculeatus</i> : LC ₅₀ 3.2 (96 h); 10% salinity, 6–16 mg/V (96 h) <i>P. promelas</i> : LC ₅₀ 4.8 or 30 mg V/l (96 h), depending on water hardness <i>L. macrochirus</i> : LC ₅₀ 6 or 55 mg V/l (96 h), depending on water hardness <i>O. mykiss</i> : LC ₅₀ 2–13 mg V/l (4–20 days); 0.16 mg V/l (28 days) <i>S. fontinalis</i> : LC ₅₀ 2–36 mg V/l (7–720 h) <i>C. auratus</i> : LC ₅₀ 0.37–1.5 mg V/l (6 days) <i>L. reticulatus</i> : LC ₅₀ 2.5–8.1 mg V/l (6 days) <i>J. floridae</i> : LC ₅₀ 11 mg V/l (96 h) <i>C. fasciatus</i> : LC ₅₀ 6.4 mg V/l (96 h) <i>F. heteroclitus</i> : LC ₅₀ 14 and 18 mg V/l at 6% and 22% salinity (96 h) <i>T. jarbua</i> : LC ₅₀ : 1 mg V/l (24 h), 0.97 mg V/l (48 h), 0.8 mg V/l (72 h), 0.62 mg V/l (96 h) LC ₅₀ : 48 mg V/l (24 h); 36 mg V/l (48 h); 19 mg V/l (72 h); 12 mg V/l (96 h)	Gravenmier et al., 2005 and references cited
Flannelmouth sucker (<i>Catostomus latipinnis</i>)	LC ₅₀ : 48 mg V/l (24 h); 36 mg V/l (48 h); 19 mg V/l (72 h); 12 mg V/l (96 h)	Hamilton and Buhl, 1997
Catfish (<i>Clarias batrachus</i>)	10 mg V/l; lipid peroxidation increased in liver, kidney, and brain	Bishayee and Chatterjee, 1994
Juvenile rainbow trout (<i>Oncorhynchus mykiss</i>)	10–900 mg V/Kg (12 weeks); all doses showed reduced growth; toxicity observed at >490 mg V/l	Hilton and Bettger, 1988
Aquatic invertebrates		
Tube-dwelling fan worms (Sabellidae; <i>Pseudopotamilla occelata</i> , <i>Perkinsiana littoralis</i>)	Hyper-accumulation of V, >5 mg/g in branchial crowns of <i>P. occelata</i> ; >10 mg/g were measured in branchial crowns of <i>P. littoralis</i>	Fattorini and Regoli, 2012
Mysid shrimp (<i>Americanysis bahia</i>)	LC ₅₀ : 9.4 (7.2–12.6) mg V/l (96 h); the no observed effect concentration was 6.4 mg V/l	Woods et al., 2004
Brine shrimp larvae (<i>Artemia salina</i>); Pacific oyster larvae (<i>Crassostrea gigas</i>); sea urchin larvae (<i>Paracentrotus lividus</i>)	Normally developed larvae and growth of normal larvae; oyster toxic at 50 µg V/l; urchin toxic at 100 µg V/l (2 days); brine shrimp toxic at 250 µg V/l (8 days)	Fichet and Miramand, 1998
Hydroid, brackish water (<i>Cordylophora caspia</i>)	Impaired population growth, 2 mg V/l (10 days); >10 mg V/l, reproduction ceased (10 days)	Ringelband and Karbe, 1996
Water plants		
Fresh-water algae (<i>Scenedesmus acutus</i> ; <i>Scenedesmus obliquus</i>)	Growth and photosynthesis are inhibited by vanadium due to competition with phosphorus	Nalewajko et al., 2008
Phytoplankton (cyanobacteria)	0.01–0.84 mg V/l, decreased photosynthesis	Nalewajko et al., 1995
Freshwater vascular plants, (12 species)	Accumulation: 5.8 mg V/kg dry weight (0.30–32 mg/kg dry weight)	Outridge and Noller, 1991
Marine macroalgae brown algae (<i>Fucus spiralis</i>); green algae (<i>Enteromorpha compressa</i>); red algae (<i>Polysiphonia urceolata</i> , <i>Goniotrichum alsidii</i> , <i>Nemalion helminthoides</i>)	400% increased growth of brown algae and 90% increased growth of green algae from 10 µg V/l (53 days)	Fries, 1982
Fresh-water green algae (<i>Chlorella pyrenoidosa</i>)	Maximal growth at 0.5 mg V/l; reduced growth at >25 mg V/l; 100 mg V/l is lethal	Meisch et al., 1977

(continued)

TABLE 37.3 (Continued)

Common Name (Family or Genus species)	Comments on Toxicity, Toxicological Endpoint, or Accumulation of Vanadium	Reference
Terrestrial plants		
Lettuce (<i>Lactuca sativa</i>); grasses (<i>Elymus virginicus</i> , (<i>Panicum virgatum</i>); broad leaf (<i>Lycopus americanus</i>), and (<i>Prunella vulgaris</i>)	0–265 mg V/g soil; broad-leaf plants more sensitive than grasses or lettuce; increased nutrient levels lowered V toxicity.	Smith et al., 2013
Chinese green mustard (<i>Brassica campestris</i> ssp. <i>chinensis</i> var. <i>parachinensis</i>)	0.43–35 mg V/l (3 weeks) administered to soil, 35 mg V/l reduced leaf and stem weight and plant height; 0–17 mg V/l showed no effects	Vachirapatama and Jirakiatkul, 2008
Soybean (<i>Glycine max</i>)	Vanadium added to two soils; >30 mg V/kg in fluvo-aquic soil caused reduced weight of shoots and roots; no effect of 75 mg V/kg in red earth soil on shoots or roots	Wang and Liu, 1999
Lettuce (<i>Lactuca sativa</i>)	0.1–1 mg V/l in nutrient solutions, fresh and dry weights inhibited at >0.2 mg V/l	Gil et al., 1995
Soybean (<i>Glycine max</i>); bush bean (<i>Phaseolus vulgaris</i>)	6 mg V/l in hydroponic solution reduced plant biomass	Kaplan et al., 1990

trout (Hilton and Bettger, 1988). All doses of vanadium (10–900 mg V/kg) inhibited the growth of these fish. An increase in the lipid peroxidation of tissues in the liver, brain, and kidneys was also found for catfish at concentrations that have been shown to be lethal for other freshwater fish (10 mg V/l, Table 37.3 (Bishayee and Chatterjee, 1994).

Vanadium in seawater is present at fairly low concentrations presumably due to the binding of vanadium compounds to silt followed by precipitation to the sea bed (NRC, 1974; WHO, 1988). Some aquatic invertebrates, however, are known to hyper-accumulate vanadium (Table 37.3). For example, tube-dwelling fan worms accumulate >5 mg/g of vanadium in the tissues of branchial crowns when the surrounding sea water concentration of vanadium is about 0.3–3.2 µg V/l (Ünsal, 1982). Studies on adult saltwater invertebrates suggest that adult invertebrates may be less sensitive than larvae invertebrates, although definitive studies comparing life stages of aquatic invertebrates have not been conducted. Mysid shrimps show no observed effects at 6.4 mg V/l with toxic effects beginning to be observed at 7.2 mg V/l. Brackish hydroid showed a reduction in growth at 2 mg V/l with reproduction ceasing at concentrations >10 mg V/l. However, studies on the development of larvae suggest that this life stage may be more sensitive than adult invertebrates. Oyster, sea urchin, and brine shrimp larvae do not develop or grow normally at concentrations of vanadium between 50 and 250 µg V/l (Table 37.3).

At low concentrations (10 µg V/l) marine algae showed mixed results with the largest increase in growth observed with brown algae (*Fucus spiralis*) followed by green algae (*Enteromorpha compressa*) (Table 37.3). No effects were observed for three species of red algae (*Polysiphonia urceolata*, *Goniostichum alsidii*, and *Nemalion helminthoides*). Freshwater green algae (*Chlorella pyrenoidosa*) showed a

range of effects from enhanced growth at low concentrations, to reduced growth at intermediate concentrations and lethal effects at high concentrations (Table 37.3). These data suggest that vanadium may be beneficial to algae in low concentrations. In contrast, the effect of vanadium on photosynthesis in phytoplankton, specifically cyanobacteria, was inhibitory even at low concentrations. Freshwater vascular plants (flowering plants, some ferns with a vascular system and well-defined roots) show a wide range of vanadium accumulation (Table 37.3). Two species (*Elodea canadensis* and *Pontederia cordata*) accumulated high levels of vanadium, 18 and 32 mg V/kg dry weight, respectively, compared to the range from the remaining 12 species (0.30–6 mg V/kg).

The effect of vanadium on terrestrial plant growth depends on a number of factors (Table 37.3), including the chemical characteristics of the soil that influence the binding of vanadium making this metal more or less bioavailable. For example, Wang and Liu (1999) showed that soybeans grown in fluvo-aquic soil was toxic to levels of vanadium >30 mg V/kg soil whereas a concentration of 75 mg V/kg in red earth soil was not phytotoxic. Similarly, the level of nutrients in soil showed an inverse toxic effect with vanadium in soils with high nutrient levels showing little, if any, toxic effects of vanadium in contrast to nutrient-poor soils that showed significant phytotoxicity. The conditions of the assay for toxicity also play a complicating factor. For example, studies of plants grown in aqueous solutions (Kaplan et al., 1990; Gil et al., 1995) showed more sensitive effects of vanadium compared to studies using soil to grow plants (Table 36.3). This may be related to the relative bioavailability of the metal with soluble vanadium being essentially 100% bioavailable; all soils will bind, to some extent, vanadium making this metal less bioavailable in soil.

MAMMALIAN TOXICOLOGY

Industrial exposure and illness have most commonly involved vanadium pentoxide; the vast majority of the toxicological literature focuses on vanadium pentoxide, and exposure standards are set accordingly. This partly reflects the importance of vanadium pentoxide in the industrial applications of vanadium. Equally important is the observation that toxicity is proportional to valence: pentavalent vanadium is the most toxic form of the metal. Furthermore, industrial exposures have almost always involved inhalation of dust and fumes containing vanadium or vanadium oxides.

The sections below focus on the major epidemiological and laboratory animal studies available in the published literature on adverse health effects following exposure to all vanadium compounds. The majority of studies focused on the respiratory effects following exposure to vanadium compounds, with the majority examining exposure to vanadium pentoxide. Laboratory animal and mechanistic studies also examined hematological, neurological, and reproductive effects. Limited studies examine other endpoints such as renal, hepatic, and immunological effects following exposure, the results of which were largely negative. Examples of both epidemiological and laboratory animal studies of vanadium compounds are summarized in Table 37.4. For more detailed reviews of the literature, please review EPA, 2011, (IARC, 2006; ATSDR, 2012).

Acute Effects

Zenz et al. (1962) (Zenz and Berg, 1967) have studied industrial vanadium toxicity in the field and in the laboratory and have written the classic summary of acute vanadium toxicity. The clinical picture of acute illness appeared remarkably uniform among these workers. The syndrome consisted of a rapidly developing, mild conjunctivitis, severe pharyngeal irritation, and nonproductive persistent cough, followed by diffuse rales and bronchospasm. After severe exposure, four men complained of skin "itch" and a sensation of "heat" in the face and forearms, but no objective evidence of skin irritation was found. A striking feature among the acute intoxications was the increased severity of symptoms with repeated exposures of lesser time and intensity. Acute inhalation studies have demonstrated respiratory difficulty and irritation of the mucosa in rats (NTP, 2002) and decreased pulmonary function in monkeys (Knecht et al., 1985) following exposure to vanadium pentoxide. Acute inhalation exposure to ammonium metavanadate in rats also resulted in increased inflammatory cells in bronchoalveolar lung fluid (Cohen et al., 1996). Acute oral studies in rats and rabbits did not show any respiratory effects following exposure to vanadium pentoxide (WHO, 2001).

Animal and clinical studies replicate the clinical studies carried out after industrial exposures (Table 36.4). With few exceptions these reports, from 1911 to the present, describe workers with irritation and inflammation of the skin, conjunctivae, and mucosae of the nasopharynx and the respiratory tract (Wyers, 1946; Sjoberg, 1951; Williams, 1952; Sjoberg, 1955; Vintinner et al., 1955; Sjoberg, 1956; Musk and Tees, 1982).

Chronic Effects

Many epidemiological researchers comment on the greenish discoloration of the tongue from coating due to dust containing vanadium. Catarrh, epistaxis, productive cough, occasional hemoptysis, wheezing, dyspnea, and occasionally bronchopneumonia are all part of the respiratory syndrome produced by dust and fumes that contain vanadium. Spirometry consistently revealed decreased forced vital capacity (FVC) and forced expiratory volume (FEV) (Lewis, 1959; Lees, 1980). Continued exposure can result in chronic respiratory changes and symptoms, but cessation of exposure usually allows the respiratory tract to return to normal. However, chronic exposure to high concentrations of dust containing vanadium has been associated with the gradual development of atrophic rhinitis and chronic bronchitis, which only partially remit with cessation of exposure.

Levy et al. (1984) coined the term *boilermakers' bronchitis* to describe the slowly resolving bronchitis that occurred in 74 of 100 workers involved in the conversion of oil-fired to coal-fired boilers. The power plant had used fuel oil, high in vanadium. Workers welding and heating inside the boilers were exposed to concentrations of vanadium pentoxide ranging from 0.05 to 5.3 mg/m³. The most common symptoms were productive cough, sore throat, dyspnea on exertion, and chest discomfort, and these symptoms were serious enough to cause 70 workers to seek medical attention. Wheezing and diminished FEV were the most common findings. The symptoms lasted from 9 to 82 days, with a median duration of 34 days. None of the workers used adequate respiratory protection.

Kiviluoto reported long-term follow-up on workers making vanadium pentoxide from magnetite (Kiviluoto et al., 1979; Kiviluoto, 1980; Kiviluoto et al., 1981a). These workers were exposed to vanadium pentoxide concentrations ranging from 0.01 to 3.9 mg/m³ for an average of 11 years. No evidence of cancer or pneumoconiosis was found, although the exposed workers had more complaints of wheezing and cough than nonexposed controls. Vanadium pentoxide inhalation exposure for 2 years was associated with a wide spectrum of nonneoplastic pulmonary lesions in both rats and mice, ranging from hyperplasia to inflammation, fibrosis, and metaplasia. Lesions were detected in the lung, larynx, and nose in both rats and mice exposed to vanadium pentoxide. Bronchial lymph

TABLE 37.4 Examples of Epidemiology and Mammalian Toxicology Studies of Vanadium

Exposure Group	Dose/Exposure Duration/Compound	Observed Effects	Reference
Human			
Controlled human exposure (<i>n</i> = 9)	0.1–1 mg/m ³ for 8 h vanadium pentoxide (inhalation)	Coughing, no other signs of irritation; no change in lung function	Zenz and Berg, 1967
Case studies (<i>n</i> = 36)	0.6–86.9 mg/m ³ vanadium pentoxide in dust over 3 years (inhalation)	Severe upper respiratory irritation; lower respiratory irritation; skin irritation; fatigue; decrease in hemoglobin levels	Sjoberg, 1951; Sjoberg, 1956
Case studies (<i>n</i> = 18)	>0.5 ug/m ³ vanadium pentoxide in air over 2 weeks; lifetime exposure range varied (inhalation)	Upper respiratory irritation; some skin irritation	Zenz et al., 1962
Cross-sectional study (<i>n</i> = 63)	0.2–0.5 mg/m ³ vanadium dust as measured on filters over 5 years (inhalation)	Upper respiratory irritation; no hematological changes observed	Kiviluoto et al., 1979; Kiviluoto, 1980; Kiviluoto et al., 1981a
Occupational study (<i>n</i> = 55)	0.05–5.3 mg/m ³ vanadium pentoxide in the boiler (inhalation)	Upper respiratory irritation; chest pain; fatigue	Levy et al., 1984
Case-control study (<i>n</i> = 31)	0.5 mg vanadium/kg/day 4, 8, 12 weeks vanadyl sulfate (oral)	No effect on blood pressure was observed	Fawcett et al., 1997
Laboratory animal studies			
B6C3F ₁ mice, M/F (<i>n</i> = up to 50)	0–4 mg/m ³ 16 days–2 years vanadium pentoxide (inhalation)	Respiratory effects: chronic inflammation, hyperplasia, adenomas/carcinomas; hematological effects: limited to 3 months only in males.	NTP, 2002
F344/N rats, M/F (<i>n</i> = up to 50)	0.1–1.1 mg/m ³ 26 weeks vanadium pentoxide (inhalation)	Impaired pulmonary function	Knecht et al., 1992
Cynomolgus monkeys, M (<i>n</i> = 8)	2.56 mg/m ³ 8 weeks vanadium pentoxide (inhalation)	CNS morphological alterations	Avila-Costa et al., 2004; Avila-Costa et al., 2005; Avila-Costa et al., 2006
CD-1 mice, M (<i>n</i> = 48)	2.56 mg/m ³ 6 weeks vanadium pentoxide (inhalation)	Inflammatory, oxidative stress and liver toxicity markers increased	Cano-Gutiérrez et al., 2012
CD-1 mice, M (<i>n</i> = 20)	2.56 mg/m ³ 12 weeks ammonium metavanadate (drinking water)	Limited hematological toxicity observed	Dai et al., 1995
Wistar rats, M (<i>n</i> = 32)	1–75 ug vanadium/g diet through day 21 postpartum sodium metavanadate (oral feed)	Developmental effects (decreased pup weight and survival)	Elfant and Keen, 1987
Sprague-Dawley rats, F (<i>n</i> = 14)	0.01–0.05 mg vanadium/kg/day 4–8 week ammonium metavanadate (drinking water)	Hematological effects (decreased erythrocyte and increased reticulocyte levels)	Zaporowska et al., 1993
Wistar rats, M/F (<i>n</i> = 46)	10.7 mg vanadium/kg/day 6 week sodium metavanadate (oral)	Hematological effects (decreased erythrocyte and hemoglobin levels)	Scibior et al., 2006
Swiss mice, F (<i>n</i> = 17)	0–60 mg vanadium/kg/day GD 6–15 sodium orthovanadate (oral gavage)	Developmental effects	Sanchez et al., 1991

node changes were detected in mice exposed to vanadium pentoxide. In nonhuman primates and rodents, inhalation or intratracheal instillation of vanadium pentoxide dust or suspensions of vanadium pentoxide, vanadyl sulfate (VOSO₄), or sodium metavanadate (NaVO₃) rapidly induced an acute inflammatory reaction with a predominance of polymorphonuclear leukocytes (Knecht et al., 1985; Knecht et al., 1992; Pierce et al., 1996; Rondini et al., 2010; Turpin et al., 2010; Schuler et al., 2011; Yu et al., 2011). The inflammation developed more rapidly with the more soluble vanadium salts, NaVO₃ and VOSO₄, and slowest with the less soluble V₂O₅. A similar gradient of intensity and rapidity was seen for the induction of proinflammatory cytokines from alveolar macrophages. Changes in pulmonary function tests included reduction in flow rates and vital capacity. Clearance of vanadium from bronchoalveolar fluid was rapid and associated with accumulation in cells and the inflammatory exudate and in lung tissue. No evidence for allergic hypersensitivity has been documented with repetitive experimental exposures.

Limited human studies examined hematological effects following exposure to vanadium pentoxide. No hematological alterations were observed in humans following short-term (Dimond et al., 1963; Zenz and Berg, 1967; Fawcett et al., 1997) or occupational exposure (Sjoberg, 1951; Vintinner et al., 1955; Kiviluoto et al., 1981a) to vanadium pentoxide dusts, ammonium vanadyl tartrate, or vanadyl sulfate through inhalation and oral exposures. Early laboratory animal studies demonstrated a decrease in red blood cells and hemoglobin levels in rats following oral exposure to vanadium pentoxide in feed (Mountain et al., 1953). A series of studies conducted by Zaporowska et al. (1993) examined the hematotoxicity of ammonium metavanadate administered in drinking water to rats for acute or intermediate durations. Results include increases in reticulocyte levels and the percentage of polychromatophilic erythroblasts in the bone marrow in male rats following 2-weeks exposure (Zaporowska and Wasilewski, 1989); a nonsignificant increase in erythrocytes was also observed at this dose level. At exposures up to 4 weeks, decreases in erythrocyte levels and hemoglobin levels and increases in reticulocyte levels were observed (Zaporowska and Wasilewski, 1989; Zaporowska et al., 1993). Similar effects were observed in rats exposed to sodium metavanadate for 6 weeks (Scibior et al., 2006) or 10 weeks (Adachi et al., 2000). Other laboratory animal studies in rats did not observe hematological alterations (Dai et al., 1995; Dai and McNeill, 1994), potentially related to the various doses and animal strains used. Blood pressure changes have also been observed in laboratory animal studies, however, the results are inconsistent. Increased systolic, diastolic, and/or mean blood pressure was observed in rats following exposure to sodium metavanadate or ammonium metavanadate [dose range 0.12–12 mg, up to 210 days] (Boscolo et al., 1994). However, no blood pressure changes were observed in rats following exposure to sodium

metavanadate, vanadyl sulfate, or ammonium metavanadate [dose range 10–63 mg, up to 52 weeks] (Dai et al., 2006).

No published studies examined developmental effects in humans following exposure to vanadium. Developmental effects were observed in animal studies following oral exposure to vanadyl sulfate, sodium metavanadate, ammonium metavanadate, or sodium orthovanadate (Paternain et al., 1987; Sanchez et al., 1991; Morgan and El-Tawil, 2003). These effects include delayed ossification, decreased fetal growth, and increase in skeletal and visceral anomalies.

Immunological effects of exposure to vanadium compounds have not been comprehensively studied, but the limited number of epidemiological and laboratory animal study results are summarized below. Case studies of occupational exposure to vanadium pentoxide have reported individuals with dermatitis, positive skin patch reactions, and bronchial reactivity, although this occurrence appears to be uncommon (Sjoberg, 1951; Zenz et al., 1962; Motolese et al., 1993). Increases in the number of inflammatory cells in nasal smears or nasal lavage fluid were observed in exposed workers but no associations were observed in relation to estimates of respirable vanadium dust or vanadium concentrations in nasal fluid (Kiviluoto et al., 1979; Kiviluoto, 1980; Kiviluoto et al., 1981b). The authors did not report increase in eosinophils, suggesting that the inflammation was due to irritation and was not an allergic response. Oral exposure to vanadium pentoxide in drinking water in rats demonstrated a non-statistically significant increase in cell-mediated immune activation (Mravcova et al., 1993). In a study in cynomolgus monkeys, skin sensitivity tests assessed immediate and delayed responses to intradermal injections of vanadium pentoxide–serum albumin conjugate (Knecht et al., 1992). The inhalation exposure in this study also demonstrated an influx of inflammatory cells in the lung. Other laboratory animal inhalation studies have also examined more specific mechanisms related to immune function and demonstrated that exposure to vanadium pentoxide did not impact platelet activation (González-Villalva et al., 2011) but led to decreases in specific immune cells following exposure to vanadium pentoxide suggesting a possible autoimmune effect of exposure (Ustarroz-Cano et al., 2012). These results suggest an impact of vanadium exposure on immune response; however, as there are only a limited number of inhalation studies that examined immune function following exposure to vanadium compounds, increased research is needed to further understand this response.

No human studies examined the impact of exposure to vanadium compounds on neurological function; however, some workers described a variety of neurological systems (e.g., headaches, dizziness) that may or may not be attributed to vanadium exposure (Vintinner et al., 1955; Levy et al., 1984). Laboratory animal studies have demonstrated impaired performance on memory tasks after as little as a 1-h inhalation exposure to vanadium pentoxide (2.56 mg/m³

vanadium pentoxide) (Avila-Costa et al., 2006). Longer-term studies (up to 8 weeks) have also demonstrated impairment of performance on memory tests and an associated loss of dendritic spines in the hippocampal region of the brain as well as CNS morphological changes in the blood–brain barrier as well as an increase in immunoreactive neurons in the basal ganglia (Avila-Costa et al., 2004; Avila-Costa et al., 2005; Avila-Costa et al., 2006; Colín-Barenque et al., 2008). Only two studies examined neurological function following oral exposure to vanadium (as sodium metavanadate, 8 weeks), with decreased travelling distance observed in one study (1.72 mg vanadium/kg) (Sanchez et al., 1998) but not the other (6.84 mg vanadium/kg) (Sanchez et al., 1999). Rats in both studies demonstrated increases in latency period following stimuli and decreases in the number of avoidance responses to stimuli.

No human epidemiology studies that examined carcinogenesis following exposure to vanadium compounds are available. There is evidence of carcinogenicity in male and female mice exposed to vanadium pentoxide based on observations of alveolar and bronchiolar neoplasms that exceeded historical controls in groups exposed to vanadium pentoxide (NTP, 2002). This study also demonstrated an increase in neoplasms in male rats, although these were not statistically significant. A more recent study has also shown lung tumor promotion in sensitive mouse strains following exposure to vanadium pentoxide (Rondini et al., 2010).

Mode of Action(s)

Currently, evidence is insufficient to establish the mode of action (MOA) for noncancer toxicity or cancer effects following exposure to vanadium compounds. The limited data to inform the mechanisms of various adverse health effects following exposure to vanadium compounds are summarized below.

Chronic Inflammation Evidence suggests that a potential mechanism of action underlying the formation of pulmonary fibroproliferative lesions may involve inflammation, leading to a regenerative hyperplastic response (i.e., presence of mitogens and observed smooth muscle thickening). Oxidative stress also has been implicated. Oxidative stress induced directly or indirectly by vanadium pentoxide may work in combination with vanadium pentoxide-induced inflammatory responses to activate signaling molecules such as extracellular signal-related kinase 1/2 (ERK1/2) and p38 kinase that lead to induction of growth factors and generation of fibrotic lesions. These potential modes of action are supported by a limited number of mechanistic analyses of inflammation and fibrosis following exposure to vanadium pentoxide.

Genotoxicity The evidence for mutagenicity in humans is limited (Ivancsits et al., 2002; Kleinsasser et al., 2003; Ehrlich et al., 2008). Few studies have examined genotoxicity in

humans *in vivo*, with equivocal results. Studies have demonstrated a genotoxic effect of vanadium pentoxide on human cells *in vitro* (Roldán and Altamirano, 1990; Rojas et al., 1996; Ramirez et al., 1997). Based on these studies, vanadium pentoxide-induced mutagenicity could occur at doses higher than those measured in these occupational exposures, could be tissue specific, and could be associated with oxidative stress rather than direct DNA damage. *In vitro* tests in bacterial and yeast systems provide mixed evidence of vanadium pentoxide-induced mutagenicity. In general, classic gene mutation assays were negative, as were tests that assessed sister chromatid exchange (SCE) and other chromosomal aberrations. DNA strand breaks (Rojas et al., 1996; Ivancsits et al., 2002) and micronucleus formation (Zhong et al., 1994) were indicated in some studies in cultured cells but depended on cell type. Fibroblasts appear to be more sensitive to vanadium exposure *in vitro* than are blood cells. Similarly, experimental data from animal studies is equivocal. NTP (2002) reported that the frequency of micronucleated normochromatic erythrocytes in peripheral blood was not increased in exposed mice compared to control mice. Several studies by Altamirano-Lozano et al. (1993, 1996, 1999), however, have noted DNA damage in specific target tissues in vanadium pentoxide-treated mice, although these studies used intraperitoneal injection as the route of exposure.

SOURCES OF EXPOSURE

Occupational

Occupational exposure to vanadium is predominantly through inhalation, although some oral and dermal exposures are possible. Occupational exposure may occur in workplaces that produce or use vanadium compounds. Vanadium compounds are used as a catalyst in the preparation of vanadium alloys and other compounds as well as in the automobile catalytic converters and in organic synthesis (OSHA, 2007). Vanadium compounds are also used as a component in welding, textile manufacturing, and ceramics production. Occupational exposure may also result from mining and processing of vanadium-containing ores and the cleaning and maintenance of furnaces, boilers, and gas turbines (OSHA, 2007).

Environmental

Vanadium is released into the environment from natural sources such as weathering of geologic formations, volcanoes, and marine aerosols. Vanadium entering the environment from anthropogenic sources is primarily due to emissions from oil and coal power plants and to a lesser extent, from ocean-going ships while in port. However, the primary source of human exposure to vanadium comes from the diet. Vanadium is found, generally at low levels, in most foods (Table 37.5). The concentration of vanadium

TABLE 37.5 Vanadium in Some Foods^a

Foodstuff	Vanadium Concentration Mean (Range) ng/g Wet Weight
Vegetables	
Garlic, onion, brussel sprouts, cauliflower, peas, leek, lettuce, carrots, cabbage, potato, tomato, radish	1.32 (0.27–3)
Spinach	35
Cereals	
Oats, barley, maize, rice, flour	14 (0.7–40)
Fruits	
Apple, pear, banana, orange, cherry, apricot, peach, hazelnut	0.76 (0.15–3.7)
Meat—beef	
Sirloin, middle rib, steak, liver, lung	7 (0.4–25)
Meat—pork	
Leg, liver, kidney, heart, fat, muscle	3.3 (0.2–8.5)
Meat—chicken	
Breast, liver, kidney, heart	17 (1.7–37)
Meat—fish	
Cod, mackerel, tuna	12 (3.5–28)
Milk and eggs	
Milk	0.17
Egg yolk	2.8 (2–3.6)
Egg white	0.8 (0.3–1.8)
Foodstuff	Vanadium Concentration Mean (Range) ng/g Dry Weight
Spinach, freeze dried	690 (533–840)
Ground parsley	1800
Wild mushrooms, 26 species	50–2000

^aAdapted from Byrne and Kosta, 1978.

in vegetables and foods varies substantially depending on the moisture content at the time of measurement. This is particularly notable in Table 37.4 for those vegetables measured dry (mushrooms, spinach, and ground parsley) compared to those vegetable measured using wet or freshly ground samples. Lokesappa et al. (2012) reported much higher levels of vanadium (mean 49 ug V/g; range 43–52 ug V/g) from vegetables (spinach, potato, coriander, ladyfinger, carrots, tulsi, rice, mung bean, and Arhar bean) dried to constant weight. Differences in the vanadium content of vegetables and foods will likely depend on the levels and bioavailability of vanadium in the soil used to grow the food. The amount of vanadium ingested daily from food has been estimated to be about 10–300 ng V/kg/day and is typically in the form of the vanadyl cation (VO^{2+}) or the vanadate anion (HVO_4^{2-}) (ATSDR, 2012).

People can also be exposed to vanadium in drinking water. The primary source of vanadium in ground water comes from leaching or dissolution of vanadium-rich rocks and minerals. Several locations in the world have unusually high concentrations of vanadium in ground water due to the geology of the surrounding area. In Italy, for example, vanadium in ground water is considered high and the health effects of such exposures are of concern. High ($\geq 50 \mu\text{g V/l}$) and moderate (25–49 $\mu\text{g V/l}$) levels of vanadium were typically measured in over 8400 ground water samples from California. These samples were collected from sources where the water was in contact with mafic and andesitic rocks and geological formations favored dissolution of vanadium (Wright and Belitz, 2010). The presence of vanadium was detected in 68% of 662 samples taken from wells of the principal aquifers in the United States; the median concentration of vanadium detected in these samples was 1.3 $\mu\text{g V/l}$ (10–90% percentile range, 0.12–20 $\mu\text{g V/l}$) (DeSimone, 2009). In addition to vanadium from ground and well water, vanadium can also enter drinking water through deposition of vanadium-enriched particles emitted from oil and coal power plants. For example, a study in Mexico suggested that the deposition of vanadium-enriched particulate matter from a thermoelectric plant using a fuel oil with high vanadium content was the origin of increased vanadium in the local ground-water (Mejia et al., 2007). In summary, vanadium concentrations in ground and well water can vary over a wide range (0.12 to $>20 \mu\text{g V/l}$) depending on the underlying geology and potential for deposition of vanadium-enriched particulate matter (Sepe et al., 2003; DeSimone, 2009). Assuming an average consumption of 2 l of water per day, one can estimate the amount of vanadium ingested from ground or well water to range from nondetectable levels to about 2.6 $\mu\text{g V per day}$.

People are exposed to vanadium through the air pollution and specifically via small particles ($\text{PM}_{2.5}$) generated from the combustion of fossil fuels. Vanadium is only one component of the complex mixture of compounds bound to particles, which makes the contribution of vanadium to adverse human health effects difficult to ascertain. Vanadium is generally recognized as the most abundant metal in petroleum products with some crude oils containing as much as 1500 mg V/kg (Turunen et al., 1995). Heavy fuel oils contain a wide range of vanadium, 18–259 mg V/kg (Shafer et al., 2012; Turunen et al., 1995; Agrawal et al., 2008) while refined petroleum such as commercial gasoline (53 $\mu\text{g V/l}$) and diesel fuel (88 $\mu\text{g V/l}$) contain about 1000-fold less vanadium. Vanadium is also found in coal; coal mined from the United States typically contains 22 mg V/kg (Finkelman, 1999). Thus, the major source of atmospheric exposure to vanadium comes from combustion by-products of coal and oil-fueled power plants and off-shore ships in ports. The mean concentration of vanadium in the

TABLE 37.6 Risk Assessments and Exposure Limits for Vanadium Compounds

Oral Value	
EPA (1996)	V ₂ O ₅ : Reference dose 9×10^{-3} mg/kg-day based on decreased hair cystine levels in rats (Stokinger et al., 1953).
ATSDR (2012)	Intermediate MRL: 0.01 mg vanadium/kg/day based on NOAEL for hematological changes following exposure to vanadyl sulfate (Fawcett et al., 1997).
Inhalation value	
ACGIH (2009)	Vanadium: A3—confirmed animal carcinogen with unknown relevance to humans. Threshold limit value (TLV)—time-weighted average (TWA) 0.05 mg/m ³ , inhalable particulate matter, measured as vanadium Based on upper and lower respiratory tract irritation.
ATSDR (2012)	Acute MRL: 0.0008 mg vanadium/m ³ based on LOAEL of incidence of lung inflammation in rats (NTP, 2002). Chronic MRL: 0.0001 mg vanadium/m ³ based on degeneration of the respiratory epithelium of the epiglottis in rats (NTP, 2002).
NIOSH (2012)	Vanadium: recommended exposure level (REL) 0.05 mg/m ³ , total dust and fume as vanadium
OSHA (2006)	Vanadium: permissible exposure level (PEL) 0.1 mg/m ³ (fume); 0.4 (respirable dust)
WHO (2000)	Vanadium: Air quality guideline for vanadium is 1 µg/m ³ based on LOAEL of 20 µg/m ³ from studies on occupationally exposed individuals, using an overall uncertainty factor of 20
Cancer characterization	
Cal EPA (2005)	V ₂ O ₅ : Added to the Proposition 65 chemical list as “known to the state to cause cancer” (orthorhombic crystalline form)
IARC (v86) (2006)	V ₂ O ₅ : Possibly carcinogenic to humans (Group 2B)—inadequate evidence in humans for the carcinogenicity of vanadium pentoxide; sufficient evidence in experimental animals for the carcinogenicity of vanadium pentoxide

atmosphere from cities using oil to generate power is about 620 ng/m³ compared to 11 ng/m³ levels in the atmosphere from cities that use a mix of power sources (ATSDR, 2012; Mamane and Pirrone, 1998).

INDUSTRIAL HYGIENE AND RISK ASSESSMENTS

The normal rapid clearance of vanadium means that removal from the exposure source usually is all that is necessary. Chelation therapy can be effective but is not usually required (Gomez et al., 1988). Attention to industrial hygiene and engineering is essential. Warning labels, appropriate ventilation, and properly fitting respiratory protection can prevent problems (Stokinger, 1962). Maintenance and repair workers must be supervised and must wear protective equipment and clothing. A history of the fuels and chemical processes in work sites, even if the site is being used for a different procedure, is an important clue to potential vanadium exposure. The exposure standards are given in Table 37.6.

ZINC

GIFFE T. JOHNSON

Target organ(s): Lungs, kidneys, immunological system

Occupational exposure limits:

Zinc Compound	OSHA PEL (mg/m ³)	NIOSH REL (mg/m ³)
Zinc oxide fume	5	5; STEL 10
Zinc oxide dust		
Respirable	5	5; STEL 15
Total	15	5; STEL 15
Zinc chloride fume	1	1; STEL 2
Zinc stearate dust		
Respirable	5	5
Total	15	10

Reference values: RfD 0.3 mg/kg/day; RfC N/A; intermittent MRL 0.3 mg Zn/kg/day; chronic MRL 0.3 mg Zn/kg/day

Risk/safety phrases: Metal fume fever

BACKGROUND AND USES

Zinc is an essential metal, ubiquitous in modern life, and necessary for human metabolism (NRC, 1989; Sandstead, 1995a). It is widely available as a nutritional supplement, and suggestions that zinc compounds may be effective in treating the common cold have increased the consumption of lozenges and vitamins containing zinc. Zinc compounds are used in many household products besides vitamins (Table 38.1) such as cosmetics, ointments, wood preservatives, solder fluxes, and paint (Goodwin, 1998). Commercially, zinc is sold in a variety of forms, including ingots, lumps, sheets, wire, shot, strips, sticks, granules, and powder (O'Neil et al., 2001).

Zinc is an essential constituent or cofactor for more than 200 metalloenzymes. Humans need zinc throughout their life span, although the amount necessary and the clinical effects of zinc deficiency vary with age, the rate of growth and activity, concomitant medical conditions, and the intake and stores of other metals.

Zinc compounds are commonly found in contemporary daily life. Zinc chloride is used as a soldering flux, a preservative for wood and taxidermy, and a disinfectant and deodorant. Zinc chloride is also used in batteries, dental cement, and petroleum refining. Zinc oxide is used as a topical sun protectant, in cosmetic powders and medicinal ointments, as a pigment and ultraviolet light absorbent for paints and for photocopying processes, as a dental cement and in temporary fillings, and as a fungicide and mildew retardant. Zinc stearate is also used in cosmetic and medicinal preparations. Zinc fluoride and zinc sulfate are used for wood preservation. Zinc chromate, zinc carbonate, and zinc sulfide are used in pigments. Zinc phosphide is used as a rodenticide (Casteel and Bailey, 1986; Cumpston, 1984; Goodwin, 1998; Mack, 1989).

Metallic zinc is used primarily for galvanizing iron and steel to protect them from oxidation and corrosion. Zinc has been used as an alloy with copper and tin. Alloys enhance the dye casting and galvanizing properties of zinc, and various alloys with cadmium, iron, titanium, aluminum, magnesium, and lead, as well as with copper and tin, have industrial and manufacturing uses (Goodwin, 1998).

PHYSICAL AND CHEMICAL PROPERTIES

Zinc (symbol Zn; CASRN 7440-66-6) is a blue-white metal in the same vertical series of the periodic table as cadmium and

TABLE 38.1 Commonly Used Zinc Compounds

Zinc Compound	Formula	CAS Number	Uses
Zinc acetate	ZnC ₄ H ₆ O ₄	557-34-6	Wood preservative, glazes, mordant
Zinc carbonate	ZnCO ₃	3486-35-9	Pigment, feed additive, ceramics and rubber production
Zinc chloride	ZnCl ₂	7646-85-7	Deodorant; disinfectant; wood preservative; soldering flux; rubber, paper, dye production; petroleum refining; fireproofing; textile treatment; dental cement
Zinc chromate	ZnCrH ₂ O ₄	13530-65-9	Pigment (zinc yellow) for paint, linoleum, rubber
Zinc cyanide	ZnC ₂ N ₂	557-21-1	Electroplating, extraction of NH ₃ from natural gas
Zinc fluoride	ZnF ₂	7783-49-5	Wood preservative, electroplating, fluoridation, phosphors for fluorescent lights
Zinc gluconate	ZnC ₁₂ H ₂₂ O ₄	4468-02-4	Nutritional supplement, cold medications
Zinc oxide	ZnO	1314-13-2	Pigment (zinc white), fungicide, flame retardant, sulfur scavenger, rubber vulcanizing
Zinc phosphide	Zn ₃ P ₂	1314-84-7	Rodenticide
Zinc stearate	Zn(C ₁₆ H ₃₅ O ₂) ₂	557-05-1	Cosmetic powders, medicated powders, ointments and tablets, rubber production, waterproofing
Zinc sulfate	ZnSO ₄	7733-02-0	Bleaching agent (zinc white vitriol), wood preservative, mordant

mercury. It is always divalent. Zinc resists corrosion; at room temperature, in the presence of moisture and carbon dioxide, it forms a superficial layer of hydrated, basic carbonate that protects the metal from further corrosion. The melting point of zinc is 419.5 °C (788 °F); at temperatures above 500 °C (932 °F), it volatilizes to form fumes of zinc oxide.

MAMMALIAN TOXICOLOGY

Acute Effects

Large oral doses of zinc salts (e.g., 200 mg or more) cause symptoms similar to those of staphylococcal food poisoning, such as intense nausea, vomiting, and diarrhea (Murphy, 1970; Potter, 1981). Sources of zinc salts include over-the-counter medications, nutritional supplements, and acidic beverages stored in galvanized containers. Zinc chloride can cause mucosal burns of the esophagus and stomach (Chobanian, 1981; McKinney et al., 1994). There are several case reports of toddlers ingesting substances containing zinc chloride. One child required a partial gastrectomy after surviving ingestion of a zinc chloride/ammonium chloride soldering flux, sustaining a peak plasma level of zinc of 1199 pg/dl (McKinney et al., 1994). The child also suffered hepatic injury and metabolic acidosis. The residual of the esophagitis and gastritis was severe scarring, hence the need for gastrectomy.

Zinc chloride is caustic, and skin contact causes dermatitis and ulcerations. Both zinc chloride and zinc sulfate cause corneal ulcerations and irritative conjunctivitis (Grant, 1993). A splash of concentrated zinc chloride solution (50%) can cause severe eye injury, with residual cataract, glaucoma, and iritis.

Most zinc salts irritate mucous membranes. Inhalation causes upper respiratory and bronchial irritation, with coryza and cough. Inhalation of zinc chloride fumes from smoke

bombs used by the military has caused cough and dyspnea, which progressed to fatal respiratory distress syndrome (Evans, 1945; Hjortsø et al., 1988a; Marrs et al., 1988). The acute pulmonary toxicity of zinc chloride fumes also affects animals and is the basis for one of the techniques for eliminating moles and burrowing rodents. Some acute-duration studies of workers exposed to zinc oxide fumes identified metal fume fever as a potentially associated outcome, at exposure levels in excess of 77–600 mg zinc/m³ (Blanc et al., 1991; Hammond, 1944; Safty et al., 2008; Sturgis et al., 1927). However, there has been concern that other pulmonary toxicants may be present in the workplace and the observed effects may not be wholly or partially related to zinc exposure.

Oliguria, renal failure, and microhematuria have been reported after ingestion or intravenous over administration of zinc chloride and zinc sulfate (Chobanian, 1981; Hjortsø et al., 1988b; McKinney et al., 1994; Potter, 1981). Hepatic injury with jaundice is a result of intravenous zinc administration (Brocks et al., 1977). Chronic ingestion of excess supplemental zinc can produce anemia and leukopenia consequent to induced copper deficiency (Hoffman et al., 1988). Patients with microcytic or hemolytic anemia, or both, and normal iron stores should be suspected of chronically abusing zinc supplements and should be evaluated for plasma zinc and copper levels. Zinc is not teratogenic or carcinogenic (Leonard et al., 1986).

Chronic Effects

Most evidence regarding chronic toxicity involving zinc relates to deficiency or prolonged oral supplementation. Zinc deficiency was clinically characterized in adolescent boys with delayed sexual maturation and growth failure (Prasad, 1996). Multiple nutritional deficiencies also were

present, which include pellagra, iron and folate deficiency, and protein-calorie malnutrition. Restoration of normal nutrition, growth, and sexual development required supplementation with zinc, without which other nutritional repletion was incomplete. Recent studies from Southeast Asia have found that undernourished, growth-retarded children responded to zinc supplementation with increased production of insulin-like growth factor I, increased rates of height and weight gain, and fewer episodes of respiratory infection and diarrhea, compared with a placebo-treated control group (Ninh et al., 1996). Zinc repletion also improved wound healing and skin rashes.

Zinc is essential for the biological activity of the lymphopoietic thymic hormone, thymulin; zinc deficiency is associated with reduced biological activity of thymulin and a decrease in the number of CD4+ cells, which can be corrected by zinc supplementation (Mocchegiani et al., 1995; Prasad, 1996). Administration of zinc to patients with acquired immunodeficiency syndrome who also had a zinc deficiency has been shown to increase the number of CD4+ cells and the plasma levels of complexed zinc, as well as active thymulin, and has been shown to reduce the frequency of opportunistic infectious episodes with *Candida* sp. and *Pneumocystis carinii* (Mocchegiani et al., 1995; Prasad, 1996). Studies in the Middle East, Asia, and South America have reported a reduction in infectious diarrhea and respiratory conditions among malnourished children given zinc supplements (Prasad, 1996; Sempértegui et al., 1996).

An association between reduced zinc intake and age-related maculopathy and night blindness has been used to popularize zinc supplements for the elderly (Mares-Perlman et al., 1996). The importance of adequate dietary zinc for older individuals is reinforced by the finding that estrogen replacement therapy in postmenopausal women diminishes zinc excretion and maintains plasma and presumably bone levels of zinc (Herzberg et al., 1996). Some claim that zinc deficiency accelerates the aging process (Fabris and Mocchegiani, 1995).

Large amounts of dietary zinc interfere with the absorption of other essential trace elements such as magnesium, copper, and other metals like mercury and cadmium (NRC, 1989; Sandstead, 1995a; Spencer et al., 1994). Since all of these metals compete for receptor, binding, and transport proteins, an imbalance in the quantities presented to the gastrointestinal mucosa can lead to an unexpected deficiency of copper and magnesium. Copper deficiency is associated with increased low density lipoprotein (LDL) cholesterol and decreased high density lipoprotein cholesterol (Sandstead, 1995b). It is noteworthy that in a study of people using zinc supplements, those with the highest serum levels of zinc had higher levels of total cholesterol, LDL cholesterol, and triglycerides (Hiller et al., 1995). The dangers of regular, excessive zinc supplementation are illustrated by case reports of transient leukopenia and gastrointestinal distress (Forsyth and Davies, 1995; Murphy, 1970).

Occupational exposures to zinc leading to chronic health effects are less prevalent than acute and sub-chronic reporting. Pneumoconiosis in zinc miners has been reported without episodes of metal fume fever or exposure to coal mine dust, though the causative agent in these cases remains uncertain (Joyce et al., 1996). Overall, the consequences of long-term occupational exposure to zinc, in the absence of acute and sub-chronic effects, are not well characterized and have yet to be definitively linked to adverse health outcomes.

Mechanism of Action(s)

Zinc is a catalytic component and a structural constituent of many enzymes, hormones and hormone receptors, neuropeptides, proteins, and polynucleotides. It is not surprising that zinc has multiple biological functions and that there is a mechanistic basis for a variety of clinical manifestations, which can be associated with deficiency or excess. The range of essential activities attributed to zinc is confusing and seemingly hyperbolic. A review of the literature produces a picture of a "supernutrient" or panacea that will act as an antioxidant, biomembrane stabilizer, growth promoter, immune stimulator, sensory restorer, pregnancy protector, osteoporosis marker, and vision protector, though these effects tend to be overstated (Phillips et al., 1996; Simon et al., 1988; Spencer et al., 1994).

About 20–50% of the ingested zinc is absorbed from the gastrointestinal tract. The dietary constituents affect absorption. Zinc absorption is diminished if zinc is consumed with calcium and phosphorus, some vegetable proteins, and phytates, which bind zinc in the gut lumen. Absorption is enhanced when zinc is consumed with animal protein. Zinc forms complexes with metallothionein intracellularly, and absorption is regulated by the availability of binding and transport proteins. In the blood, it is bound to albumin or to α_2 -macroglobulin.

Tissue concentrations of zinc vary considerably. The liver sequesters about 50% of a tracer dose initially, but the hepatic concentration declines in 5 days to about 25% of the tracer dose. The highest concentration of zinc is found in the prostate gland presumably because of the content of acid phosphatase, one of the many zinc-containing enzymes. Zinc is also concentrated in the pancreas and the retina, but because of the volume of muscle mass, the greatest quantity of zinc is found in the skeletal muscle (Cumpston, 1984).

Zinc is excreted slowly; the biological half-life is more than 300 days. Most of it is excreted via the biliary and gastrointestinal tract. Roughly 15% is excreted in the urine and sweat. In hot climates, as much as 25% can be secreted in sweat alone. Breast milk, the product of a modified sweat gland, contains a substantial concentration of zinc. Urinary excretion by normal adults ranges from 300 to 600 $\mu\text{g}/\text{day}$. Urinary excretion of zinc correlates with zinc consumption in the diet or zinc obtained from other exposures. Excretion can

be enhanced by chelation with dimercaprol (BAL), calcium disodium ethylenediamine tetraacetic acid (EDTA), diethylene-triamine pentaacetic acid (DTPA), and N-acetyl-cysteine. Renal tubular reabsorption of zinc is inhibited by diuretics, especially the thiazides (Cumpston, 1984; Domingo et al., 1988; NRC, 1989).

The usual plasma zinc concentration ranges from 85 to 110 µg/dl. Because zinc is sequestered in red blood cells, the zinc concentration in whole blood is as much as five times that in plasma. Zinc deficiency can reduce plasma zinc to 40 µg/dl and urinary excretion may decline to 100 µg/day or less. Laboratory evaluation of zinc metabolism in patients suspected of zinc deficiency or intoxication should include measurement of serum levels and 24-h urinary excretion.

Zinc homeostasis can be altered by clinical disorders such as inflammatory bowel disease, prolonged diarrhea, and malabsorption. Genetically determined metalloprotein disorders can be associated with zinc deficiency (acrodermatitis enteropathica) or zinc overload (juvenile biliary cirrhosis). Chronic disease, such as renal failure, alcoholic cirrhosis, neoplasia, intestinal parasites, and drug therapy, is associated with zinc depletion, as are diuretics, corticosteroids, and some antibiotics. Patients receiving total parenteral nutrition or dialysis, or both, require regular administration of zinc.

Additionally, *in vitro* studies have demonstrated that zinc enhances cytokine production by endotoxin and diminishes monocyte activation by superantigens and staphylococcal enterotoxins (Driessens et al., 1995a, 1995b; Falus and Benes, 1996). These effects are concentration and dose dependent, which in effect mean that extremely large doses of zinc may actually impair response to infectious disease pathogens.

Metal fume fever is believed to be an immunological response to zinc oxide fumes. Bronchoalveolar lavage fluid in zinc-exposed persons who developed metal fume fever demonstrated a correlation between the concentration of airborne zinc and the number of all types of T-cells (helper, inducer, suppressor, and killer) (Blanc et al., 1991). This may be exacerbated by the influx of inflammatory factors such as cytokines TNF, IL-6, and IL-8 from zinc oxide fume inhalation as demonstrated by Kuschner et al., 1997.

SOURCES OF EXPOSURE

Occupational

Most workers are exposed to zinc compounds rather than elemental zinc. Workers exposed to elemental zinc are typically employed in the fabricated metal products industry as millwrights or assemblers. Workers in the primary metal industries that work with fabricated metal products, such as stone, clay, and glass products, or in special trade contractors industries, are typically exposed to a variety of zinc compounds. Other potentially exposed workers include molding and casting

machine operators, janitors and cleaners, and machinists within the fabricated metals industry (NIOSH, 1984).

The most common occupational exposure is to zinc oxide fumes, produced during foundry operations in which galvanized steel, brass, or other zinc alloys are melted or produced by torch welding and cutting operations. Metal fume fever has been observed after inhalation of many metallic oxides, but zinc oxide is the most common and a characteristic causal agent when exposures exceed the threshold for toxicity (Bourne et al., 1968; Hamdi, 1969; Marquart, 1989; NRC, 1989).

Environmental

Zinc is widely distributed in nature and the human diet. The average concentration of zinc in the soil and the earth's crust is about 40 mg/kg. The zinc concentration in the air usually is below 1 µg/m³ but is higher in industrial areas. In water the concentration varies from 1 to 10 µg/l, with higher concentrations around mines, smelters, and industries that use zinc (NRC, 1989). The principal mineral is sphalerite (ZnS), often found with various amounts of cadmium, arsenic, manganese, lead, and copper. The major ore producers are Canada, parts of the Confederated States (formerly the USSR), Mexico, and Peru. The United States produces about 5% of the world's supply of the finished metal.

The principal source of zinc in the general population is food. Zinc is present in seafood, meat, dairy products, whole grains, nuts, and legumes. Garden vegetables take up zinc if it is applied to the soil or is present in high concentrations naturally. The average daily intake of zinc in humans is on the order of 5.2–16.2 mg zinc/day (EPA, 1987; Pennington et al., 1986). Most of this daily dose comes from food, but use of any number of materials containing zinc compounds can increase exposure.

INDUSTRIAL HYGIENE

Health hazards from zinc in the workplace are well known and regulated. Except for accidents or carelessness, health problems caused by zinc are likely to be sporadic and related to domestic use. Proper ventilation is the most effective industrial method to control freshly generated zinc oxide or other metal fumes. Fume hoods and area air filters may help to reduce area exposure levels. A properly fitted cartridge filter respirator or powered, self-contained respirator is effective protection for short-term exposure and required when exposure levels exceed the Occupational Health and Safety Administration (OSHA) permissible exposure levels (PELs) (Fishburn and Zenz, 1969; Safty et al., 2008). To prevent cases of metal fume fever, the National Institute for Occupational Safety and Health (NIOSH) and the OSHA have set the standard 8-h time-weighted average (TWA) for

zinc oxide fumes and respirable dust at 5 mg/m³. The NIOSH additionally recommends a 10 mg/m³ ceiling limit for zinc oxide fumes (NIOSH, 2007).

Worker education is essential. In any environment where workers are producing zinc oxide fumes or other irritant zinc compounds, protective clothing that covers exposed skin should be used. Eye protection is recommended, particularly for those producing zinc oxide fumes by soldering, welding, or working in the galvanization process.

MEDICAL MANAGEMENT

Acute effects such as abdominal cramps, fever, hematemesis, and hematochezia from large zinc exposures are occasional events. Resolution of symptoms takes several hours or a few days. Removal from exposure and supportive care with fluid and electrolytes usually is all that is needed. This applies to those affected by metal fume fever. Sub-chronic zinc poisoning is treated with supportive management. A severely intoxicated patient may need ventilator support, fluid and electrolyte management, and even administration of corticosteroids, though the benefit of corticosteroids remains controversial. Chelation therapy may be helpful but does not accelerate clinical recovery. As zinc alters absorption of other nutrient metals, supplementation of iron, calcium, magnesium, and copper may be considered to resolve homeostasis (Anthony et al., 1978; Hassaballa et al., 2005; Safty et al., 2008).

HAFNIUM AND ZIRCONIUM

KAMBRIA K. HAIRE, JAYME P. COYLE, AND RAYMOND D. HARBISON

First Aid: [zirconium and hafnium] Irrigate the eyes immediately for at least 15 min; wash the skin copiously with soap. If inhaled, provide respiratory support. If ingested, seek medical attention immediately; do not induce vomiting.

Target organ(s): [zirconium] Eyes, skin, lungs; [hafnium] eyes, lungs

Occupational exposure limits:

[zirconium (As Zr)] OSHA PEL: 5 mg/m³ TWA; NIOSH REL^a: 5 mg/m³ (10-h TWA); STEL (15 min) 10 mg/m³ TWA; ACGIH TLV: 5 mg/m³ TWA; STEL 10 mg/m³; IDLH: 25 mg/m³

[hafnium (As Hf)] OSHA PEL: 0.5 mg/m³ TWA; NIOSH REL: 0.5 mg/m³ (10-h TWA); ACGIH TLV: 0.5 mg/m³ (8-h TWA); IDLH: 50 mg/m³

Reference values: None established for either element

Risk/safety phrases:

[zirconium oxide]: R36/37 (irritating to the eyes and respiratory system); S26 (in case of contact with eyes, rinse immediately with plenty of water and seek medical advice); S39 (wear eye/face protection); signal word: flammable

[hafnium (powder)]: R17 (spontaneously flammable in air); S33 (take precautionary measures against static discharges)

BACKGROUND AND USES

Zirconium (symbol Zr; CASRN 7440-67-7) and hafnium (symbol Hf; CASRN 7440-58-6) are commonly found together in hafnon ((Hf,Zr)SiO₄) and zircon (ZrSiO₄; CASRN 14949-68-2); the former typically contains mostly hafnium with approximately 2% zirconium, while the latter typically contains mostly zirconium with 0.5– 5% hafnium. As their respective atomic and ionic radii are similar, their chemical properties are consequently similar. However, their differences, especially regarding neutron absorption cross section and heat refractory properties, require extensive purification and separation prior to end use industrially (Marschner, 2007). Neither of the compounds is biologically essential.

Sand blends containing zirconium are used for sand blasting and foundry moldings. Zirconium compounds are used for reflective surfaces and as a pigment in television tubes. Zirconium and zirconium-aluminum compounds have been used as antiperspirants, antipruritic agents, and abrasives. Incorporation in ceramics and alloys increases thermal protection of furnaces, kilns and crucible mortar, and of jet engine components (Opeka et al., 1999). The nuclear power industry is the leading industry that utilizes hafnium-free zircaloy, which consists of 95% Zr alloyed with nickel (0.05%), chromium (0.1%), iron (0.12%), and tin (1.5%). Zircaloy is used to form nuclear reactor claddings given its low effective neutron absorption cross section (USGS, 2013).

^aExcludes zirconium tetrachloride

Zirconium oxide (ZrO_2) is used as a diamond imitation gemstone and is gaining widespread use in medical industries, especially in dental crowns as an alternative to porcelain and as an alloy in biometallic prosthetics.

Hafnium use is limited due to low abundance. The primary use of hafnium is in the nuclear industry, where it is used in fuel rods to regulate fission given its high neutron absorption cross section. Similar to zirconium, hafnium is alloyed with niobium and carbide to produce high temperature refractory materials for furnaces and jet components as well as for plasma cutters. In addition, hafnium oxide is increasingly being used to augment or replace silicone oxide-based microprocessor chips in certain applications as well as in cathodes and capacitors (Field et al., 2011).

PHYSICAL AND CHEMICAL PROPERTIES

Zirconium is a hard, silvery transition metal with a melting and boiling temperature of 1854°C (3369°F) and 4406°C (7963°F), respectively. It has a negligible vapor pressure, and is insoluble in water, especially as zirconium oxide. The primary valence state is +4. Zirconium and its alloys react violently with strong acids and are incompatible with strong metal alkalis and strong oxidizers but are inert to most weak acids and alkalis. Pure zirconium powder may explode spontaneously in air, while zirconium hydrides react with water to produce a flammable gas. Zirconium tetrachloride is highly corrosive, which hydrolyzes in water to form zirconyl chloride.

Hafnium is a lustrous silvery, ductile metal typically found in the +4 oxidation state. In metallic form, the melting and boiling points are 2230°C (4046°F) and 4600°C (8312°F), respectively, with a negligible vapor pressure. It is poorly soluble in water as a pure metal. It is relatively unreactive to alkalis and strong acids, except hydrofluoric acid and is frequently alloyed with iron, niobium, tantalum, and titanium. Pure hafnium powder is pyrophoric and may spontaneously ignite in air, especially under conditions of high moisture. Hafnium powder reacts violently with strong oxidizers and strong acids (Pohanish, 2011). When heated to around 200°C , hafnium metal may react with several period 2 inorganic elements as well as silicone and sulfur. Hafnium oxide (HfO_2) is poorly soluble in water and is a refractory compound, which is highly resistant to corrosion. With halogens, it may react to form tetrahalides.

MAMMALIAN TOXICOLOGY

Both hafnium and zirconium are valued in the industry for their resistance to heat and corrosion, and neither of them is considered particularly toxic to humans. The conventional separation of zirconium and hafnium industrially utilizes

sodium isocyanate complexation in methyl isobutyl ketone; exposure to these may potentially be more hazardous than to the elements themselves (Rezaee et al., 2012). Dermal exposure and inhalation may cause local irritation and induce localized granulomas (Bigardi et al., 1992; Leininger et al., 1977; Shelley and Hurley, 1958).

Acute Effects

Rats exposed to zirconium silicate (CAS #14940-68-2) dust in high concentrations for 7 months developed radiographic changes from radiopaque particle accumulation but showed no effects to pneumocytes on histological examination (Zhilova and Kasparoz, 1966). In rabbits, daily short inhalation exposures to a mist containing sodium zirconium lactate produced peribronchial granulomas and alveolar inflammation. In humans, pulmonary and ocular irritation can occur, but these are rare adverse events.

Zirconium-based antiperspirants, typically containing aluminum zirconium tetrachlorohydrex glycerin and sodium zirconium lactate, have been associated with reversible dermal granulomas and hypersensitivity, consisting of papules. Papules disappear after exposure cessation though the reversal of zirconium salt irritation typically takes weeks to months rather than days (Browning, 1969; Epstein et al., 1963; Lisi, 1992; Price and Skilleter, 1986; Sullivan and Krieger, 1999). Similar dermal lesions occurred after the application of zirconium oxide cream for the treatment of poison ivy, which has restricted its use (Williams and Skipworth, 1959). Zirconium(IV) chloride hydrolyzes in water to form a corrosive solution. Upon standing, zirconium(IV) chloride solution liberates hydrochloric acid fumes, which can cause irritation and chemical burns to mucous membranes. However, reports of chemical burns from zirconium (IV) chloride are lacking.

Hafnium dust is an explosive hazard. Like zirconium, hafnium salts can irritate mucosae and skin, although granulomas are not produced. Hafnium chloride given intravenously was fatal at doses of 10 mg/kg in cats (Haley et al., 1962). *In vitro* exposure of immortalized cells to hafnium oxide nanoparticles does not demonstrate significant cytotoxicity (Field et al., 2011). Reports of acute effects to hafnium exposure apart from dermal and pulmonary irritation are lacking.

Chronic Effects

Chronic particulate or fume exposure typically occurs in industries involving the mining, cutting, and purification of zirconium-containing materials. Chronic exposure has not been associated with significant adverse human health effects though isolated incidences have been documented. Dermal and pulmonary sequelae ranging from mild irritation to focal granulomatous lesions are the most common adverse health outcomes upon exposure to ZrO_2 and zirconium salts

(Bigardi et al., 1992; Leininger et al., 1977; Shelley and Hurley, 1958).

Inhaled zirconium compounds are generally of low toxicity, but occasional reports of severe pulmonary fibrosis exist in those with long-term daily exposure (Bartter et al., 1991; Hadjimichael and Brubaker, 1981; Reed, 1956). Chronic exposure to zirconium compounds in the ceramic and foundry industries has yielded three reports of granulomatous pulmonary lesions with bilateral diffuse radiopacities; any indication of an infective etiological agent was absent. One case had a markedly decreased pulmonary function with bilateral crepitations (Bingham et al., 2001; Liippo et al., 1993; Romeo et al., 1994); one of these workers later died. The cause of death was an acute allergic alveolitis-like hypersensitivity pneumonitis marked by severe bronchioli inflammation and epithelial ulcerations (Liippo et al., 1993). One nonsmoking worker in the nuclear industry chronically exposed to zircaloy dust for 16 years presented with recurrent progressive pneumonia, bilateral lower lobe interstitial infiltrations, and altered alveolar morphology due to the presence of sarcoid granulomatosis. Again, no infective agent was detected. The role of zirconium as an etiological agent in this case cannot be confirmed, as zircaloy contains several constituents (Werfel et al., 1998). Studies on several cohorts did not find associations between zirconium exposure, both particulate and fume, and chronic effects, possibly indicating that adverse effects are rare and influenced by other factors (Mackison et al., 1981; Marcus et al., 1996).

Ceramic fibers that may contain up to 20% ZrO₂ have been classified as B2 (probable human carcinogen) by the U.S. EPA. In one study, chronic exposure to zirconium oxide-containing ceramic fibers produced contact dermatitis. Patch testing ruled out zirconium oxide as the probable allergenic agent, as cobalt and chromium produced profound allergic reactions (Kieć-Swierczyńska and Wojczak, 2000). However, the pulmonary effects are more consistent with known toxicological data of silicates, which compose a fraction of the ceramic fibers.

Animal studies with rats have documented mild hepatocellular vacuolization with chronic ingestion of hafnium chloride (HfOCl₂; CASRN 13759-17-6), and the mean lethal dose (LD₅₀) of intraperitoneal hafnium chloride is 112 mg/kg (Haley et al., 1962). These results suggest hepatotoxicity. However, no reports on human chronic effects from exposure to hafnium compounds have been documented to date; thus, animal models may be particularly sensitive to hafnium compounds, especially given the low bioavailability during inhalational and dermal exposure.

Mechanisms of Action

Parenteral injection of zirconium salts results in systemic bioavailability with localized irritation at the site of injection; the absorption fraction accumulates preferentially in the

bone. Oral ingestion results in very low bioavailability with the majority excreted in feces (Venugopal and Luckey, 1978). Beryllium sulfate, BeSO₄, and zirconium sulfate, Zr(SO₄)₂ (CASRN 14644-61-2) act as lymphocyte mitogens *in vitro* (Shelley and Hurley, 1971), which partly explains the induction of granulomas *in vivo* by these metals. Zirconium tetrachloride is corrosive to the skin, similar to the action of other strong inorganic acids.

No mechanism of action for hafnium has been elucidated as adverse events are rare.

SOURCES OF EXPOSURE

Occupational

Occupational exposure to zirconium compounds is most likely in foundry workers, ceramic workers, and firefighters. However, the zirconium found in cosmetics and hygienic products is a more common source of health problems than that of occupational setting.

Zirconium dust and shavings ignite easily when exposed to air or moisture, which can result in an explosion. Fires involving zirconium cannot be extinguished by ordinary means; instead, they must be suffocated with a pulverized mineral carbonate such as dolomite. Inhalation and dermal contact are the primary routes of exposure to zirconium.

Both hafnium and zirconium are used to store tritium. Over time, decay and mechanical abrasion leads to radioactive Hf³H and Zr³H aerosol and particle formation that can burden the respiratory tract. Clearance was shown to be biphasic with an initial rapid half-life but a long-term secondary half-life (Zhou et al., 2010).

Environmental

Neither of the elements is abundant in the environment to be a significant source of exposure.

INDUSTRIAL HYGIENE

Zirconium oxide powder is often naturally radioactive (Lischinsky et al., 1991). However, its level of radioactivity is so low that the level of radiation at the threshold limit value (TLV) is only about 6% of the Nuclear Regulatory Commission's maximum permissible limit of 0.19 Bq/m³. Therefore, researchers have concluded that the radioactivity of zirconium oxide powder can safely be ignored for industrial hygiene purposes. Nonradioactive particulates should be controlled similarly to benign dust, using general ventilation, respirators to limit inhalation, and wet cutting to reduce airborne dust.

The American Conference of Governmental Industrial Hygienists (ACGIH), the Occupational Safety and Health

Administration (OSHA), and the National Institute for Occupational Safety and Health (NIOSH) have set the TLV, the permissible exposure limit (PEL), and the recommended exposure limit (REL), respectively at 5 mg/m³ for zirconium compounds. The ACGIH and NIOSH have set an additional 15 min short-term exposure limit (STEL) of 10 mg/m³. An immediately dangerous to life and health (IDLH) limit has been set for zirconium at 50 mg/m³ (ACGIH, 2011; NIOSH, 2007). Zirconium and zirconium compounds are not classified as carcinogens by the ACGIH (class A4) and have not been investigated by the International Agency for Research on Cancer (IARC).

The ACGIH, OSHA, and NIOSH have set the TLV, PEL, and REL, respectively, at 0.5 mg/m³ for hafnium and hafnium compounds (ACGIH, 2011; NIOSH, 2007).

Zirconium has not been classified as a carcinogen by either the ACGIH (group A4) or the IARC (group 3) (IARC, 1999). Hafnium has not been classified as a carcinogen by the ACGIH, and no data are available on hafnium, except that it is more acutely cytotoxic than zirconium (IARC, 1999).

MEDICAL MANAGEMENT

No specific procedures have been devised specifically for zirconium or hafnium; however, dermal and ocular exposures should be rinsed with copious amounts of water. Patients exposed to high air concentrations of dust should be moved to fresh air.

In the case of the nuclear industry worker with recurrent progressive pulmonary pneumonia and sarcoid granulomatosis, a prednisone regime proved palliative with partial restoration of pulmonary function; the worker was able to resume work during treatment (Werfel et al., 1998).

METAL FUME FEVER AND METAL-RELATED LUNG DISEASE

THOMAS TRUNCALE

Metal fume fever (MFF) is a self-limiting illness and one of several febrile flu-like respiratory syndromes encountered in the occupational setting. In addition to metal exposure, workers exposed to the dusts of unprocessed cotton, vegetables, contaminated water reservoirs, or exposure to the thermal breakdown products of polytetrafluoroethylene (Teflon), develop an acute febrile syndrome (Table 40.1). The shared physiologic mechanism and clinical picture has led to a unifying diagnosis “inhalation fever” which was first proposed in 1978 and gained wider acceptance in 1991 (Rask-Anderson, 1992). Regardless of the cause, inhalation fever is characterized by the onset of symptoms (fever, malaise, myalgias, cough, and chills) within 3–12 h after an exposure. Signs and symptoms are generally short-lived and in most cases resolve spontaneously within 24–48 h (Table 40.2). Because the syndrome results in a blunted response (tachyphylaxis) with continued exposure (Monday morning fever in cotton mill workers), workers with no prior exposure are at particularly high risk (Blanc, 1997).

Metal fume fever is the classic example of inhalation fever. Initially thought to be a malaria type sickness among foundry men or any one exposed to the vapors, which arise from metal, Thackrah was the first to recognize a separate “affection” peculiar to brass workers (Hayhurst, 1911). Over the years, the afflictions came to be known as brass founder’s ague, brass chills, smelter shakes, zinc shakes, zinc fume fever, metal malaria, or Monday morning fever among brass foundry workers or welders of galvanized steel (Table 40.3). Metal fume fever has since been recognized as the syndrome of an acute, self-limiting flu-like illness following exposure to metal fumes, primarily zinc oxide but other metal oxides,

including manganese, nickel, and chromium have been described (Table 40.4). Welding, brazing, soldering, or thermal cutting of galvanized metal are the main causes of zinc exposure, although exposure can occur in the manufacture of brass (zinc–copper alloy) or industrial processes that use other binary zinc alloys, including aluminum, cobalt, antimony, and nickel. Welders are at particular high risk, as the composition of welding fumes will vary based upon the type of metal being used. Mild steel will produce fumes containing aluminum, magnesium, fluoride, potassium, calcium, manganese, iron, titanium, and trace amounts of cobalt, zinc, and lead. Welding of stainless steel will provide additional exposure to chromium and nickel oxides (Brooks et al., 2007). Galvanized steel, a coating of zinc over steel provides additional protection from rust and corrosion. Because zinc melts and vaporizes at a lower temperature than non-coated steel, the zinc vapor reacts with oxygen and immediately produces zinc oxide as a fine dispersion of dry particles of 1 µm in size, small enough to reach the terminal bronchioles and alveoli when inhaled (Rohrs, 1957; Brown, 1988). Although it is widely accepted that MFF is caused by the exposure to freshly generated zinc oxide fumes, Blanc (Blanc, 1997) in a concise review of inhalation fever references case reports of MFF following heavy exposure to finely ground zinc dust in the absence of a fresh fume exposure.

Despite the general acceptance that an exposure to metal fumes other than zinc oxide causes MFF, there is little scientific evidence to support this conclusion. The association of MFF following exposure to magnesium oxide fumes was first described in the 1920s (Drinker et al., 1927); however, more recent work has failed to validate a systemic

TABLE 40.1 Causes of Inhalation Fever

Disorder	Exposure	Occupation
Metal fume fever	Oxides of metals (most commonly zinc)	Welding (most common), also seen in soldering, melting, casting, grinding, bronzing, and forging
Organic dust toxic syndrome	Organic dusts (moldy hay, grain dusts, wood chips, mulch, silage, compost) contaminated with bacteria, fungi, and endotoxin	Agriculture/farming/environmental
Vegetable and grain dusts		
Mill fever, Gin fever, Monday morning fever, mattress fever	Cotton dust, stained cotton (others include soft hemp (hemp fever), kapok)	Agricultural/yarn-manufacturing, thread mills, fabric manufacturing, textile (upholstery, mattresses)
Heckling fever	Flax	Agricultural/yarn-manufacturing, thread mills, fabric manufacturing, textile (upholstery, mattresses)
Grain fever	Wheat, barley, oat, corn, rice, sorghum, airborne grain dust	Grain workers
Wood trimmer's Disease	Dried contaminated (moldy) wood	Sawmills
Contaminated water reservoirs		
Humidifier fever	<i>Naegleria gruberi</i> , Pseudomonas likely other Gram negative species and possibly endotoxin	Printing industry

TABLE 40.2 Characteristics of Inhalation Fever

1. Acute high level exposure
2. Onset of symptoms within 3–12 h (fever, dyspnea, myalgias, malaise, chills)
3. No history of prior sensitization
4. Blunted response with repeated exposure (tachyphylaxis)
5. Pulmonary function is normal
6. Chest X-ray reveals no acute findings
7. Hypoxia is not present
8. Increased pulmonary polymorphonuclear leukocyte response
9. Increased proinflammatory cytokine (IL-6, IL-8, TNF) response
10. ROS, nanoparticles, and TRPA1 activation likely play a role
11. Self-limiting course
12. No chronic sequela expected

Source: Adapted from Blanc PD (1997); Blanc PD (2007).

response, abnormal pulmonary function, or changes in proinflammatory cell or cytokine concentrations in bronchoalveolar lavage (BAL) fluid following inhalation of magnesium oxide particulates (Kuschner et al., 1997). Similar reports documenting the adverse effects of copper fumes are also limited. In a systemic review of the scientific literature, Borak (Borak et al., 2000) concluded that there was insufficient evidence to suggest a causal link between exposure to copper dust or fumes and MFF.

Symptoms

Metal fume fever is characterized by the acute onset (usually within 3–12 h of welding galvanized steel) of respiratory symptoms including cough, wheezing, dyspnea, and chest tightness accompanied by systemic symptoms of a flu-like

illness; fever, malaise, myalgias, chills, metallic taste in the mouth, dry throat, nausea, and headache (Table 40.5). Spontaneous resolution of symptoms occurs within 24–48 h of exposure. Tachyphylaxis develops during the workweek with continued exposure, as patients often complain of symptoms at the start of the week, which improve or completely resolve at the week's end (Krantz and Dorevitch, 2004). New workers, those who have been off for the weekend or for a week's vacation are at highest risk. Once back at work, they develop symptoms upon re-exposure following a 2–3 day period of abstinence.

Diagnosis

On initial presentation, MFF may be difficult to differentiate from other forms of acute febrile respiratory syndromes namely influenza, other viral illnesses, or acute lung injury (ALI) following exposure to cadmium fumes or zinc chloride. The latter are discussed in detail in a following section. It is essential to obtain an accurate occupational history that exhausts all possible exposures to exclude the possibility of acute pneumonitis following exposure to cadmium or zinc chloride. Routine diagnostic tests, including chest X-ray, pulmonary function tests (PFTs), diffusion capacity, and arterial oxygenation in MFF are always normal (Ahsan et al., 2009). In rare instances where the forced vital capacity (FVC) is reduced (Sturgis et al., 1927) or hypoxia and patchy opacification on chest X-ray have been described (Kaye et al., 2002), complete resolution occurs within 24–48 h. In the setting of ALI following exposure to cadmium, nickel carbonyl, and zinc chloride, there is progression of the pulmonary infiltrates and worsening hypoxia in the days following the exposure, where MFF is expected to resolve during that period of time. If abnormal diagnostic studies are

present following an exposure to metal fumes, a careful investigation for other causes should be pursued. These conditions are outlined in Table 40.6 and are described below.

Pathogenesis

The pathogenesis of MFF appears to be related to a dose-dependent inflammatory response in the lung followed by the release of various cytokines, which in turn induce the systemic symptoms of fever and flu-like symptoms. Blanc (Blanc et al., 1991) first studied 14 participants who welded galvanized mild steel in an environmental chamber specifically designed to correspond to real work exposures. Varying concentrations of zinc oxide fume were correlated with BAL fluid cell counts at 8 h (early group) and 22 h (late group). They found a dose-dependent increase in the polymorphonuclear leukocyte count in the BAL fluid 22 h following the exposure. First, establishing a dose-dependent pulmonary inflammatory response, Blanc et al. (1993) measured TNF, IL-1, IL-6, and IL-8 in the BAL supernatant of 15 subjects 3, 8, and 22 h following exposure to inhaled zinc oxide fumes. They found a statistically significant dose- and time-dependent increase in TNF in the early follow-up group (3 h) compared to the late (8 and 22 h) group. Additionally, they found a significant exposure response in IL-6 and IL-8, 8 h after the exposure, supporting their earlier hypothesis that the delayed (22 h) increase in the polymorphonuclear count is mediated by the early release of IL-8, a neutrophil chemoattractant. Subsequent studies measuring TNF, IL-6, and IL-8 using a similar model (Kuschner et al., 1998) and *in vitro* human mononuclear cell lines exposed to zinc oxide (Kuschner et al., 1997) have verified these findings.

Additional mechanisms to explain the inflammatory response seen in MFF appear linked to the formation of oxygen radicals produced by activated neutrophils. Human neutrophils exposed to zinc oxide demonstrate an increased oxidative metabolism causing the release of oxygen radicals within 35 min of exposure (Lindahl et al., 1998). reactive oxygen species (ROS) and the generation of free radicals are also produced from stainless and mild steel welding fumes, and have the potential to cause cellular membrane disruption, protein or DNA damage, and may lead to the generation of ROS or signaling associated changes in airway inflammation. Additionally, combustion derived nanoparticles originating from welding fumes among others, have the potential to cause lung injury through oxidative stress and inflammation (Kim et al., 2010). The possibility that increased oxygen radical formation from activated neutrophils or exposure to welding derived nanoparticles contribute to the pathogenesis of MFF requires further study. Furthermore, the finding of increased glutathione levels, a known antioxidant and free radical scavenger, among welders exposed to zinc may help to explain why MFF is a self-limiting illness (Jin-Chyuan

TABLE 40.6 Metal-Related Lung Disease

Occupational Lung Disease	Cause	PFT's	Chest X-ray	Chronic Sequela
Occupational asthma	Platinum salts, nickel, chromium, tungsten carbide, cobalt, aluminum, palladium, vanadium, zinc	Variable airway obstruction, airway hyper-responsiveness	Normal, may show hyperinflation	Variable: Short duration of exposure correlates to better outcome, longer duration may result in persistent airway responsiveness, obstruction, inflammation, and remodeling
Delayed and immediate anaphylactoid reaction	Chromium, zinc	Normal, exposure induces bronchospasm and airway hyper-responsiveness	Normal	The possibility of re-current symptoms exists upon re-exposure, long-term sequela unknown
Hypersensitivity pneumonitis	MWF contaminated with atypical Mycobacterium	Acute: restriction with decreased DLCO (reversible if removed from the exposure) Chronic: mixed restriction and obstruction with reduced DLCO and hypoxia at rest or with exercise	Acute: normal to mid to upper zone predominance of reticular, nodular or ground glass opacities Chronic: Reticular nodular with honeycombing and/or emphysema.	Variable: acute presentation is associated with better outcome. Greater intensity and duration of exposure results in accelerated lung function decline
Berylliosis or metal-related granulomatous disease	Beryllium, aluminum, cadmium, hard metal disease (cobalt/tungsten carbide), nickel and mercury(rare)	Restrictive (reduced FEV1, FVC, TLC, FRC, and RV) diminished DLCO	Acute: alveolitis with diffuse infiltrates Chronic: diffuse interstitial opacities with fibrosis and honeycombing	Progressive: workers can have resolution of symptoms if removed from exposure, in long standing exposure restrictive lung function and fibrosis are irreversible
Acute pneumonitis	Aluminum, cadmium, manganese, mercury, zinc chloride, vanadium	Normal to restrictive if patient survives	Diffuse bilateral infiltrates, with or without pulmonary edema	Acute form may be reversible, chronic form will lead to fibrosis, restrictive lung disease, and possibly death
Lung cancer	Aluminum, beryllium, arsenic, cadmium, chromium, nickel	Variable	Lung nodule, mass	Depends of stage, overall poor 5 year survival
Metal fume fever	Oxides of metals (zinc most common)	Normal	Normal	None

et al., 2009). Finally, selective expression of transient receptor potential A1 (TRPA1) in a subpopulation of bronchopulmonary C-fiber afferents following chemical irritant or heavy metal exposure is worth mentioning. Chemical stimulation of the nasal mucosa, glottis, larynx, and lower airways activates TRPA1 and triggers chemosensory nerve endings to release neuropeptides (Substance P and calcitonin gene-related peptide (CGRP)) inducing neurogenic inflammatory dilatation of blood vessels, leaky capillary membranes, and increased secretions. This in turn provokes the cough reflex and can trigger sneezing, tracheal and bronchial constriction, bronchospasm, excessive mucus secretion, and further neurogenic inflammation. TRPA1 can be activated by a variety of chemical irritants, including acrolein, mustard oil, chlorine, aldehydes, ROS, and noxious by-products of smoke (Bessac and Jordt, 2008). Recent studies have shown that heavy metals, zinc, cadmium, and copper stimulate pulmonary sensory neurons through direct activation of TRPA1 (Gu and Ruei-Lung, 2010). Once activated, TRPA1 appears to augment the inflammatory response seen in MFF and may lead to the long-term changes associated with chronic inflammation seen in asthma and COPD (Geppetti et al., 2010). TRPA1 antagonism also offers a promising pharmacologic target for anti-inflammatory and cough medications. Further human study is required, however, to confirm the role of TRPA1 in chemical irritant and heavy metal exposure.

Treatment

Treatment for MFF is supportive, although antipyretics, beta agonists and inhaled or intravenous steroids have been used. No long-term sequela has been found to be associated with this self-limiting illness. The occurrence of MFF suggests poor ventilation or noncompliance with the use of personal protective equipment primarily respirators and warrants a careful engineering and work practice investigation. Lastly, an episode of MFF may identify a worker who may be at risk for developing other welding-related lung diseases, namely asthma (Malo and Cartier, 1987).

METAL-RELATED LUNG DISEASE

Occupational Asthma

Occupational asthma (OA) has been defined by the presence of reversible airflow obstruction and/or airway hyper-responsiveness caused by an exposure to sensitizing agent and/or irritants in the workplace (Chan-Yeung, 1990; Tarlo et al., 2008). Asthma can also be exacerbated in the workplace in those with pre-existing asthma, known as work-aggravated asthma. The reported estimates of all causes of asthma attributed to work ranges from 5 to 29% (Janson et al., 2001). Occupations that appear to be at higher risk include

bakers, laundry workers, shoemakers and repairers, tanners, fell mongers and pelt dressers, and metal plating and coating workers (Karjalainen et al., 2002). In workers exposed to metal aerosols or fumes, OA appears to range from 3 to 10% (Bakerly et al., 2008; El-Zein et al., 2003). While cigarette smoking and atopy do not appear to be important risk factors in most cases of metal-induced OA, smoking, and intensity of exposure definitely play a role in exposure to platinum salts (Calverley et al., 1995). Agents that stimulate an immunologic form of OA are classified into two categories. High molecular weight antigens derived from plant or animal antigens are capable of causing an IgE-mediated response while low molecular weight antigens (LMWA), which are synthetic compounds used in the manufacture of plastics and rubber, act as incomplete antigens (haptens) and combine with human proteins; allergic sensitization, and IgE-mediated OA (Cromwell et al., 1979). Of all exposures to metal dusts, aerosols, or fumes, platinum salts are recognized as the most potent inducers of sensitization and IgE-mediated asthma (Malo, 2005). Exposure to cobalt, nickel, chromium, and palladium (other LMWA) in the form of metal dusts or fumes among welders, electroplaters, metal/hard metal workers, jewelers, or refinery workers are additional causes of metal-induced sensitization and IgE-mediated OA (Chan-Yeung, 1986; Daenen et al., 1999; Kusaka et al., 2001; Leroyer et al., 1998; Malo et al., 1982; Malo and Chan-Yeung, 2009; Novey et al., 1983; Shirakawa et al., 1989). Non-immunologic mechanisms also play a role in the development of metal-induced OA. The demonstration of a 24% reduction in FEV1 following exposure to galvanized heated zinc without evidence of skin sensitization or a specific IgE antibody to zinc in a worker who developed OA suggests an alternative pathway (Malo et al., 1993). At present, the exact immunologic or cellular mechanism to explain how other metals, including zinc, aluminum (potroom asthma), and vanadium are capable of inducing OA is unknown.

IgE-MEDIATED ACUTE AND LATE PHASE REACTIONS

Rarely, exposure to metal fumes has resulted in MFF-like symptoms associated with an immediate and late anaphylactoid reaction. Farrell (Farrell, 1987) describes an employee of a zinc smelting plant who developed generalized pruritus, urticarial lesions, and flu-like symptoms (typical of MFF) after welding galvanized steel. His flu-like symptoms resolved by the next morning, however, his hives and itching worsened. He then developed angioedema of the face, lips, and throat requiring medical treatment with epinephrine and diphenhydramine. On return to work 1 week later where welding of zinc was being done, he immediately developed swelling of the lips, itching, and some swelling in his throat. The presence of an immediate reaction similar to MFF and a

late phase reaction (hives and angioedema) suggests an immunologic response distinct from the response seen in MFF.

HYPERSensitivity PNEUMONITIS

Hypersensitivity pneumonitis (HP) or extrinsic allergic alveolitis is an inflammatory lung condition that involves both a type III and type IV hypersensitivity reaction. The reaction is mediated by immune complexes, Th1 T cells and CD8+ predominate lymphocytic inflammation in the lung parenchyma to repeated environmental antigen exposure that results in immunologic sensitization and immune-mediated lung disease (Mohr, 2004; Mason, 2010). Repeated and prolonged exposure may result in interstitial lung disease, which is characterized by an increase in CD4+/CD8+ ratios and a skewing towards Th2 cells as opposed to Th1 (Barrera et al., 2008). In contrast to MFF and acute HP prolonged exposure (10 years or greater in most cases) to an environmental antigen results in interstitial fibrosis on CT scan and restrictive lung disease on PFT.

Most often, all (acute, subacute, and chronic) forms of HP are associated with exposure to moldy or wet hay, grain dust or wood contaminated with fungi. Bacterial contamination of sugar cane, wood dust, and water reservoirs also play a significant role and together they make up the most common causes of HP (Table 40.7). For the years 1990–1999, agricultural production industries (livestock, crops, and farming) were associated with a significantly increased risk for developing HP (DHHS, 2007). Interestingly, HP has been recognized among metalworkers exposed to atypical mycobacterium in contaminated metal working fluids (MWF). Seven cases of HP were identified in three facilities manufacturing automobile parts in Michigan. All of the affected employees had been working in a machining environment for many years before they developed HP. High concentrations of *Mycobacteria immunogenum* were reported from several of the MWF reservoirs (Gupta and Rosenman, 2006). Additionally, *Mycobacteria chelonae* was identified in high numbers in bulk coolant samples and in air samples around colonized machines in a patient who worked in an engine production facility 2 years before developing cough dyspnea and hoarseness. The patient's in-hospital evaluation included

TABLE 40.7 Occupational Related Hypersensitivity Pneumonitis

Etiologic Agents	Disease	Exposure
Microbial agent

Fungi		
Aspergillus spp	Malt workers lung/tobacco workers lung/compost lung	Moldy malt, barley, Tobacco, compost
Penicilium spp	Cheese workers lung, suberosis	Moldy cheese, moldy cork
Cladosporium spp	Hot tub lung	Contaminated hot tub mists
Alternaria spp	Wood pulp workers disease	Contaminated wood pulp
Cephalosporium spp	Sewer workers lung	Contaminated basement sewage
<i>Trichosporon cutaneum</i>	Japanese summer time HP	Contaminated house dust
	Animal proteins	
Bird proteins	Bird fanciers lung, pigeon breeders lung, Duck fever, lab workers lung, furriers lung	Bird, goose, rat, animal pelt, and other animal proteins
Chemicals		
Isocynates, trimetalic anhydrides, phthalic anhydride, pyrethrum, sodium diazobenzene sulfate (Pauli's reagent)	Chemical workers lung	Isocyanates (in polyurethane paints, adhesives, and foam production), epoxy resins, coatings, paints, Pauli's reagent
Metals		
Zinc fumes	Zinc fume hypersensitivity pneumonitis	Smelter exposed to zinc fumes

a chest X-ray that showed bilateral interstitial infiltrates, a high resolution CT scan consistent with alveolitis and a decreased diffusion capacity on PFTs. A diagnosis of HP was made and the patient's condition improved with corticosteroid treatment and relocation to an office environment at work (Shelton et al., 1999). Of additional interest is a case report of HP in a smelter exposed to zinc fumes while working for 3 years in a nonferrous metal foundry. The patient presented with complaints of acute onset of shortness of breath, fever, cough, and purulent sputum. His chest X-ray showed a mild reticular pattern in the periphery of both lungs. PFTs revealed a moderate obstructive pattern and a significant decrease in diffusion capacity. Bronchoalveolar lavage showed increased lymphocyte counts with a predominance of CD8+ lymphocytes and a decrease in the CD4+/CD8+ ratio resembling HP. After a period of 6 months without contact with zinc fumes, the patient was symptom free and his diffusion capacity returned to normal. The clinical course of this patient, that is; the late emergence of symptoms, similar to HP in metal fluid workers and aluminum workers described below, long-lasting changes in PFT and physiologic findings on BAL are not expected in MFF or ALI from zinc chloride or cadmium exposure. These findings suggest an alternative hypersensitivity reaction (Ameille et al., 1992).

In addition to HP, sarcoid-like granulomatous disease has been identified in workers exposed to aluminum dust. A 50-year-old woman, who worked in a metal reclamation factory for 15 years and was exposed to aluminum, iron, copper, zinc, and nickel dust presented with an intermittent cough, white frothy sputum, and dyspnea. A high resolution CT scan of the chest revealed bilateral ground glass and patchy areas of consolidation with reticular hyperattenuating areas and traction bronchiectasis. Her PFTs showed a restrictive pattern and severe reduction in diffusion capacity. An open lung biopsy showed clusters of well-formed non-necrotizing granulomas with multinucleated giant cells; fibrosis, and honeycombing were absent. Scanning electron microscopy of the granulomas yielded discrete peaks for aluminum. After exclusion of infectious agents and sarcoidosis and based upon her occupational history, the authors conclude there was a distinct relation between the aluminum deposits and pulmonary sarcoid-like granulomas (Cai et al., 2007). The descriptions of sarcoid-like granulomas on histologic examination of the lung following aluminum exposure are not unique to this study and have been described by others (Chen et al., 1978; DeVuyst et al., 1987). Furthermore, chronic beryllium disease (berylliosis or CBD) resulting from long-term exposure to beryllium dust or fumes in the electronic or aerospace industry is also characterized by a cell-mediated or delayed hypersensitivity reaction with granulomatous inflammation. Genetic susceptibility has been established (Fontenot and Maier, 2005; Saltini et al., 1998) through human leukocyte antigen class II marker (HLA-DP Glu69), which has been found to be strongly

associated with CBD. Other metals that promote granuloma formation include barium, cobalt, copper, gold, titanium, zirconium, and lanthanides (Newman, 1998).

METAL PNEUMCONIOSIS

The 2002 work-related lung disease (WORLD) surveillance report published by NIOSH (DHHS, 2007) included mortality data focusing on the various occupational-relevant lung diseases, including pneumoconioses seen in the United States. Reporting on the contributing or cause of death, they identified the majority of cases of dust-associated lung disease (pneumoconiosis) caused by the inhalation of mineral dusts are from asbestos, coal, or silica exposure; however, several metallic dust exposures pose an increased risk of interstitial lung disease, pneumoconiosis, and mortality. The primary pneumoconiotic metallic agents include beryllium and cobalt, although rarely aluminum welding fume-induced pneumoconiosis has been described (Hull and Abraham, 2002). Of all metallic causes of pneumoconiosis, increased risk of mortality is seen in the coal or metal mining industry and in the production of glass and glass products. Occupations at a particular high risk are mining machine operators, welders, and electricians (DHHS, 2007). The diagnosis of pneumoconiosis is suggested when a worker complains of cough, shortness of breath, and activity intolerance with a corresponding history of an occupational exposure. The diagnosis is supported by chest X-ray findings of interstitial fibrosis with diffuse small nodular and reticular patterns and high resolution CT scan revealing bilateral ground glass or consolidation, reticular opacification, traction bronchiectasis, and honeycombing in advanced disease. Pulmonary function tests invariably showed a restrictive pattern with a decreased diffusion capacity (Chong et al., 2006; Gotway et al., 2002). In a worker exposed to hard metal (tungsten carbide particles in a matrix of cobalt metal), the presence of multinucleated giant cells on lung biopsy is pathognomonic for hard metal lung disease (Ohori et al., 1989).

Occupational exposure to other metallic agents may lead to the radiographic appearance of pneumoconiosis without evidence of restrictive lung disease or a diminished diffusion capacity on PFTs or interstitial fibrosis on CT scan of the chest. Potkonjak (Potkonjak and Pavlovich, 1983) described 51 subjects who worked in a smelting plant and were exposed to dust containing predominately antimony oxide. The presence of diffuse, densely distributed punctate opacities <1 mm, round and irregular in shape characterized the X-ray findings in what was termed "antimoniosis" following exposure to antimony oxide. The clinical manifestations included productive and non-productive cough, upper airway inflammation, wheezing, chest tightness, and shortness of breath. No characteristic pulmonary function abnormalities

were identified. Other benign, non-fibrotic causes of pneumoconiosis with distinctive X-ray findings with or without bronchial irritation and no evidence of a ventilatory or diffusion defect on PFTs include tin (stannosis) (Robertson et al., 1961), barium (baritosis) (Doing, 1976), and iron (siderosis) (Nemery, 1990).

There are a few case reports of symptomatic respiratory disease, abnormal pulmonary function with associated interstitial fibrosis in welders exposed to iron (McCormick et al., 2008) and in tanners exposed to tin fumes (Yilmaz et al., 2009). In an attempt to explain how pulmonary fibrosis and restrictive lung disease can develop in those exposed to the benign non-fibrotic causes of pneumoconiosis, it is often suggested that there is cross contamination resulting from non-welding inhalation exposures to mixed dusts (silica, asbestos, coal) termed mixed dust pneumoconiosis (Antonini et al., 2003). A number of studies examining the histology of lung tissue of symptomatic welders have identified a large amount of iron deposits in the fibrotic areas of the lung without evidence of coexisting silicosis or other mixed dusts supporting the possibility for welders exposed to iron to develop interstitial lung disease (Funahashi et al., 1988; Rosler and Woitowitz, 1996).

ACUTE PNEUMONITIS

Acute pneumonitis, acute inhalation pneumonitis, chemical pneumonitis, toxic pneumonitis, chemical or toxic pneumonia, and toxic inhalation syndrome are terms used to describe the development of non-cardiogenic pulmonary edema following an exposure to solvents, welding fumes, grain and fertilizer dusts, smoke, or highly soluble irritants, including chlorine and ammonia. Irrespective of the cause, the physiologic consequence of these exposures results in ALI. Acute lung injury is characterized by the direct toxic effect on lung cells and the indirect acute systemic response; increased permeability that is associated with a collection of clinical, radiographic, and physiologic abnormalities that cannot solely be explained by abnormal heart function or by pulmonary hypertension (Bernard et al., 1994). In its severe form, ALI can progress to adult respiratory distress syndrome (ARDS) where progressive hypoxia, decreased lung compliance, diffuse alveolar damage, and pulmonary fibrosis develop. Table 40.8 describes the recommended criteria for distinguishing ALI and ARDS.

The development of acute chemical pneumonitis has been described following the inhalation of metal fumes containing cadmium and manganese, exposure to mercury vapor or vanadium pentoxide as a byproduct of oil burning furnaces, nickel carbonyl exposure in a waste treatment factory and in military personnel exposed to zinc chloride smoke during combat exercises (Barceloux, 1999; Cooper, 2007; Fernandez et al., 1996; Lilis et al., 1985; Milne et al., 1970; Nemery,

TABLE 40.8 Definition and Characteristics of ALI and ARDS

Onset

Always Acute (ALI and ARDS)

P/F Ratio (measure of oxygenation)

$\text{PaO}_2/\text{FiO}_2 \geq 200 \text{ mmHg} \leq 300 \text{ mmHg} \Rightarrow \text{Acute lung injury}$

$\text{PaO}_2/\text{FiO}_2 \leq 200 \text{ mmHg} \Rightarrow \text{Adult respiratory distress syndrome}$

Chest X-Ray

Bilateral infiltrates without pleural effusions (ALI and ARDS)

Pulmonary Capillary Wedge Pressure

$\leq 18 \text{ mmHg}$ when measured (ALI and ARDS)

No clinical evidence of left atrial hypertension (ALI and ARDS)

1990; Seet et al., 2005; Zerahn et al., 1999). In most of these cases, patients present acutely with mild symptoms characterized by fever, chills, shortness of breath, and cough similar to those found in MFF. However, their clinical course was complicated by the development of diffuse alveolar infiltrates or non-cardiogenic pulmonary edema on chest X-ray, progressive hypoxia, increasing shortness of breath, and sometimes pneumothorax or fatal hemorrhagic pulmonary edema. In those that survive mercury or zinc chloride exposure, restrictive lung disease and diffusion abnormalities persist despite treatment (Lilis et al., 1985; Zerahn et al., 1999). The pathologic features on post-mortem examination of the lungs in those who do not survive reveal evidence of diffuse alveolar damage, hyaline membranes, and the early stages of intra-alveolar fibrosis consistent with ARDS (Milne et al., 1970; Seet et al., 2005). There are several case reports of diffuse alveolar damage following inhalation of zinc oxide fumes and a description of a severe form of MFF following inhalation of zinc chloride fumes (Barbee and Prince, 1999; Blount, 1990; Bydash et al., 2010; Taniguchi et al., 2003). Although initially patients present with symptoms of MFF, a self-limiting illness, symptoms uniformly progress in the days following the exposure. Hypoxia, radiographic evidence of alveolar injury and pathologic evidence of ALI and ARDS become evident. These findings are not consistent with MFF caused by exposure to zinc oxide and suggest an alternative physiologic mechanism.

METAL-INDUCED LUNG CANCER

Occupational inhalation exposures to several metals are recognized to cause cancer. The International Agency for Research on Cancer (IARC) have classified aluminum, arsenic, beryllium, cadmium, chromium, and nickel as Group 1 known human carcinogens (Straif et al., 2009). These metals along with the occupation and types of cancer they cause are listed in Table 40.9. Cobalt with tungsten carbide is the only

TABLE 40.9 Metal Associated Malignancies

International Agency for Research on Cancer (IARC) Group 1 Metals for Which There is Sufficient Evidence for Cancer in Humans		
Metal Exposure	Occupation	Malignancy
Aluminum compounds	Smelting, mining, construction, manufacturing, explosive and paper industries	Lung, bladder, pancreas, lymphosarcoma/reticulosarcoma, leukemia
Arsenic and arsenic compounds	Metal smelting, coal production and burning, production and use as wood preservative, glass and semiconductor manufacture	Lung, skin, bladder
Beryllium and beryllium compounds	Mining, electronic, nuclear and aerospace industries	Lung
Cadmium and cadmium compounds	Mining and ore processing, smelting, electroplating, spraying of paints with cadmium pigment, welding, smelting, nickel cadmium battery production	Lung
Chromium VI (hexavalent) compounds	Electroplating, welding, cement production, metallurgical production	Lung, paranasal sinuses
Nickel compounds	Refineries, smelting, welding, electroplating, production of jet engine parts, nickel cadmium battery production	Lung, paranasal sinuses, and nasal cavity
International Agency for Research on Cancer (IARC) Group 2A Metals Probably Carcinogenic in Humans		
Metal Exposure	Occupation	Malignancy
Cobalt with tungsten carbide*	Aircraft engine production, steel applications, diamond grinding tools, refining and production of alloys in hard metal industry	Current epidemiological evidence suggests an increase lung cancer risk** but falls short of providing convincing evidence for a carcinogenic effect of exposure to cobalt with tungsten carbide in humans

metal found in Group 2A: a probable carcinogen in humans (IARC, 2006; Moulin et al., 1998; Hogstedt and Alexandersson, 1990).

CHRONIC OBSTRUCTIVE LUNG DISEASE OR EMPHYSEMA

While cigarette smoking remains the most common cause of airflow limitation, occupational exposure to organic and inorganic dusts, inhaled particulates, and chemicals (vapors, irritants, and fumes) make up an underappreciated risk factor for COPD (Global Initiative for Chronic Obstructive Lung Disease, 2014). The NHANES III survey (Hnizdo et al., 2002) of almost 10,000 US workers aged 30–75 estimated the fraction of COPD attributable to work was 19.2% overall and 31.1% among those who never smoked. After adjusting for age, smoking, body mass index, education, and socio-economic status they found an increased risk for COPD in the following industries: rubber, plastics, and leather manufacturing; utilities; office-building services; textile mill products manufacturing; agriculture, construction, transportation, and trucking; repair services and gas stations. Occupations associated with increased odds ratios for COPD included freight,

stock, and material handlers; records processing and distribution clerks, sales; transportation-related occupations; machine operators; construction trades; and waitresses. Additionally, exposure to metal gases, aluminum production, processing, and welding is also associated with chronic airway obstruction (Meldrum et al., 2005). In a cohort of over 9000 U.S. workers at seven beryllium-processing plants, Schubauer-Berigan (Schubauer-Berigan et al., 2011) found a clear exposure–response association between beryllium exposure and COPD. Emphysema was also reported among survivors from a foundry manufacturing copper-cadmium alloy. Those with the highest exposures recorded a 398 ml drop in FEV1 and a significant reduction in the diffusing capacity (Burge, 1994). As growing evidence suggests that specific industries and occupations are associated with the risk of developing obstructive lung disease, occupational exposure becomes significantly more important as a cause of COPD: independent of exposure to tobacco smoke.

SECTION III

CHEMICAL COMPOUNDS I

SECTION EDITOR: RAYMOND D. HARBISON

41

INTRODUCTION

RAYMOND D. HARBISON

In a fundamental sense, chemicals are essential for human existence. Everything that is not a form of energy, such as sunlight or sound, comprises a chemical or chemicals. Although this is true, it has long been recognized that occupational overexposure to some chemical agents may cause illness and disease. Sections III and IV of this book address the major chemical compounds considered relevant to occupational exposure and disease. Although an effort has been made to cover each chemical or group of chemicals representing an occupational hazard, these sections should not be considered all inclusive. Some chemical compounds are discussed in more specific sections, such as Metals and Metalloids, Pesticides, and Organic High Polymers.

Great advances have been made in understanding the effects of chemical exposures in the recent past. Both industrial experience and animal testing have provided a more complete understanding of the risk of occupational exposure to various chemicals. This improved understanding, in turn, has allowed the development of exposure guidelines and better safety programs for the workplace.

In the field of occupational medicine, attention to chemical agents has shifted from acute overexposure to chronic exposure and illness. Although acute exposure still occurs

and must be controlled, it is much less common than during Alice Hamilton's day in the early part of this century. An occupational physician is more likely to be confronted with cancer or a chronic illness that may be work related. As is discussed in the chapter, Diagnosis of Occupational Disease (Chapter 1), these illnesses are much more ambiguous than an acute overexposure. Association with actual occupational exposure is complicated and often inconclusive.

Although our knowledge of the effects of occupational exposure to chemical agents has improved, it is important to remember that thousands of new compounds are produced each year, some of which are destined for widespread industrial use and potential occupational exposure. Thus the workplace must be continually evaluated to identify potential new chemical hazards and to reevaluate existing ones.

While reading the following chapters, a constant reminder is proposed: Exposure is only the opportunity for contact with a chemical; the dose determines the effect or lack of effect. Many factors can affect exposure and, ultimately, the dose of chemical received. As Emil Mrak said, "There are no harmless substances, only harmless ways of using substances."

CARBON DIOXIDE

DEBRA J. PRICE

Target Organ(s)	Respiratory and Cardiovascular System
Occupational exposure limits	OSHA: PEL: 5000 ppm TWA NIOSH: REL: 5000 ppm TWA STEL: 30,000 ppm TWA IDLH: 40,000 ppm
Risk/safety phrases	Dusts of various metals are ignitable and explosive when suspended in carbon dioxide. Forms carbonic acid in water

BACKGROUND AND USES

Carbon dioxide is a colorless, odorless gas at low concentrations; but at higher concentrations, it has a sharp, acidic odor. It is a physiologically important gas produced by the body as a result of cellular metabolism. Carbon dioxide's main mode of action is as an asphyxiate, although it also exerts toxic effects at the cellular level. Low concentrations up to 1% (10,000 parts per million (ppm)) CO₂ have little toxicological effects. However, exposure to 2% concentration for several hours can produce headache, increase in blood pressure, and deep respiration, and exposure to 9–10% CO₂ can cause unconsciousness in about 5 min (Patnaik, 1999).

It is widely used in carbonation of beverages, in fire extinguishers, in the manufacture of carbonates, as dry ice for refrigeration, and as a propellant for aerosols. It is a normal constituent of the atmosphere and occurs naturally at a concentration of approximately 0.03% by volume. It is part of the carbon cycle known as photosynthesis and is used by

plants, algae, and cyanobacteria which absorb CO₂, light, and water to produce energy for themselves and oxygen as a waste product. It is also produced by the combustion of coal, in the fermentation of liquids, and during exhalation in animals. It is expelled into the atmosphere via springs, wells, and volcanoes. In the atmosphere, it acts as a greenhouse gas and is a source of ocean acidification, dissolving in water to form carbonic acid.

PHYSICAL AND CHEMICAL PROPERTIES

Carbon dioxide (carbonic acid gas, carbonic anhydride, carbonic oxide, dry ice (solid phase); CO₂; CASRN 124-38-9) has a density of 1.527 (air = 1), freezes at -78.5 °C, is soluble in water at 20 °C, is less soluble in alcohol and ether, and is absorbed by alkalis to form carbonates.

MAMMALIAN TOXICOLOGY

Acute Effects

There are no obvious symptoms of toxicity if the CO₂ concentration is below 3%. Carbon dioxide concentrations above 3% for a 30-min exposure can cause dyspnea and an acute headache caused by CO₂-induced vasodilation of meningeal vessels or CO₂-induced acidosis. Hearing and vision impairments may occur within several minutes of 6% CO₂ exposure. With higher concentrations of 15–20% CO₂ in inspired air, respiratory distress is rapid, causing loss of consciousness and spasms of muscle twitching, even if sufficient oxygen is present to prevent hypoxia (Johnston, 1959). A total of 20–30% CO₂ in inspired air causes

convulsions within 1–3 min after the onset of exposure, with death occurring after severe acidosis (Marquardt et al., 1999).

Studies of health effects of high levels of CO₂ have made CO₂ poisoning accidents a rare event. However, in earlier years, there were CO₂ poisoning events that occurred. Troisi (1957) reported deaths among workers who entered silos containing green fodder. Another case of CO₂ poisoning was reported by Lillevik and Geddes (1943), where a man was asphyxiated by a 10-min exposure to CO₂ in a grain elevator where 4700 bushels of flaxseed had been stored for 58 days. The man was rescued at once and promptly treated with oxygen inhalation but died within 48 h. The air just over the flaxseed bin had an oxygen content of 1.8% and a CO₂ content of 11.1%; within the bin, the oxygen content was 0.4% and the CO₂ content, 12.6%. Bacteria and saprophytic fungi were believed to be responsible for the abnormally high respiratory activity of the flaxseed. Residues in brewery vats have caused cases of fatal poisoning in the United States and in England; the manufacture of compressed yeast caused six cases of poisoning in a German factory, as reported by Brezina (Hamilton and Hardy, 1949).

Carbon dioxide poisoning also has been reported aboard ships. Dalgaard et al. (1972) reviewed literature dealing with cases of unconsciousness and death in the holds of industrial fishing ships containing trash fish and fish meal. High CO₂ levels (up to 22%) and low O₂ concentrations were blamed although hydrogen sulfide (H₂S) may also have been a factor. In 1958 Williams described a fatal incident aboard a ship with a cargo of onions and crude brown sugar (Williams, 1958). The two dead men had cyanosis of the oral mucosa and nail beds and markedly congested conjunctivae. All those who survived had headache, giddiness, tinnitus, and weakness, signs and symptoms considered consistent with CO₂ poisoning. Another incident involved removal of the cargo from the wrecked liner *Celtic*, which lay for a year at the entrance to Cork Harbor, fastened to the rocks, so that it could not be floated off. While working in one of the holds, 19 men were overcome by poisonous fumes and four died. Since the fumes apparently were generated by rotting apples, it was determined that the gas was carbon dioxide. Similar accidents have been reported when dry ice has been used in large quantities as a refrigerant. An additional hazard of dry ice or carbon dioxide snow is injury to the skin from improper handling.

Medical uses of carbon dioxide have been known to cause CO₂ toxicity as an unusual complication. Carbon dioxide is used during laparoscopic procedures in the abdominal cavity to allow visualization of the peritoneal cavity. A case was reported of a patient with delayed CO₂ elimination that led to signs of toxicity (Rittenmeyer, 1994).

A natural disaster in 1986 emphasized the toxicity of carbon dioxide in high concentrations. A massive release of CO₂ from Lake Nyos, Cameroon, a volcanic crater, killed 1700 people and injured 845. Clinical findings were

compatible with an asphyxiant rather than an irritant gas cause. Both survivors and the dead exhibited cutaneous erythema and bullae, which were likely to have occurred secondary to a prolonged coma state resulting from exposure to high levels of CO₂. Survivors also experienced headache, weakness, malaise, limb swelling, and cough (Baxter et al., 1989).

Several studies have been conducted to measure occupational exposure to air pollutants from motor vehicle exhaust, and carbon dioxide has been studied as one of the components of motor vehicle exhaust. In a study of 40 sites visited, Groves and Cain (2000), using personal and background exposure data, found that the principal gaseous components of diesel engine exhaust are CO₂, CO, and NO_x. None of the measurements for CO₂, CO, and NO_x exceeded the UK 8-h time-weighted average (TWA) occupational exposure limits of 5000 ppm CO₂, 50 ppm CO, or 3 ppm NO_x. The measurement of CO₂ may not represent exposure to diesel exhaust as a whole, but it may be an indication of the overall adequacy of control measures. An occupational exposure study by Wheatley and Sadhra (2004) measured nine diesel distribution depots engaged in the supply of drinks to the licensed trade. No smoking was allowed at any of the depots, thereby eliminating confounding sources of pollutants of interest. Personal sampling over 7–10 h measured levels of respirable dust, elemental and organic carbon, PAHs, ultrafine particles, and CO₂ and CO. Current guidance in the UK is that diesel exhaust fumes adverse health effects are unlikely if exposure to CO₂ emissions is less than 1000 ppm. Most levels of CO₂ measured at the nine depots were below 600 ppm. These studies have shown that the role of various diesel exhaust fractions in causing ill health is not yet clear.

Chronic Effects

Chronic poisoning is improbable under most conditions. Prolonged exposure to excessive concentrations is most likely in sealed quarters, such as submarines and spacecraft. Respiratory acclimatization to 3% carbon dioxide has been demonstrated by several investigators (Schaefer, 1963). Schaefer (1961) pointed out that although the health of submarine personnel exposed continually to 3% CO₂ was only slightly affected if the oxygen content of the air was maintained at a normal level, more studies in the U.S. Navy established the need to keep CO₂ concentrations below 1% for conditions of continuous, prolonged exposure. Impairment of performance was noted during prolonged exposure to 3% carbon dioxide even when the oxygen concentration was 21%. Prolonged exposure to 1.5% CO₂ resulted in respiratory acidosis that was not compensated until after the 24th day (Schaefer et al., 1963). Gibbons (1977) reviewed reports that show that actual or potential CO₂ poisoning from the use of carbon dioxide fire extinguishers, and significant loads of dry ice aboard pressurized aircraft

could have serious consequences but that small amounts of dry ice in unpressurized planes probably were safe. Similar hazards could be associated with the use of CO₂ fire extinguishers aboard planes. Sevel and Freedman (1967) described cerebral and retinal degeneration in a patient who was in coma for 11 months after asphyxiation in a wellhead chamber during the dismantling of an artesian well in Central London. Earlier, these researchers had described neurological and ocular changes in two patients who survived CO₂ asphyxia in a similar incident (Freedman and Sevel, 1966). Specifically, they reported headache, photophobia, abnormalities of eye movements, constriction of peripheral visual fields, enlargement of blind spots, deficient dark adaptation, and personality changes, largely depression and irritability.

INDUSTRIAL HYGIENE

Carbon dioxide is mainly produced as an unrefined side product of the burning of fossil fuels, in the production of hydrogen by steam reforming, in ammonia synthesis, and fermentation. It is one of the gases found in mines, natural gas wells, silos, the holds of industrial fishing ships, and vats where fermentation has occurred. Miners traditionally have tested the air in shafts with candles that are extinguished when the oxygen level falls to 18% or the carbon dioxide level rises to 8–10%.

It is produced commercially in one of several ways. The combustion of all carbon-containing fuels will yield carbon dioxide, and in most cases, water. In the production of quicklime (CaO), limestone is heated at about 850°C to produce CaO and CO₂. Iron is reduced with coke in a blast furnace to produce pig iron and CO₂. Yeast metabolizes sugar to produce ethanol and CO₂ in the production of beer, wine, and bioethanol. Finally, all aerobic organisms produce CO₂ in the oxidation of carbohydrates, fatty acids, and proteins.

It is widely used in industry and research laboratories. It is typically stored in cylinders and tanks under pressure but can also be stored at low temperatures in a solid form (dry ice). Dry ice is often used in the wine-making process to cool down bunches of grapes after picking to prevent spontaneous fermentation by wild yeast. Gaseous CO₂ is used in the textile, leather, and paint industries and in the manufacture of drugs. Because it is relatively inert, CO₂ is used in fire extinguishers, as an aerosol propellant, and as a pressure medium in food preservation, in pressurized gas systems, in portable pressure tools, and in purging pipelines and tanks. It is widely used in the production of carbonated soft drinks and soda water. The agricultural industry adds CO₂ to the atmosphere of greenhouses to sustain and increase plant growth.

The quality of indoor air has been a public health issue for over 30 years. Widespread reports of fatigue, headache, and mucous membrane complaints led to a syndrome designated as

the sick building syndrome, a phenomenon of sealed buildings and poor ventilation. No single contaminant has been identified as responsible for the syndrome, but a CO₂ level below 0.1% (100 ppm) is the criterion for adequate ventilation (Mendell and Smith, 1990; NIOSH, 1994).

To protect the health of workers, the current tolerance limit is 0.5% of CO₂ for an 8-hr daily exposure. The National Institute for Occupational Safety and Health (NIOSH) has recommended a limit of 1% by volume, determined as a TWA concentration, for up to a 10-h work shift in a 40-h workweek, with a ceiling concentration of 3% by volume for a sampling period not to exceed 10 min (NIOSH, 1994). For higher concentrations of CO₂, respiratory protection is satisfactory only with a self-contained air supply respirator or a hose mask with a blower. The American Conference of Governmental Industrial Hygienists (ACGIH) has set the threshold limit value at 5000 ppm and the short-term exposure limit at 30,000 ppm (ACGIH, 1996).

MEDICAL MANAGEMENT

The treatment of overexposure to CO₂ consists of removing the patient from the area, with care being taken to ensure that the rescuers are not overexposed. Immediate administration of oxygen and cardiopulmonary life support are the basics of emergency care. The best management, however, involves primary prevention, based on proper ventilation and worker education.

CARBON MONOXIDE

ERIN L. PULSTER AND JAMES V. HILLMAN

Target organ(s): Lungs, blood, central nervous system, cardiovascular system

Occupational exposure limits: OSHA PEL: 50 ppm (55 mg/m³) 8 h TWA, 200 ppm (229 mg/m³) STEL; ACGHI TLV: 25 ppm (29 mg/m³) TWA; NIOSH REL: 35 ppm (40 mg/m³), 200 ppm STEL; NIOSH IDLH: 1200 ppm

Risk/safety phrases: Flammable gas, incompatible and reactive with strong oxidizers, bromine trifluoride, chlorine trifluoride, lithium

BACKGROUND AND USES

Excluding carbon dioxide, carbon monoxide (CO) is considered as one of the most abundant and widely distributed air pollutants in the lower atmosphere (Jaffe, 1970). The formation of CO can be the result of both biogenic and anthropogenic sources. The dominant source of CO in the northern midlatitudes is believed to be from fossil fuel combustion while biomass burning, methane oxidation, biogenic non-methane hydrocarbons, and other volatile organic carbons are the dominant sources in the tropics (Duncan et al., 2007; Goldstein and Galbally, 2007; Logan et al., 1981). It has been estimated that CO in the atmosphere is produced at a rate of 5×10^{15} g by chemical oxidation, 25 times greater than from combustion sources and has a global average lifetime of approximately 2 months (Drori et al., 2012; Weinstock and Niki, 1972). Between 1988 and 1997, the overall estimated global budget for CO in the troposphere ranged between 305 and 350 Tg depending on the season (Duncan et al., 2007). The seasonal cycle and production of CO by methane

oxidation as well as the removal by carbon monoxide oxidation is associated with hydroxyl radicals (Weinstock and Niki, 1972; Drori et al., 2012). Biomass burning is widely believed to also contribute to the seasonal variations in carbon monoxide levels (Conway et al., 2002–2003). Oxidation of methane is the largest source of CO in the atmosphere and may produce 3 billion metric tons of CO annually in the northern hemisphere alone.

Tremendous amounts of carbon monoxide are released into the atmosphere as a result of human activities. In North America alone, the United States Environmental Protection Agency (USEPA) estimated a total carbon monoxide contribution of 89,170,000 short tons annually, of which 93% is due to anthropogenic sources and the remaining 7% is from biogenic sources (USEPA, 2013). Mobile emission sources account for 86% of the emission source sector (fuel combustion, industrial, fires, solvent, etc.) in the United States (USEPA, 2013) and between 55 and 60% of global man-made emissions of carbon monoxide. Between 1980 and 2012, the national U.S. average of atmospheric carbon monoxide was reduced by 83% (USEPA, 2013). This reduction has been aided by EPA regulations, for example, the installation of catalytic converters in all cars produced since 1975 as well as the 1992 addition of methyl tertiary-butyl ether to gasoline to improve its combustion properties and diminish CO emissions. The CO concentration of automobile exhaust, which once measured as high as 30%, typically is now <1.2%. Over the course of a decade (1988–1997), a slight decrease (2%) was observed in global emissions primarily due to the major North American and European declines being offset by the 51% increase in Asia as a result of rapid economic development (Duncan et al., 2007).

The sources of the carbon monoxide budget in the ocean is primarily from photochemical sources (42%), microbial sinks (27%) and microbial and gas exchange (32%) (Zafiriou et al., 2003). Early estimates suggest that a significant oceanic source of CO is generated by kelp, siphonophores (e.g., Portuguese Man of War; jellyfish), and deep-sea coelenterates (Jaffe, 1970; Chapman and Tocher, 1966; Pickwell, 1970). Other biogenic sources include volcanoes, forest and grass fires, marsh gases, electrical storms, terpene oxidation, and the destruction of chlorophyll in autumn. Endogenously produced carbon monoxide is through the normal catabolism of hemoglobin, which in the absence of environmental sources of CO accounts for a blood carboxyhemoglobin (COHb) level of about 0.4–0.7% in a healthy person.

Carbon monoxide emissions can also be produced from stationary sources (space heaters, water heaters, furnaces) and from industrial processes, coal mine explosions, and solid waste disposal procedures. Because most plastics contain carbon, CO is one of the primary gases generated by heating and burning plastics. Appreciable concentrations of CO can result from the pyrolysis of some vinyl plastics. Carbon monoxide plays a necessary part in the production of steel because it is used in the reduction process to take up oxygen. Additional anthropogenic sources of carbon monoxide include the manufacture of synthetic methanol and other organic compounds from CO, industrial and residential fires, charcoal burning, carbide manufacture, distillation of coal or wood, operations near furnaces and ovens, pyrolysis and oxidation of lubricants in air compressors, operation of snow-melting machines, testing of internal combustion engines, and indoor use of propane-powered machines such as forklifts, buffers, portable stoves, ice-resurfacing machines in indoor skating rinks, and internal combustion engines in general.

PHYSICAL AND CHEMICAL PROPERTIES

Carbon monoxide (CO; CASRN 630-08-0) is a nonirritating, odorless, colorless, tasteless gas with no warning properties. It has a vapor pressure >1 atm, and a vapor density of 0.968 (air = 1). Because it is only slightly less dense than air, it mixes readily without stratification. Carbon monoxide has a molecular weight of 28.01, a boiling point of -191.5°C , and a solubility in water of 27.6 mg/l at 25°C . Because of its low boiling point, carbon monoxide is shipped as a nonliquefied compressed gas. It is also known as carbon oxide, flue gas, and monoxide. Carbon monoxide is a flammable gas and is incompatible or reactive with strong oxidizers, such as bromine trifluoride, chlorine trifluoride, and lithium. Additional chemical and physical properties are presented in Table 43.1.

TABLE 43.1 Carbon Monoxide Chemical and Physical Properties

Characteristic	Properties
Chemical name	Carbon monoxide
Synonyms	Carbon oxide, oxocarbon, oxomethylene, carbonic oxide, flue gas, carbon(II) oxide
CASRN	630-08-0
Molecular formula	CO
Molecular weight	28.01 g/mol
Boiling point	-191.5°C (-312.7°F)
Melting point	-205°C (-337°F)
Vapor pressure	35 atm (26,600 mmHg)
Density	789 kg/m ³ liquid, 1.145 kg/m ³ at the rate 25°C , 1 atm
Ionization potential	14.01 eV
Solubility	27.6 mg/l (25°C) in water

MAMMALIAN TOXICOLOGY

Acute Effects

Toxic effects of CO are primarily caused by its ability to bind to heme, and alter the function and metabolism of proteins (Tian et al., 2013). More specifically, CO interferes with oxygen transport at the cellular level, possibly impairing normal cellular functions (Kealey, 2009; Hardy and Thom, 1994). Before considering the range of symptoms, which develop at various levels of CO, it must be understood that consciousness can be lost with few symptoms if the concentration of CO is high. It is also important to note that high concentrations may be rapidly fatal without producing significant warning symptoms (OSHA, 1978). Symptoms depend on the level and duration of exposure, as well as the overall health status and condition of the victim. Initial symptoms are very nonspecific and may be mistaken for flu-like symptoms, especially in children (Little, 1995). In order of increasing severity, the most commonly reported signs and symptoms are frontal headache, temporal headache, severe headache, roaring in the ears, weakness, dizziness, darkened vision, sleepiness, muscular weakness and incoordination, prolonged reaction time, impaired judgment, collapse, increased pulse and respiration, unconsciousness, involuntary evacuation, muscle contractions, coma, intermittent convulsions, cardiorespiratory depression, and death. As the level of absorbed CO rises, weakness and confusion increases and the victim may become indifferent to the danger and soothed to drowsiness. The majority of CO toxicity victims recover completely.

Acute poisoning has the potential for serious injury to major organs, brain, heart, kidney and muscles, yet it is not believed to accumulate. Tissue accumulation of CO was investigated in rats after acute exposures of CO air concentrations of 1, 0.4, and 0.12% for 4 min, 40 min, and 12 h,

respectively (Sokal et al., 1984). After acute intoxication, CO levels did not appear to accumulate in either the heart or skeletal muscles and elimination of CO from the brain was similar to that of blood. Moreover, all the rats exposed for 4 min at 1% and 40 min at 0.4% were unconscious and did not survive higher CO concentrations.

Pulmonary edema is commonly found in victims who die as a result of acute exposure. Aspiration pneumonia, the result of potential vomiting while the victim is unconscious, is also often seen. Ischemia or infarction of brain and cardiac cells can occur, especially if underlying disease is a factor. The effects of CO exposure are the result of the tissue hypoxemia. This can also occur in skeletal and renal tissue producing rhabdomyolysis, compounding potential renal failure. Furthermore, a number of reports have described the delayed neuropsychiatric syndrome (DNS) or the delayed postanoxic encephalopathy (DPE), estimated to occur in 10–30% of CO toxicity victims from acute CO poisoning (Sawa et al., 1981; Choi, 1983; Min, 1986; Hart et al., 1988; Seger and Welch, 1994; Ernst and Zibrak, 1998; Kwon et al., 2004). Neurological complications have been reported to appear between 3 and 240 days after exposure, and 50–75% of the patients have had a full recovery within a year of onset. Symptoms include cognitive and personality changes, incontinence, dementia, psychosis, depression, concentration difficulties, and Parkinsonian movement. The mechanisms are not well understood, although theories include hypoxia, postischemic reperfusion injury, vascular endothelium effects and oxygen radical-mediated brain lipid peroxygination (Thom, 1993).

Chronic Effects

Well-informed observers and research workers throughout the world have differing opinions as to whether chronic carbon monoxide poisoning exists. Some believe that chronic effects actually are the result of a slow accumulation of daily damage, which results in pathological change. Much more than in acute poisoning, confounding factors such as cigarette smoking, outdoor air pollution, and endogenous production of CO make the study of effects of chronic low level exposure particularly challenging. It is further complicated by the paucity of objective signs that can help the physician make the diagnosis unless an abnormal level of COHb can be detected in the blood.

Symptoms of chronic CO effects that are most commonly reported and observed include headache, irritability, insomnia, and personality disturbances (Table 43.2). Time-interval discrimination, vigilance, tracking, and the ability to drive a vehicle also are reported to be impaired. These manifestations are related to the effects of hypoxia on the nervous system. Lesions of the basal ganglia have been observed in both humans and experimental animals after CO exposure. Additional effects include an increase in the hematocrit, a

TABLE 43.2 Signs and Symptoms of Carbon Monoxide [CO] Exposure

Inhaled CO Concentration		
Percent	ppm	Symptoms
0.02	200	Possible mild frontal headache in 2–3 h
0.04	400	Frontal headache and nausea after 1–2 h, occipital headache after 2–3 h
0.08	800	Headache, dizziness, and nausea in 45 min, with collapse and possibly unconsciousness in 2 h
0.16	1600	Headache, dizziness, and nausea in 20 min; collapse, unconsciousness, and possibly death in 2 h
0.32	3200	Headache and dizziness in 5–10 min; unconsciousness and danger of death in 30 min
0.64	6400	Headache and dizziness in 1–2 min; unconsciousness and danger of death in 10–15 min
1.28	12,800	Immediate effect; unconsciousness and danger of death in 1–3 min

decrease in exercise tolerance, and fetal changes in pregnant women. Exposure to low levels of CO can provoke transient ischemic attacks, strokes, angina, and myocardial infarctions in workers with underlying cardiovascular or cerebrovascular disease. Carbon monoxide also may be atherogenic.

In addition to the effects that may be associated with chronic low level exposure, chronic sequelae can be seen after high level, acute exposure that causes unconsciousness and hypoxia or anoxia. Elimination of CO does not always halt the changes that have been initiated in cells, especially in those of the central nervous system, which may proceed to profound degeneration with late and progressive neuropsychiatric syndromes, motor and sensory involvement, vision loss, cardiac disturbances, or hemorrhage from a sudden rise in blood pressure.

Mechanism of Action(s)

Major endogenous sources of carbon monoxide are produced in small amounts from the natural break down of heme, resulting in normal background levels of COHb (Laing, 2010). Normal CO levels for nonsmokers are typically <2%, while the range for smokers is between 5 and 13% (Prockop and Chichkova, 2007). Endogenously produced CO is believed to have significant protective effects on intracellular signaling processes, including inflammation, proliferation, and apoptosis (Prockop and Chichkova, 2007; Ryter et al., 2006). The few mechanisms most commonly described with the endogenous production of CO include the modulation of mitogen-activated protein

kinase (MAPK) activation and the stimulation of calcium-dependent potassium channel activity (Ryter et al., 2006). Because endogenously produced CO has essential physiological functions and is vital to cellular hemostasis, there is increased research investigating the potential therapeutic use of administering low doses of CO (Schmidt et al., 2012).

The main exposure route for exogenous carbon monoxide is inhalation, although dermal absorption and eye contact are plausible. The most widely accepted theory for CO toxicity is due to hypoxia as a result of hypoxemia from COHb formation (Gorman et al., 2003). Carbon monoxide's affinity for hemoglobin is 210–240 times greater than that of oxygen, allowing CO to rapidly bind to hemoglobin thereby displacing oxygen. As the CO exposure increases, the level of CO attached to the blood (COHb) also increases. This interferes with the dissociation of the remaining oxyhemoglobin, thereby reducing the red blood cell's ability to transport oxygen, shifting the oxyhemoglobin dissociation curve to the left. Tissues that consume large amounts of oxygen are particularly susceptible to CO-induced effects. The brain and the heart are the most susceptible to CO toxicity due to their high metabolic rate (Prockop and Chichkova, 2007). Intracellular CO binds with cytochromes of the mitochondria, interrupting normal cellular functions, and ultimately stopping the production of adenosine triphosphate (ATP). Without ATP, aerobic metabolism converts to anaerobic metabolism producing lactic acid, which results in cellular death. If this process is not reversed, it can lead to organ failure and death. Cardiac ischemia, reduction in myocardial contractility, and decreased cardiac output is believed to be caused from CO binding to intracellular myoglobin in cardiac tissues, impairing the oxygen supply to the mitochondria, and consequently the energy source for the heart muscle (Prockop and Chichkova, 2007).

SOURCES OF EXPOSURE

Occupational

Carbon monoxide is primarily the result of incomplete combustion; therefore, exposure is a particular risk for occupations that release CO during such processes. Occupations with the highest risk include acetylene workers, blast furnace workers, boiler room workers, brewery workers, carbon black makers, coke oven workers, customs workers, diesel engine operators, dockworkers, garage mechanics, metal oxide reducers, miners, organic chemical synthesizers, petroleum refinery workers, pulp and paper workers, steel-workers, tollbooth and tunnel attendants, and warehouse workers. However, recent studies suggest welding practices can also generate CO at rates ranging from 386 to 1293 ml/min, depending on equipment configurations (Ojima, 2013).

A study in Washington state, analyzing occupational claims over a 6-year time period, determined that the construction industry (20%), wholesale trade (15%), and agricultural industries (12%) were the major industries responsible for the majority of the incidences (Reeb-Whitaker et al., 2010). Of all the incidents, fuel-powered forklifts and autos/trucks/buses were responsible for 29% and 26% of the cases reported, respectively. Another possible route of exposure to carbon monoxide is metabolism of absorbed methylene chloride (dichloromethane, CH_2Cl_2), a principal ingredient of many paint strippers. Methylene chloride is absorbed through the lungs and converted into CO in the liver after entering circulation (Varon et al., 1999). Barrowcliff and Knell (1979) reported a case of serious cerebral deterioration in a middle-aged man who had used methylene chloride as a solvent for 3 years in a road material laboratory. They suggested the possibility of an immediate risk of anoxia arising from carboxyhemoglobinemia and of a long-term hazard of chronic CO toxicity affecting the brain. Cases of acute myocardial ischemia and infarction related to the use of methylene chloride in poorly ventilated areas have been documented.

Environmental

Carbon monoxide is found in combustion fumes as the result of vehicle emissions, gas appliances, such as stoves, lanterns, and the burning of charcoal or wood. If these fumes are allowed to accumulate in enclosed or semi-enclosed spaces, it can cause sudden illness and even death. Accidental poisonings from these types of sources are preventable with the correct ventilation, installation, and usage. Unintentional, non-fire related poisonings are the leading cause of poisonings in the United States (Iqbal et al., 2012). Accidental exposures tend to be seasonal, with higher incidences occurring during winter months as a result of an increased use of space heaters, furnaces, and alternative energy sources. Exposure to CO results in nearly 440 deaths, more than 2000 hospitalizations, and >20,000 emergency room visits annually (Iqbal et al., 2012). Nonfatal exposures were found to be more common among children and females, whereas hospitalization and fatalities were higher among males and adults over 65 years of age. Hospitalization rates for unintentional, non-fire related, poisonings decreased by approximately 50% between 1993 and 2007. Decreases have been correlated to the increased number of homes with working CO monitors, and the reduction of CO content in vehicle emissions with the introduction of catalytic converters (Iqbal et al., 2012; Hampson, 2005).

Although tobacco smoking contributes negligible amounts of carbon monoxide to the air, cigarette smokers are the most heavily exposed nonindustrial portion of the population, and this exposure obviously affects industrial workers as well. The CO concentration of cigarette smoke is 10,000–40,000 parts per million (ppm). During the smoking process, CO is diluted with air to the extent that alveolar CO concentrations average

400–500 ppm (Klus and Kuhn, 1982). There also have been reports of carbon monoxide exposure in surgical patients given general anesthesia. Lentz (1995) provides supporting evidence of an interaction of halogenated volatile anesthetics and carbon dioxide absorbent in the breathing circuit, especially if an anesthesia machine had been unused for a period of time.

INDUSTRIAL HYGIENE

Carbon monoxide is considered as the oldest of the industrial hazards, because it must have attacked the first people who used heat to break stone for implements or who burned wood with little air to make charcoal. Today, almost any industrial item produced involves the use of fire, oxidation, or combustion at some point during its manufacture. Carbon monoxide poisoning is now the most common of all poisonings in industry and is responsible for more than half of the poisoning fatalities reported each year in the United States. It is a leading agent of lethal inhalation in the United States. The danger of CO lies in its ubiquity and lack of warning properties. In addition, early symptoms can resemble other common disorders, such as the onset of a cold or stomach flu. Carbon monoxide poisoning remains a serious public health problem, and everyone in modern society is at risk (Cobb and Etzel, 1991).

To protect the health of workers, the Occupational Safety and Health Administration (OSHA) has set a permissible exposure limit (PEL) for CO of 50 ppm, or 55 mg/m³ (8-h time-weighted average [TWA]) and a ceiling limit of 200 ppm, or 229 mg/m³ (15-min TWA) (OSHA, 1978). Exposure to 1200 ppm or more is considered Immediately Dangerous to Life and Health (IDLH). The National Institute for Occupational Safety and Health (NIOSH) has set the recommended exposure limit (REL) at 35 ppm (40 mg/m³) with a ceiling limit of 200 ppm (NIOSH, 1994). The American Conference of Governmental Industrial Hygienists (ACGIH) has recommended a threshold limit value (TLV)–TWA of 25 ppm, or 29 mg/m³ (ACGIH, 1995). Of course, the OSHA-mandated Hazard Communication Standard requires employers to educate workers about any occupational hazard created by CO. The use of carbon monoxide detectors has been increasing, which adds a margin of safety in many situations.

It is a good industrial hygiene to use engineering controls, whenever they are available, to reduce environmental CO concentrations to the lowest level possible. However, when engineering and work practice controls are not technically feasible, respirators may be required to protect the workers' health. If respirators are required, the proper type must be used and a complete respiratory protection program must be instituted that includes regular training, maintenance, inspection, cleaning, and evaluation. Employees should be

provided with impervious clothing that would prevent the skin from freezing upon contact with liquid CO or its canisters. Safety goggles should be provided if there is a reasonable possibility of liquid carbon monoxide being splashed into the eyes. Finally, any clothing wet with liquid CO should be removed immediately because of its flammable nature.

MEDICAL MANAGEMENT

Occupational Safety and Health Administration recommends workers who have inhaled large volumes of carbon monoxide be moved to fresh air immediately. If an exposed worker is found unconscious, they should be moved to fresh air immediately and established emergency procedures should be followed.

Victims of a suspected carbon monoxide poisoning should be given 100% oxygen immediately while blood tests to assess the COHb levels are pending. In addition to measuring COHb, complete blood chemistries, cardiac biomarkers, basic chemistries, ethanol and toxicology screens, and a urinalysis are needed (Laing, 2010). Pulse oximetry is not highly recommended, as it can over estimate arterial oxygenation; in contrast, spectrophotometric blood gas analysis is the best method to measure COHb levels (Rosenthal, 2006). Normal CO levels for nonsmokers are typically <2% while the range for smokers is between 5 and 13% (Prockop and Chichkova, 2007). Carboxyhemoglobin levels exceeding 70% are typically associated with cardio-pulmonary arrest.

Hyperbaric oxygen is required for pregnant women, regardless of COHb levels and may also be required for victims of severe poisoning. The biological half-life ($T_{1/2}$) of CO varies with minute ventilation, cardiac output, and the concentration of oxygen inhaled. Generally, the $T_{1/2}$ is approximately 4–5 h at room air, 60–90 min at 100% oxygen, and <25 min in hyperbaric oxygen at 2 atm. Unconsciousness or increased respiratory distress would require intubation and mechanical ventilation. Patients receiving oxygen should be consigned to bed rest and monitored closely. In severe poisoning events, serum pH levels should be monitored closely to evaluate for lactic acidosis. High risk patients for cardiovascular complications may require electrocardiography, echocardiography, and additional blood work to assess cardiac health. Patients displaying cognitive dysfunction may require a CAT scan or MRI. In addition, improved emergency department neurological and cognitive dysfunction can be assessed using the carbon monoxide neuropsychological screening battery (CONSB), a tool consisting of six exercises to specifically assess cerebral impairment from CO poisoning (Messier and Myers, 1991). It has been suggested that hyperbaric oxygen treatment may prevent delayed brain injuries (Gorman et al., 2003).

CARBON DISULFIDE

DEBRA J. PRICE

Target organ(s): Eyes, nerves, liver, kidney, heart, cardiovascular system, male reproductive system, female reproductive system

Occupational exposure limits: OSHA: PEL—20 ppm, STEL—10 ppm TWA; NIOSH: REL—1 ppm, STEL—10 ppm TWA, Immediately Dangerous to Life or Health (IDLH)—500 ppm; ACGIH: TWV—10 ppm TWA

Reference values: RfD (oral) 0.1 mg/kg/day; RfC (inhalation) 0.7 mg/m³

Risk/safety phrases: NIOSH and the ACGIH also assign a “Skin” notation, which indicates that the cutaneous route of exposure, including mucous membranes and eyes, contributes to overall exposure

BACKGROUND AND USES

Carbon disulfide is used as a raw material in the production of such things as rayon, cellophane, semiconductors, and carbon tetrachloride, and to make some pesticides. It is used as an industrial solvent and chemical intermediate to dissolve rubber to produce tires (ATSDR, 1996), as well as in grain fumigation, analytical chemistry research, degreasing, dry cleaning, and oil extraction (Finkel et al., 1983). Natural sources of carbon disulfide include the open ocean, coastal areas of high biological activity, microbial reduction of sulfates in soil, marshlands, and some higher plants where the source of carbon disulfide is the tree roots (Carroll, 1985; Khalil and Rasmussen, 1984).

Previously, carbon disulfide was used as a pesticide, where it was typically mixed with carbon tetrachloride in a 20/80 mixture, respectively. This mixture was used to

exterminate insects and rodents from entire boxcars of wheat, corn, rye, and other grains (Peters et al., 1988). Grain fumigators can be acutely intoxicated and may be chronically exposed to carbon disulfide. Therefore, in the late 1980s, all pesticides containing carbon disulfide as an active ingredient were cancelled by the United States Environmental Protection Agency (U.S. EPA) (U.S. EPA, 1999).

PHYSICAL AND CHEMICAL PROPERTIES

Carbon disulfide (carbon bisulfide; CS₂; CASRN 75-15-0), in its pure form is a colorless liquid that evaporates readily at room temperature, with a sweet aromatic odor similar to that of chloroform. In its impure commercial and reagent form, however, carbon disulfide is a yellowish liquid with a foul-smelling odor. It has a vapor pressure of 297 mmHg and solubility in water by weight of 0.3% at 20 °C (68 °F). Once carbon disulfide is in the air it will break down into simpler substances within a few days after release (OEHHA, 2001).

Acute Effects

Although acute exposure is rare, acute effects can range from mild irritation to death and include the following: (1) mild to moderate irritation of skin, eyes, and mucous membranes from liquid or concentrated vapors; (2) headache; (3) garlicky breath, nausea, vomiting, and diarrhea; (4) weak pulse and palpitations; (5) fatigue, weakness in the legs, unsteady gait, and vertigo; (6) hyperesthesia, agitation, mania, hallucinations of sight, hearing, taste, and smell in acute, massive exposures; (7) central nervous system depression with

respiratory paralysis; and (8) death may occur during coma or after a convulsion (Gosselin et al., 1984).

Typically the acute effects mentioned above are via inhalation and dermal contact; however, there are a few documented cases of carbon disulfide ingestion. These individuals had spasmodic tremors, Cheyne–Stokes respirations, large pupils, low body temperature, pallor and, finally, coma and death (Foreman, 1886).

Chronic Effects

Neurological Effects The most widely known and extensively studied aspect of carbon disulfide toxicity is its neurological effects, which were first noted by the French in the mid-1800s (Hamilton, 1937). Auguste Delpech, a physician in Paris, conducted a thorough study of the effects of carbon disulfide exposure between 1856 and 1863. His research involved the study of more than 100 chronically exposed patients and some animal experiments. He described in detail the “carbon disulfide neurosis,” a disorder characterized by an early stage of excitation followed by a second stage of depression. Delpech’s observations were accurate, but it took almost a century for the details of carbon disulfide poisoning to spread throughout Europe and England and finally to the United States (Davidson and Feinleib, 1972).

It is now accepted that excessive exposure to carbon disulfide causes extensive neurological problems. One study by Aaserud et al. (1990) investigated the neurological symptoms of 24 men formerly and currently employed in the manufacture of viscose rayon. When clinical neurological examinations were performed with the 16 subjects still employed in rayon production, only one was considered normal. Nine had minor neurological deficits. Six had facial palsy, reduced tempo or coordination, asymmetrical reflexes, or a positive Romberg’s test. Half of the workers with reflex abnormalities also had distal hyporeflexia.

Peters et al. (1988) investigated the neurological effects of carbon disulfide fumigants in granary workers. They found that 50–80% exhibited a range of symptoms, including cogwheel rigidity, decreased associated movements, distal sensory shading, intention and resting tremulousness, and conduction abnormalities.

Neurological damage caused by chronic carbon disulfide poisoning also is responsible for hearing loss among workers. Experiments have demonstrated that high frequency hearing is most impaired (Zenk, 1970). Some studies have suggested a synergistic or additive ototraumatic interaction between carbon disulfide and noise-induced hearing loss (Morata and Dunn, 1994). Study of brainstem auditory-evoked responses demonstrated that carbon disulfide has an effect on the auditory pathways in the brainstem (Hirata et al., 1992a, 1992b).

Because of the neurotoxicity of carbon disulfide, the exposure can have dramatic effects on a worker’s personality. Patients and family members often complain of emotional

upset, depression, irritability, sleeplessness, fatigue, and loss of memory. Many of the victims of carbon disulfide poisoning in the 1800s and early 1900s were confined to mental hospitals with diagnoses such as “etiology occupational” or “unknown.” Mancuso and Locke (1972) found an association between exposure to carbon disulfide and an increase in the suicide rate.

Cardiovascular Effects The cardiovascular effects of carbon disulfide exposure were not recognized until long after its neurotoxicity had been established. The current prevalence of lower level exposure has increased awareness of chronic cardiovascular effects.

The first thorough study of ischemic heart disease (IHD) and carbon disulfide exposure was published by Tiller et al. (1968). Investigators found a relative risk of 5.6 for coronary deaths when rayon workers were compared with matched controls. Subsequent research has confirmed this association and clarified the mechanism by which carbon disulfide increases IHD mortality (Balcarova and Halík, 1991). Sweetnam et al. (1987) reported that the association between carbon disulfide exposure and IHD mortality was most pronounced when workers were heavily exposed in the preceding 2 years. A study by Prince et al. (2000) looked at mortality rates among rubber chemical manufacturing workers. They found that IHD mortality among the workers was elevated relative to IHD mortality in the US population, especially in the under 50 years of age category. A significant difference was also found between different age groups of rubber chemical manufacturing workers. The standard mortality rate (SMR) for IHD among all workers in the rubber chemicals department ranged from 1.2 to 1.5, and SMRs in the under 50 age group ranged from 1.9 to 2.5, a significant difference. This evidence suggested that carbon disulfide has a direct, reversible cardiotoxic effect.

A study by Egeland et al. (1992) investigated the low density lipoprotein concentration (LDL_c), and diastolic blood pressure of workers exposed to a carbon disulfide concentration of 0.6–11.8 parts per million (ppm). When the workers were ranked according to level of exposure, researchers found a direct, linear relationship between diastolic blood pressure and the level of exposure to carbon disulfide. A similar relationship was demonstrated for the LDL_c . Carbon disulfide exposure did not correlate with triglyceride, high density lipoprotein concentration (HDL_c), fasting glucose concentration, or systolic blood pressure. These findings are especially significant given the relatively low level of exposure and the potential these factors have for increasing the risk of IHD. Vanhoorne et al. (1992) also found a direct relationship between LDL_c and the level of carbon disulfide exposure, but they reported an inverse association with HDL_c . Krstev et al. (1992) reported an increase in triglyceride levels in highly exposed workers. The difference between these findings could be explained by the fact that workers classified as high

exposure in the Krstev study had exposure levels twice than that of the workers in the Egeland report. All of these studies support the conclusion that carbon disulfide has a direct, dose-related, reversible cardiotoxic effect.

Other Effects Although research has failed to find a strong association between carbon disulfide exposure and adverse male reproductive effects (Vanhorne et al., 1994); the same cannot be said for female exposure to carbon disulfide. In fact, women appear to be more sensitive than men to the neurotoxic effects of carbon disulfide (Gosselin et al., 1984). In one study, women employed in viscose rayon textile jobs had an increased rate of spontaneous abortions, and the wives of men employed in the same textile jobs also had increased rate of spontaneous abortions. No evidence was found, however, that the level of exposure was associated with the risk of spontaneous abortions (Hemminki and Niemi, 1982). In another study of female viscose rayon workers, CAI and BAO (1981) showed placental transfer of carbon disulfide and secretion into mother's milk. The umbilical blood from the female workers, the milk from breast-feeding workers, and the urine from the breast-fed babies all contained carbon disulfide.

Earlier research suggested that the renal toxicity of carbon disulfide is primarily associated with atherosclerosis and its effects on renal function (Browning, 1965). However, Rubin (1990) found that the kidneys of rats and mice were capable of carbon disulfide bioactivation and that this bioactivation was only partly responsible for the total nephrotoxic effect of carbon disulfide.

Effects on eye-sight have been documented prior to other symptoms, with an increase in eye sensitivity to light (Kirk, 1978) and the degeneration of the retina or hemorrhaging of blood vessels (ARD-EHP-11, 2006).

In one study, 350 fiber workers that were exposed to carbon disulfide were examined to determine if there were any alterations to their oral cavity. The group that was exposed for <5 years had significantly lower pH values for both the mucous membrane and the saliva compared to the control group (NIOSH, 1977).

Mechanisms of Action

Even though carbon disulfide is highly lipophilic and can be readily absorbed through the skin, it is not known to bioaccumulate in the body. This may be because most of the carbon disulfide taken into the body is quickly exhaled unchanged. Only about 0.05% of the carbon disulfide absorbed by an individual is excreted in the urine. The remaining absorbed portion not exhaled is metabolized (Bus, 1985; McKenna and DiStefano, 1977).

Carbon disulfide spontaneously reacts with free amine and sulfhydryl groups of amino acids and polypeptides. This reaction produces dithiocarbamates (from amine groups) and trithiocarbonates (from sulfhydryl groups), which may in part

account for the neurotoxic effects of carbon disulfide. Both of these metabolites are water soluble and may be excreted efficiently by the kidneys. In rats exposed to carbon disulfide, 90% of carbon disulfide found in the blood was in the form of AL CS₂ in red blood cells (RBCs) (Lam and DiStefano, 1986). The authors also found carbon disulfide bound to fractionated human RBCs in proportion to the amount of hemoglobin.

In rats exposed to carbon disulfide, blood levels increased dramatically and leveled off after 2 h, and then dropped quickly after exposure ceased (McKenna and DiStefano, 1977). Carbon disulfide was concentrated rapidly in fat and organs with high lipid content (e.g., the liver and adrenals). To a lesser extent, it is also collected in the kidneys, brain, muscles, and heart. The availability of free amino acids in these organs may enhance AL CS₂ formation. With the exception of fat and skeletal muscle, the rate of AL CS₂ formation in these organs is greater than the rate of elimination (McKenna and DiStefano, 1977). It is now recognized that neural responses to carbon disulfide are influenced by the mineral content of the animal's diet, where a high mineral content diet offers protection from neurologic effects (ACGIH, 1991). These data suggest that, at least in animals, bioaccumulation may occur with repeated exposure.

Chemical Pathophysiology

Peters et al. (1988) found evidence of central demyelination in cranial magnetic resonance imaging scans. This is consistent with the findings in animal studies that have demonstrated fragmentation and disruption of myelin sheaths in rats exposed to carbon disulfide (Dietzmann and Laass, 1977).

Wilmarth et al. (1993) showed that in rats exposed to carbon disulfide, protein phosphorylation in neurofilaments increased. This finding suggests a physiological route by which carbon disulfide may cause filament disassembly and diminish the transport rate in the axon. Ruijten et al. (1990) demonstrated that exposure to carbon disulfide affected the conduction velocity of slower motor fibers but not the motor nerve conduction velocity or sensory nerve conduction velocity. Graham et al. (1995) found that carbon disulfide causes neurofilament-filled swellings of the distal axon in both the central and peripheral nervous systems. Also, there have been case reports of axonal degeneration and loss of myelinated fibers in patients treated with disulfiram (Ansbacher et al. 1982).

Hoffmann and Klapperstück (1990) reported that carbon disulfide had a depressive effect on intra-cardiac impulse generation, conduction, and contractile force in urethane-anesthetized rats.

Vanhorne et al. (1993) found that viscose rayon workers exposed to carbon disulfide had significantly lower levels of prolactin. This indicates that carbon disulfide may have an effect on the endocrine system.

In rats, high doses of carbon disulfide have been reported to diminish hepatic cytochrome P-450 (P-450) and the activity of microsomal mixed function oxidase (Kivistö et al., 1995).

Research suggests that carbon disulfide may have a direct, toxic effect on human lymphocytes. Garry et al. (1990) found that exposure to carbon disulfide increased sister chromatid exchanges and chromosomal aberrations *in vitro*. S-9 liver fraction was required to produce these effects suggesting that metabolic activation was responsible for toxicity.

SOURCES OF EXPOSURE

Occupational

The toxicity of carbon disulfide first became apparent in the 1800s, when it was used for "cold" vulcanization of rubber throughout Europe. Cold vulcanization was never in common use in the United States, which partly accounts for the late recognition of the risks associated with carbon disulfide exposure.

Exposure to carbon disulfide is typically occupational via inhalation and dermal contact with the vapor, or dermal contact with the liquid. While workers engaged in any process that uses carbon disulfide have the potential for some degree of exposure, in practice, only workers in the viscose rayon industry are exposed to high concentrations (WHO, 1979). In a 3-year survey, National Institute for Occupational Safety and Health (NIOSH) statistically estimated that 44,441 workers, including 4882 females, were exposed to carbon disulfide in the United States (NOES Survey 1981–1983). The survey excludes trade names that may contain the chemical; therefore, exposure may be considerably higher than the survey results (NIOSH, 1985).

Although many industries use carbon disulfide, currently the largest user, and most common form of occupational exposure to this chemical is in the viscose rayon fiber industry in the technological process. For every kilogram of viscose rayon produced, about 20–30 g of carbon disulfide and 4–6 g of hydrogen sulfide are emitted (NIOSH, 1977). This process is used for more than 80% of the world's supply of rayon (artificial silk) and requires large amounts of carbon disulfide (Davidson and Feinleib, 1972).

The manufacturing of viscose rayon begins with sheets of cellulose pulp. The pulp is steeped in caustic soda and then broken into crumbs, which are aged further in a caustic soda solution. Next, the crumbs are churned with carbon disulfide, becoming a material known as xanthate crumb. The xanthate crumb is dissolved in caustic soda, and a solution is formed that resembles honey in appearance and consistency. After further aging and filtering, this viscose material is pumped into spinning tanks. The solution is forced through nozzles into a sulfuric acid bath, where it coagulates to form

filaments. During this step, hydrogen sulfide and carbon disulfide are liberated. Thousands of filaments are hardened simultaneously and guided into a spinning box, where yarn is collected. The yarn continues to release carbon disulfide and hydrogen sulfide gases for hours after removal from the spinning machine. The workers in the spinning rooms are at greatest risk of carbon disulfide exposure. They also constitute the largest group of potentially exposed workers. The churning process is another area of potentially high exposure. A study by Sweetnam et al. (1987) showed that the viscose workers in the spinning rooms have a significantly higher mortality than the least exposed group of workers, and that the excess mortality is largely accounted for by IHD.

Environmental

The general population may also be exposed to carbon disulfide via inhalation of ambient air or pharmaceuticals containing the chemical. Concerning ambient air, one study by Phillips (1992) suggested that urbanites may be constantly exposed to low levels of carbon disulfide. This low level, potentially lifelong exposure could have some of the chronic consequences, but more research is needed to determine whether this is the case.

Concerning pharmaceuticals, the drug disulfiram (Antabuse), which is used to treat alcoholism, and sodium diethyldithiocarbamate (ditiocarb, ditiocarb sodium), which is used in the treatment of patients infected with the human immunodeficiency virus (HIV), both are metabolized to carbon disulfide in the body. The blood level of carbon disulfide in patients treated with disulfiram averaged 9.5 µg/l compared with 0.26 µg/l in controls (Brugnone et al., 1992). The total concentration of carbon disulfide (free and blood bound) averaged 40 µg/l in patients and 0.9 µg/l in controls. For comparison purposes, Campbell et al. (1985) found that workers exposed to an average carbon disulfide level of 10 ppm had acid-labile (AL) blood levels of 332.6 µg/l. Martens et al. (1993) determined that Ditiocarb in aqueous solution at physiological pH and temperature decomposes to carbon disulfide. Chronic exposure to low levels of carbon disulfide can have serious consequences, especially to the nervous system and cardiovascular system. It is uncertain at this time whether the use of these pharmaceuticals poses a risk of carbon disulfide intoxication similar to a low level occupational exposure. However, physicians should be aware of this factor when prescribing Antabuse or ditiocarb for patients who may have been exposed to carbon disulfide.

INDUSTRIAL HYGIENE

To protect the health of workers, the Occupational Safety and Health Administration (OSHA) has set a permissible

exposure limit for carbon disulfide of 20 ppm, with a short-term exposure limit (STEL) of 10 ppm for 15 min (time-weighted average [TWA]). The OSHA has also set a 30-min maximum peak at 100 ppm. The standards set by the NIOSH are somewhat stricter, with a recommended exposure limit of 1 ppm and a STEL set at a TWA of 10 ppm for 15 min (NIOSH, 1994). The NIOSH considers a carbon disulfide level of 500 ppm to be immediately dangerous to life and health. The American Conference of Governmental Industrial Hygienists (ACGIH) has set the threshold limit value at a TWA of 10 ppm (ACGIH, 1996).

MEDICAL MANAGEMENT

Diagnosis and Treatment

Diagnosis of carbon disulfide should include a complete history and physical examination in order to detect existing conditions that might place the exposed employee at increased risk, and to establish a baseline for health monitoring. Signs and symptoms for carbon disulfide exposure include upper respiratory burning, cranial nerve palsies, double vision, dizziness, headache, sleeping problems, weakness, exhaustion, anxiety, gastritis, kidney and liver damage, skin and eye irritation, breathing difficulty, increased blood pressure, abdominal pain, nausea, vomiting, diarrhea, neuritis, psychosis, and tremor. Therefore, a complete physical examination should include the central and peripheral nervous systems, kidneys, liver profile, skin examination, eyes, urinalysis, and an electrocardiogram (NIOSH/OSHA, 1981). Evidence of excessive exposure to carbon disulfide combined with the above-mentioned health effects known to be produced by carbon disulfide would be an indication of intoxication.

Chapman et al. (1991) found that individuals exposed to carbon disulfide exhibited markedly different finger tremor amplitude compared with matched controls. The authors believe that this subclinical manifestation may serve as an early indication of carbon disulfide exposure.

There is no specific treatment to enhance the reversibility of the effects of carbon disulfide exposure. In acute situations the patient should be removed from the source of exposure immediately and decontaminated. Special attention should be paid to breathing and circulation. Symptomatic treatment may be given as necessary.

Biomonitoring

For biomonitoring of carbon disulfide, urine, blood, breath, and milk samples can be examined. For urine testing, the iodine-azide test has been available for testing exposure to carbon disulfide for several decades (Vasak et al., 1963). In this test, organosulfur metabolites in the urine, the result of

carbon disulfide exposure, are measured by the decolorization of iodine. This method is now considered ineffective because it cannot reliably measure levels of exposure below 15 ppm, levels which are typical of occupational exposures (van Doorn et al., 1981).

Currently, the most effective method for monitoring carbon disulfide exposure is testing the levels of 2-thio thiazolidine-4-carboxylic acid (TTCA) in urine (Campbell et al., 1985; Meuling et al., 1990). This method is extremely sensitive and can detect carbon disulfide exposure as low as 0.5 ppm (Riihimäki et al., 1992). The current biological exposure index is 5 mg TTCA/ creatinine (end of shift) (ACGIH, 1996).

Blood samples also can be used to determine exposure to carbon disulfide accurately, but they are less practical for routine biomonitoring (Campbell et al., 1985).

Breath samples provide an indication that exposure has occurred if measurements are taken shortly after possible exposure (Phillips, 1992). However, because carbon disulfide is eliminated so quickly through the lungs, these measurements are not an accurate reflection of the level of exposure.

Finally, milk samples may be useful as a qualitative indicator of exposure to carbon disulfide (Ryan and Terry, 1997).

45

HYDROGEN SULFIDE

STEPHEN C. HARBISON AND JACOB R. BOURGEOIS

First aid: Remove from exposure. Give fresh air. Immediately irrigate eyes, wash the skin with soap. Provide respiratory support. If frostbite has occurred, seek medical attention. If ingested by swallowing, seek immediate medical attention.

Target organs: Central nervous system, respiratory system (especially lungs), mucosal membranes, eyes.

Risk/safety phrases: Irritant gas; chemical asphyxiant; flammable. Liquid hydrogen sulfide can cause frostbite.

Exposure limits and threshold limit values for hydrogen sulfide:

	CASRN	PEL ¹ , ppm	REL, ppm	TLV-TWA, ppm	STEL, ppm	IDLH, ppm
Hydrogen sulfide (general industry)	7783-06-4	20 (ceiling) 50 (peak)	10 (10 min ceiling)	1	5	100
Hydrogen sulfide (construction)	7783-06-4	10 (TWA)				
Hydrogen sulfide (shipyard)	7783-06-4	10 (TWA)				

¹ Exposures must not exceed 20 ppm with the following exception: if no other measurable exposure occurs during the 8 h shift, exposures may exceed 20 ppm, but no more than 50 (peak), for a single time period up to 10 min. Source: www.osha.gov/STLC/hydrogensulfide/standards.html.

Chemical Abstract Service (CAS); permissible exposure limit (PEL), set by the Occupational Safety and Health Administration (OSHA); recommended exposure limit (REL), set by the National Institute for Occupational Safety and Health (NIOSH); threshold limit value (TLV), set by the American Conference of Governmental Industrial Hygienists (ACGIH); short-term exposure limit (STEL), set by the ACGIH; IDLH, immediately dangerous to life and health, set by the NIOSH; time-weighted average (TWA).

BACKGROUND AND USES

Hydrogen sulfide (H_2S) is a powerful chemical asphyxiant and irritant gas, which can result in loss of consciousness and sudden death when encountered at high concentrations. Its distinctive rotten egg odor earned it nicknames of swamp gas, sewer gas, and stink damp. Hydrogen sulfide is produced naturally as well as found in industrial settings where it is

used as a reactant or is the result of manufacturing or industrial processes. As a natural source, H_2S is one of the principal components in the sulfur cycle and is present in volcanic gases, sulfur springs, undersea vents, swamps, crude petroleum, and natural gas (Lancia et al., 2013). Hydrogen sulfide is also naturally produced from the decomposition of organic sulfur-containing matter and from the reduction of inorganic sulfides (Chen and Wang, 2012). Some scientists have speculated that the extinction of certain species during the planet's evolutionary history may have been due to the natural release of large amounts of built-up H_2S (Wang, 2012). It is recognized as one of the dangers in

gypsum, sulfur, and coal mining, since subterranean pools of water collect H_2S formed by the decomposition of iron pyrites.

Hydrogen sulfide is the second most common cause of fatal gas inhalation exposures in the workplace and casualties usually occur in more than one person as would-be rescuers rush to save their coworkers and in their haste neglect to use proper personal protective equipment (PPE) (Guidotti,

2010). It is frequently found in the following industrial settings as a by-product of an industrial process: tanneries, waste water treatment facilities, manure and sewage facilities, rayon manufacturing plants, sulfur producers, coke oven plants, Kraft paper mills, iron smelters, food processing plants, tar and asphalt manufacturing plants, petrochemical plants, and oil refineries (Guidotti, 2010). Ramazzini is generally considered the first notable physician to associate its presence with occupational risk through his observation of health changes in sewer workers (Wang, 2012).

PHYSICAL AND CHEMICAL PROPERTIES

Hydrogen sulfide is generally found as a pungent colorless flammable gas, although it is commonly shipped as liquefied compressed gas (NIOSH, 2011). Its characteristic odor of “rotten eggs” cannot be considered indicative of its concentration, as olfactory fatigue occurs quite rapidly, even at relatively low concentration levels (100–150 ppm). It has a vapor density of 1.19, which makes it heavier than air and will cause it to accumulate in low lying areas rather than disperse easily in air and thus can present a hazard for workers in basements, subterranean locations, and confined spaces. It is soluble in water to a maximum of 0.4% by mass at room temperature. The auto ignition temperature is 260 °C and the flammable limits in air, % by volume are 4.5 (lower) and 45.5 (upper). The tendency for belowground accumulation, coupled with its water solubility and flammability has proven to be a significant hazard for those who conduct work in underground tunnels or sewers (Adelson and Sunshine, 1966; Chen and Wang, 2012). Reactivity can occur from contact with strong oxidizers and oxidizing materials and result in fires and explosions. Hydrogen sulfide also attacks many metals resulting in the formation of sulfides and can lead to metal integrity issues.

MAMMALIAN TOXICOLOGY

Hydrogen sulfide is classified as both a chemical asphyxiant and irritant gas. Guidotti (2010) states that H₂S toxicity is one of the most unusual and reliable toxicodromes in medical toxicology and remains an important and frequently lethal occupational and environmental hazard.

Asphyxiation is the most frequent cause of death related to occupational exposure to H₂S, where it interferes with cytochrome oxidase and aerobic metabolism (Lancia et al., 2013). At high concentrations, H₂S acts as a chemical asphyxiant as it is a potent inhibitor of cytochrome oxidase. The inhibition interferes with cellular metabolism causing blockage of the proper utilization of oxygen by the cell, ultimately resulting in cytotoxic anoxia despite normal blood flow and oxygen content. At sufficiently high concentrations, these actions

may occur before the irritant (i.e., physiological warning) effects of H₂S have time to develop.

Postmortem examinations of fatalities indicate that the primary targets of H₂S poisonings appear to be the central nervous and respiratory systems. Distinctive changes such as a greenish discoloration of the brain, viscera and blood, coupled with pulmonary edema, petechia, and hepatic and visceral congestion are often seen on these postmortem examinations (Adelson and Sunshine, 1966; Arnold et al., 1985; Park et al., 2009).

Acute Effects

Acute H₂S poisoning may present with both irritant and asphyxiant effects. At low concentrations (50 ppm), it can cause local effects (irritative action), acting mainly on the mucous membranes of the airways, lungs, eyes, and digestive organs (Nogue et al., 2011). In tests on small animals, 50 ppm exposures were consistently associated with conjunctival irritation (Evans, 1967). Exposures in excess of 200 ppm are consistently associated with impairment to the respiratory system and mucosal membranes (Dorman et al., 2000; Snyder et al., 1995), although Chen and Wang (2012) noted that respiratory impairment symptoms have been noted in some studies using exposures as low as 10 ppm. Pulmonary edema is another acute effect of H₂S toxicity, because the gas has the ability to travel deep into the respiratory tract and cause alveolar injury especially when exposure is prolonged (Guidotti, 2010).

At higher concentrations, H₂S is a central nervous system depressant, particularly of the respiratory center, and inhibits cytochrome oxidase, preventing mitochondrial oxygen utilization and thereby blocking cellular respiration (Nogue et al., 2011). At sufficiently high concentrations, these actions may occur before the irritant effects of H₂S have time to develop. An example of this is a phenomenon known as “knockdown” which has been reported by oil field workers and described as a sudden, brief loss of consciousness associated with amnesia, followed by immediate full recovery (Doujaiji and Al-Tawfig, 2010). Traumatic injuries from falls have been reported as a result of the sudden loss of consciousness. Dorman et al. (2000) pointed out that the disruption of memory and motor functions, personality changes, and hallucinations that categorize the “knockdown” syndrome were also consistent with anoxia-induced effects of asphyxiants such as carbon monoxide. Significant respiratory tissue and function damage leading to unconsciousness can occur between 250 and 500 ppm, and exposures in excess of 700 are most frequently associated with respiratory arrest and cardiovascular failure and death (Dorman et al., 2000; Snyder et al., 1995). Table 45.1 presents health effects of H₂S at various approximate exposure levels.

Hydrogen sulfide is also transported under high pressure in a liquefied form. Exposure to liquefied H₂S can chill or freeze the skin causing frostbite.

TABLE 45.1 Exposure Concentrations and Health Effects from H₂S Exposures

Concentration, ppm	Health Effects
0.01–0.03	Odor threshold (highly variable)
1–5	Moderate offensive odor, may be associated with nausea, tearing of the eyes, or headaches
10	Anaerobic metabolism threshold during exercise
20	Odor very strong; conjunctivitis may occur
20–50	Conjunctivitis and lung irritation. Possible eye damage after several days of exposure; may cause digestive upset and loss of appetite
100	Eye and lung irritation; olfactory paralysis, odor disappears
150–200	Sense of smell paralyzed; severe eye and lung irritation
250–500	Pulmonary edema may occur, especially if prolonged
500	Serious damage to eyes within 30 min; severe lung irritation; “knockdown” and death within 4–8 h; amnesia for period of exposure
1000	Breathing may stop within one or two breaths; immediate collapse

Source: Guidotti (2010).

Chronic Effects

Although the negative effects of acute exposure to high concentrations of H₂S have been clearly identified, little information has been confirmed about the deleterious effects of chronic exposure to low level concentrations. Chronic exposures have been shown to affect olfactory senses, and may alter the threshold for odor detection or cause complete anosmia. In either case, the individual may be less able to detect the presence of the H₂S; however, recognition of odor does not necessarily correlate with existing concentrations and thus should not be relied upon as a means of ensuring worker safety.

Due to the targeting of the central nervous system and respiratory system in acute exposures, studies have been performed to evaluate potential health effects from chronic low dose exposure. Two studies have attempted to identify effects of low dose exposure to H₂S by exposing asthmatic subjects to 2 ppm and healthy exercising individuals to 5 ppm of H₂S for 30 min (Jappinen et al., 1990; Bhambhani et al., 1994). No respiratory or other adverse health effects were reported in either study. In a 2-year study of a New Zealand city situated among volcanic vents, Bates et al. (2013) found no significant increase in asthma risk among the residents continuously exposed to H₂S levels varying between 0 and 764 parts per billion (ppb) in ambient air. The study suggested that low level exposures (i.e., 20 ppb mean) could be associated with a reduction in symptoms of respiratory obstructive diseases (e.g., asthma), potentially due to the

induction of smooth muscle effects of H₂S. Inserra et al. (2004) performed a neurobehavioral study of residents of a city located in Nebraska who had been routinely exposed during the 1990s to ambient air levels of H₂S ranging from 100 to 5000 ppb. Other than the two tests (match to sample and a grip test) which had marginal differences, the remaining 26 tests showed no difference in exposed and nonexposed residents. In a laboratory exposure study, subjects exposed to H₂S as low as 0.05 ppm did report more increased anxiety related to ratings of irritation due to odor, but no cognition performance differences were observed in a dose-response association. There were indications of decreased word-learning retention; however, as performance increased with increasing ppm, it is possible that the odor may have been a distraction that faded with olfactory fatigue, not a physiological impediment (Fiedler et al., 2008).

The above studies lend weight to claims that chronic exposure to low to moderate levels of H₂S are not associated with significant or permanent injury. In his study of the physiological detoxification process of H₂S exposure, Evans (1967) pointed out that the continued respiration of low doses of H₂S without adverse effect show that H₂S exposures are not cumulative. Adelson and Sunshine (1966) attribute the lack of cumulative damage to the rapid oxidation of H₂S in the blood to sulfate and thiosulfate. Bhambhani et al., (1994) similarly attributes the body's rapid detoxification of H₂S as the protection against cumulative damage.

The USEPA has conducted a human health assessment for H₂S (revised 2003) and developed an inhalation reference concentration (2E-3 mg/m³) with the critical effect being nasal lesions of the olfactory mucosa based on a rat subchronic inhalation study conducted by Brenneman et al. (2000). The USEPA noted that the focus of the human health assessment is on long-term chronic exposures.

Carcinogenicity

Hydrogen sulfide has not been established as a human carcinogen. The USEPA reports that data are inadequate for an assessment of the carcinogenic potential of H₂S and that no relevant data could be located from which to develop an assessment.

Mechanism of Action(s)

The primary route of exposure for H₂S is inhalation; therefore it will be primarily absorbed through the lungs and broadly distributed in the blood throughout the body. Metabolism of H₂S proceeds through three primary pathways which include oxidation, methylation, and reaction with metalloproteins or disulfide-containing proteins. Oxidation in the liver is the major pathway and generally occurs under conditions of low concentrations, causing H₂S to be rapidly oxidized into a sulfate or thiosulfate by oxygen bound to

hemoglobin in the blood. A small portion of the H₂S may enter the muscles, where it undergoes a similar transformation by oxygen bound to myoglobin. The trace amounts of remaining gas are eliminated by the lungs as dissolved H₂S. This detoxification process occurs rapidly so that at low concentrations, H₂S does not act as a cumulative toxicant. A study by Dorman et al. (2000) showed no evidence of fertility and developmental neurotoxicity effects in Sprague-Dawley rats that were exposed to occupationally relevant exposure concentrations levels (10, 30, or 80 ppm) of H₂S 2 weeks prior to breeding, the 2 week mating period, and the gestation period.

In the event that the detoxification capacity is exceeded, excess H₂S undergoes a third metabolic process involving a protein reaction into toxic metabolites. These metabolites can suppress aerobic metabolism in the various tissues by inhibiting mitochondrial respiration, specifically cytochrome oxidase. In this way, H₂S exerts its systemic toxic effects in a manner similar to cyanide (Beauchamp et al., 1984; Bhambhani et al., 1994; Sams et al., 2013).

Ballerino-Regan and Longmire (2010) stated that postmortem blood sulfide levels can be suitably indicative of poisonous exposures if taken within 2 h of exposure, unlike sulfhemoglobin levels, which are not. They reported that the blood levels of thiosulfide recorded in postmortems were found to be 8–77 times the normal level of 0.3 µg/ml, with elevated levels also found in brain and lung tissue samples. Bott and Dodd (2013) also found that thiosulfate has been reported to be a useful indicator for H₂S exposure and that levels in fatal human cases have ranged from 0.025 to 0.143 mmol/l². Chaturvedi et al. (2001) noted that blood sulfide levels from 8 to 5.0 µg/ml were associated with H₂S exposure in postmortems.

SOURCES OF EXPOSURE

Hydrogen sulfide is a well-recognized occupational and industrial hazard causing fatalities of workers in a variety of settings. Inhalation is considered the main route of exposure.

Occupational

Perhaps the most significant occupational exposure source of H₂S is within the petroleum and natural gas industry. Crude oil is “saturated” with H₂S while natural gas can contain levels up to 900,000 ppm (Arnold et al., 1985). Doujaiji and Al-Tawfig (2010) stated that H₂S is the primary chemical hazard of natural gas production and found in a retrospective review from the oil and gas industry in Canada (1969–1973) that 221 cases of H₂S exposure were reported and 173 patients were transported to the hospital with 14 of the victims dead on arrival. The presence of high levels of

H₂S offer more than just a direct health risk; H₂S can cause metal stress leading to equipment or pipeline failure, and it can combine with other chemicals to create secondary toxic gases. Sams et al. (2013) states that deaths related to H₂S have traditionally involved accidents from workplace exposure to sewer gas or fatal exposures in commercial manufacturing and that OSHA reported 13 work-related H₂S asphyxiation deaths in 2007.

In any industrial process in which sulfides or sulfates may contact a reducing agent, consideration of the handling and disposal methods of the products or by-products must be carefully examined. For example, a truck driver accidentally transferred sodium hydrogen sulfide into a tank with 4% sulfuric acid and ferrous sulfate, causing his immediate collapse and death (Chaturvedi et al., 2001). In another incident, four deaths were attributed to the presences of H₂S generated in the sludge from the combination of a decolorizer and a pH balancer in the waste water (Kage et al., 2004). In the review of cases during two time periods between 1979 and 1983, Arnold et al. (1985) noted that over 75% of H₂S exposures results in 2 days’ work loss or less, while 8% resulted in >2 weeks loss, or mortality. Eighty-six percent of the exposures were related to the natural gas and petroleum industry with the remaining exposures, including university laboratories and food processing industries.

In 2011, the USEPA lifted an Administrative Stay of the Emergency Planning and Community Right-to-Know Act (EPCRA) section 313 TRI reporting requirements for H₂S. Therefore facilities that manufacture, process, or otherwise use H₂S in amounts above activity thresholds must report their environment releases and other waste management quantities annually. Hydrogen sulfide is subject to the standard activity thresholds of 25,000 pounds for manufacturing and processing and 10,000 pounds for otherwise use. It falls under the de minimis exemption because it is not considered a carcinogen by OSHA definition and therefore is exempt in a mixture at a concentration lower than 1.0%.

Environmental

Hydrogen sulfide occurs as a natural by-product from the decay of organic material containing sulfur and can be found naturally in the environment. It is found commonly in the later stages of volcanic eruptions. Along with sulfur dioxide and carbon dioxide, it is considered one of the most potentially hazardous volcanic gases because it is heavier than air and has the potential to accumulate in hollows. Its concentrations in ambient air range from 0.1 to 1 µg/m³ as a result of natural emissions while concentrations above 100 µg/m³ have been reported near industrial plants (WHO, 2003).

Low levels of H₂S have been found in water due to natural sources and industrial processes; however, drinking water is not currently considered a significant source of H₂S exposure and no drinking water quality standard has been set.

INDUSTRIAL HYGIENE

It is important to monitor air concentrations in occupational settings where H₂S exposure is a risk, keeping concentrations within occupational permissible levels and using appropriate sampling techniques and analytical methods. Standards and guidelines for H₂S in the occupational setting vary between organizations. OSHA, the only organization with enforceable standards, has different PELs depending upon the occupational setting. “General Industry” exposures have a ceiling limit of 20 ppm, with an exception when exposure is sporadic. In such a case where an exposure may only occur once within the work-day, OSHA requires that the exposure not exceed 50 ppm for a single time period up to 10 min, i.e., there is no use of a TWA. For “Construction” and “Maritime” industries, the OSHA PEL is a TWA of 10 ppm. The working level established by ACGIH is a TLV-TWA of 1 ppm and a STEL of 5 ppm, based on its review of upper respiratory irritation and central nervous system involvements. (ACGIH, 2013) The NIOSH REL has a ceiling limit (10 min) of 10 ppm and the concentration IDLH is 100 ppm (NIOSH, 2011).

The pungent odor of H₂S cannot be considered a reliable indicator of the continued presence of the gas as olfactory fatigue occurs rapidly at low levels. Fortunately, most occupational exposures are below an 8 h TWA of 10 ppm (Dorman et al., 2000) and thus decrease the likelihood of olfactory fatigue and paralysis in a routine work environment.

Engineering controls to limit H₂S exposure should be exercised wherever feasible. Prevention of skin and eye contact is recommended through the use of PPE, especially in moist areas where work garments may become damp and eye wash stations should be readily available in the event of an accidental exposure. If engineering controls and work practices are not feasible, respirators may need to be used. In this case, only approved respirators should be permitted and a respiratory protection program should be developed and include training requirements, maintenance, inspection, cleaning, and evaluation. The corrosivity of H₂S, especially in moist environments, should be considered as well in the selection of PPE and respiratory support equipment.

Many of the fatalities due to occupational exposure to H₂S were caused by untrained workers or even first responders succumbing to its effects as they attempted a rescue. Thus, education and training should be conducted for all personnel that work in areas where H₂S levels could exceed allowable levels. General safety awareness should include the characteristics, potential sources, and hazards of H₂S, as well as the proper use of PPE, rescue equipment, detection methods, and occupational permissible levels.

Even in industrial settings not specifically involving H₂S as a product or by-product, H₂S poisoning can occur by the inadvertent mixing of chemicals used for innocuous purposes

such as cleaning and site maintenance. Proper storage and training in the handling of these chemicals must also be a priority in the occupational setting.

MEDICAL MANAGEMENT

The diagnosis of H₂S poisoning is primarily dependent upon the awareness of the circumstances of exposure and industry in which the exposure takes place. When the source of injury is unknown, a history of rotten egg smells may provide some insight. No specific physical or laboratory findings are definitive in the diagnostic process making any information of exposure circumstances of paramount importance. The sudden collapse of a worker in an area of potential H₂S production should elicit an immediate assessment for H₂S poisoning (Ballerino-Regan and Longmire, 2010).

Treatment for H₂S exposure is not specific and there is no proven antidote with medical treatment consisting primarily of supporting respiratory and cardiovascular functions. In cases of mild exposure where dermal or conjunctival irritation is the primary complaint, immediate irrigation of any exposed surfaces should be initiated and continued until all burning sensation ceases at which point subsequent medical evaluation should be sought. Concentrated H₂S can cause chemical burns and should be treated in the same manner as a thermal burn. Liquefied H₂S can cause frostbite if it comes into contact with the skin and should be treated by rewarming the affected areas and seeking medical attention. In the case of inhalation exposure, supportive care should be administered and early administration of hyperbaric oxygen, amyl nitrite, and sodium nitrite may be beneficial (Doujaiji and Al-Tawfiq, 2010). According to Nogue et al. (2011), medical treatment should include 100% oxygen and ensuring correct metabolic acidosis with bicarbonate, utilizing CPR if warranted. Evans (1967) also recommends that 100% oxygen be administered immediately, as well as ventilatory support provided if needed as the ability of the body to detoxify H₂S is directly related to the oxygen content of the blood. Due to the corrosivity of H₂S, children may be more vulnerable to respiratory compromise because of the smaller diameter of their airways (ATSDR, 2014). Treatment for hypotension, if present, should involve supportive therapy, such as fluids. Because of the mechanistic similarity to cyanide poisoning, treatment with the cyanide antidote sodium nitrite has been suggested. The rationale is to generate methemoglobin, which competes for H₂S by forming sulfmethemoglobin, freeing the cytochrome oxidase (Chen and Wang, 2012; Evans, 1967). While some anecdotal evidence has been associated with successful treatment, there has been no concrete evidence for the human efficacy of this treatment to date (Burnett et al., 1977; Chen and Wang, 2012; Morii et al., 2010; Stine et al., 1976).

CYANIDE

ERIN L. PULSTER AND JAMES V. HILLMAN

Target organ(s): Cardiovascular and respiratory system, thyroid, eyes, skin and blood

Occupational exposure limits: OSHA PEL: 4.7 ppm (5 mg/m³) 8 h TWA (skin); ACGHI TLV: 4.7 ppm (5 mg/m³) ceiling (skin); NIOSH REL: 4.7 ppm (5 mg/m³) STEL (skin) and ceiling (10 min); NIOSH IDLH: 25 mg/m³.

Risk/safety phrases: Compound dependent, most are incompatible with water, acids, and strong oxidizers.

BACKGROUND AND USES

Cyanide is a rapid acting and potentially fatal chemical, which exists in a variety of chemical complexities and forms (gas, liquid, or solid), all of which contain a CN moiety. While many chemical forms of cyanide exist from both natural and anthropogenic sources, the cyanide anion (CN⁻) is the primary toxic agent, regardless of origin (Simeonova and Fishbein, 2004).

Natural sources are derived from a variety of bacteria, fungi, algae, and plants (<2000 species). Fruits, vegetables, and seeds contain cyanogenic glycosides which can be released when ingested. Cyanogenic glycosides are present in a number of staple foods consumed in tropical regions, such as cassava (tapioca, manioc) and sorghum (grasses raised for grain). Other foods containing cyanogenic glycosides include sweet potato, lima beans, corn, cabbage, linseed, bitter almonds, bamboo shoots and the pits of wild cherries, apricots, peaches, apples, and pears (Way, 1984; Simeonova and Fishbein, 2004; ATSDR, 2006). Well-described cyanogenic glycosides include amygdalin, linamarin, dhurrin, prunasin, lautaustralin, and taxiphyllin.

Clinical trials tested the efficacy of using a chemically modified form of amygdalin (i.e., laetrile) found primarily in the kernels of apricots, peaches, and almonds as a chemotherapeutic agent; however, it was concluded that it was not an effective cancer treatment (Moertel et al., 1982).

Anthropogenic sources of cyanides consist of the manufacturing and processing of plastic, rubber, paper, textiles, fumigants, insecticides, pesticides, and chemicals for photography processing. Cyanide compounds can be formed from the combustion of synthetic materials (e.g., plastics) and fossil fuels (e.g., vehicle emissions) or the product of solid waste incinerators, biomass burning, fumigation operations, and the production chelating agents, carbon black, coke, or coal carbonization procedures (Simeonova and Fishbein, 2004).

Cyanide compounds have been used in medicine, fishing, pest control, mining, industrial organic chemistry, food (as an additive), and as a poison. For instance, it was used during World War II as a genocidal agent by the Germans. Cyanide salts are used in metallurgical industries for electroplating, metal cleaning, and the extraction of silver and gold. The major end uses of hydrogen cyanide are in the production of adiponitrile, cyanuric chloride, sodium cyanide, chelating agents, and nitrilotriacetic acid.

PHYSICAL AND CHEMICAL PROPERTIES

Cyanides comprise a wide range of compounds, all of which have a CN molecule and exist in either a solid, liquid, or gaseous form. Differing physical characteristics and chemical characteristics of some selected cyanide compounds are shown in Table 46.1. Physical characteristics range from a colorless or

TABLE 46.1 Physical Properties of Selected Cyanide Compounds

Species	Synonyms	CASRN	Molecular Formula	Molecular Weight (Da)	Boiling Point (°C)	Melting Point (°C)	Solubility
Cyanide	Cyanide anion, cyanure, hydrocyanic acid	373-51-3 57-12-5	CN	26.02	26	No data	Soluble at 25 °C (mg/l) in water
Hydrogen cyanide	Prussic acid, hydrocyanic acid, formic ananmonide	74-90-8	HCN	27.03	26	-13	Miscible in H ₂ O at 30 °C
Sodium cyanide	Cyanide of sodium, natriumcyanide	143-33-9	NaCN	49.02	1496	564	48 g/100 ml (10 °C) in H ₂ O
Potassium Cyanide	Cyanide of potassium, kaliumcyanide	151-50-8	KCN	65.11	1625	634	In water and glycerol
Calcium cyanamide	Calcid, calsyan	156-62-7	CaCN ₂	80.10	No data	1340	Insoluble
Cyanamide	Dormex, hydrogen cyanamide	420-04-2	NH ₂ CN	42.04	132–138	43–47	In organic solvents
Cyanogen	Carbon nitrile, dicyanogen, dicyan, oxalic nitrile	460-19-5	NCCN	52.03	-21	-28	In water, alcohol, and ether
Cyanogen chloride	Cyanic chloride, cyanicchlorid, chloride cyanide	506-77-4	ClCN	61.47	14	-6.5	In ethanol and ether

pale blue liquid with a faint bitter almond-like odor (hydrogen cyanide, HCN) to a white solid, powder, or crystalline hygroscopic salt (sodium cyanide, NaCN) to a colorless toxic gas also with an almond-like odor (cyanogens, NCCN). Cyanide compounds are either organic or inorganic. Organic cyanides contain a noncovalent CN functional group and are typically called the cyano group or nitriles. A common nitrile is methyl cyanide, also known as acetonitrile (CH₃CN). Inorganic cyanides have a negatively charged polyatomic cyanide ion (CN⁻) and are generally referred to as cyanides. This group includes the cyanide salts (i.e., sodium cyanide, NaCN) which are considered the most toxic form.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute cyanide poisoning is associated with accidental ingestion, homicide or suicide cases, occupational exposures, and

fire smoke (Borron and Baud, 1996; Alarie, 2002). Depending on the type of cyanogen, lethal doses in rats ranged from 57 to >5000 mg/kg, 14 to 2778 mg/kg, and 10 to >5000 mg/kg, for oral, intraperitoneal, or subcutaneous, respectively (Rao et al., 2013, Table 46.2). Inhalation LC₅₀ values for rats exposed to hydrogen cyanide were observed at 158 mg/m³ for 60 min exposures and 3778 mg/m³ for 10 s exposures (Ballantyne, 1983). In humans, inhalation of airborne cyanide compounds in excess of 100 ppm can result in death within an hour, whereas concentrations exceeding 300 ppm are generally fatal within minutes (Beasley and Glass, 1998). Similarly, the lethal dose of sodium or potassium cyanide is 200–300 mg within seconds of inhalation. Ingested hydrogen cyanide has a lethal dose of 50 mg with effects beginning within 30 min.

Acute cyanide poisonings primarily affect the central nervous system and result in cardiovascular problems. Inhalation, dermal or dietary (ingestion) exposures to small amounts of cyanide may result in immediate signs and symptoms consisting of dizziness, headache, nausea,

TABLE 46.2 Route-specific LD₅₀ (mg/kg) for Various Cyanogens in Rats

	Oral	Intraperitoneal	Subcutaneous
Acetonitrile	>5000	2388 (2053–2778)	>5000
Acrylonitrile	95 (82–111)	95 (82–111)	95 (82–111)

Table modified from Rao et al., 2013.

vomiting, tachypnea, tachycardia, restlessness, and weakness. Exposures to large amounts of cyanide by any exposure route can result in convulsions, loss of consciousness, hypotension, lung injury, respiratory failure, bradycardia, and death. Pulmonary edema and lactic acidosis have been reported after cyanide ingestion (Graham et al., 1977; Beasley and Glass, 1998). Many life-threatening intoxications, including loss of consciousness, have resulted in complete recovery (Peden et al., 1986; Scolnick et al., 1993). Mild cases of exposure in fumigators and factory workers have resulted in symptoms of oxygen deprivation.

Chronic Effects

Toxicological interest primarily focuses on acute cyanide poisoning; however, its most widely distributed toxicological problems are due to chronic toxicity from dietary, industrial, and environmental factors (Way, 1984). Most of the evidence is based on observational studies, with few controlled experiments. The unknown contribution of other factors makes this a complex problem. However, chronic exposure appears to involve the central nervous system and endocrine system.

One of the most widespread pathological conditions associated with cassava consumption is tropical ataxic neuropathy (Osuntokun et al., 1969; Way, 1984; Ernesto et al., 2002). This is a diffuse degenerative neurological disease characterized by irreversible paraparesis that has previously been correlated with concentrations of plasma thiocyanate. Thiocyanate, one of the major detoxification products, acts as a goitrogenic agent by preventing the uptake of iodine. Recent expansion of cassava processing in Nigeria has revealed significantly higher thiocyanate levels in workers compared with non-cassava processors (Adewusi and Akindahunsi, 1994).

Evidence of endocrine toxicity was also apparent in the Nigerian study. Goiter was more prevalent in cassava processors than in other workers. Studies of electroplaters have revealed that workers in this industry, many of whom have enlarged thyroid glands, may be at risk for chronic disease related to cyanide (Way, 1984). A study in rural Mozambique evaluated thyroid function in a population suffering from epidemic spastic paraparesis resulting from the consumption of cassava (Cliff et al., 1986). This study found that subjects had altered thyroid function. However, the authors also noted that if iodine intake is adequate, high levels of dietary cyanide may be tolerated without overt goiter or hypothyroidism.

In addition, a case report of cyanide-induced Parkinson's disease described magnetic resonance imaging changes resulting from either direct cyanide toxicity or from cerebral anoxia, occurring secondary to cyanide intoxication (Rosenberg et al., 1989). Perhaps the most convincing evidence of cyanide CNS toxicity is tobacco amblyopia. Victims have a history of heavy smoking, visual disturbances, and depletion of vitamin B₁₂. The condition is reversed by treatment with a cyanide antagonist, hydroxocobalamin.

El Ghawabi et al. (1975) investigated the effects of chronic cyanide exposure in the electroplating sections of three factories in Egypt that employed 36 workers. A significant correlation was established between urinary excretion of thiocyanates and the concentration of airborne CN (4.2–12.4 ppm) in the workplace. The exposed workers had significantly higher hemoglobin values and lymphocyte counts compared with the unexposed controls, and 78% also had punctate basophilia. Cyanmethemoglobin was only detected in the exposed group, 20 of whom had variable thyroid enlargement, presumably from the thiocyanate. The symptoms noted with greatest frequency were headache, weakness, changes in taste and smell, giddiness, throat irritation, vomiting, and effort dyspnea. Studies with rat hepatocytes suggest that cyanide toxicity depends on adenosine triphosphate (ATP) formation, which maintains mitochondrial membrane potential (Snyder et al., 1993; Nieminen et al., 1994). Fructose was protective against cyanide toxicity through glycolytic ATP formation. Another study by Niknahad et al. (1994) found that all glycogenic and gluconeogenic amino acids and carbohydrates were protective against cyanide toxicity in rat hepatocytes.

Dermatitis is a familiar condition in workers, such as electroplaters, who are chronically exposed to cyanide solutions that tend to be strong irritating agents causing severe itching in sensitive individuals. Cyanide rash is described as usually consisting of pruritic papules and vesicles. Occasionally a blotchy eruption of the face may follow low level exposure to HCN vapors and solutions of cyanide salts. According to Braddock and Tingle (1930), the cyanide rash is more attributed to the caustic action of quicklime rather than cyanides among American gold miners.

Mechanism of Action(s)

The form of cyanide a victim is exposed to does not influence distribution, metabolism, or excretion from the body (Simeonova and Fishbein, 2004). Cyanide is rapidly absorbed through the lungs, skin, and gastrointestinal tract because of its unionized state and low molecular weight. The majority in blood is sequestered in red blood cells and a relatively small amount is transported to target organs via plasma, yet it has not been shown to accumulate in either blood or tissues (ATSDR, 2006; Simeonova and Fishbein, 2004). Symptoms occur within seconds of inhalation and within minutes of ingestion of cyanide salts. Gastrointestinal absorption of nitriles and cyanogens can produce symptoms up to 12 h after ingestion. The nitriles are readily absorbed through skin and through respiratory and gastrointestinal routes.

The central nervous system is particularly vulnerable to cyanide poisoning primarily due to its high dependence on oxidative metabolism and limited anaerobic capacity (Thomas and Brooks, 1970; Way, 1984; Simeonova and Fishbein, 2004; ATSDR, 2006). The principle impairment of

cyanide poisoning is the inhibition of cytochrome oxidase, the terminal enzyme of the mitochondrial electron transport chain (Isom and Way, 1974; Way, 1984; Beasley and Glass, 1998). In turn, oxygen available for tissues is impaired resulting in a state of histotoxic anoxia (tissues inability to utilize oxygen). Essentially, cyanide inhibits the enzymes used for basic cellular respiration. Cyanide can also inhibit approximately 40 other enzymes that may be equally, if not more, sensitive to cyanide (Way, 1984; Simeonova and Fishbein, 2004), which include nitrate reductase, myoglobin, horseradish peroxidase, xanthine oxidase, alkaline phosphatase, copper, and iron. Many of the sensitive enzymes are metalloenzymes containing molybdenum or iron. It has been suggested that the inhibiting properties of cyanides may be attributed to its ability to complex with metals (Way, 1984; Hartung, 1994). This binding to metalloenzymes inhibits many additional enzyme reactions, the most critical one being the ferric ion in cytochrome oxidase. This inhibits the final step of oxidative phosphorylation, prevents the production of ATP, and results in anaerobic metabolism. Cellular anoxia results from the inability to use oxygen, and a severe lactic acidosis ensues.

Cyanide can be metabolized through several routes, only two of which are clinically important and also serve as the basis for the treatment of cyanide poisonings. Approximately 80% of cyanide is detoxified through the liver by the mitochondrial enzyme rhodanese, which transfers sulfur from thiosulfate to cyanide, forming the less toxic thiocyanate, a more easily excreted compound through urine. Both cyanide and thiocyanate can also be metabolized by combinations of cyanide and hydroxocobalamin and cyanide and cystein. Thus, the concentration of sulfur containing substrates (i.e., thiosulfate, cysteine, cystine) is the limiting factor in metabolism. Although hydroxocobalamin serves as a minor route of detoxification, it is considered an important antidote. The resulting cyanide metabolites are then normally eliminated through urine while trace amounts may be excreted through the lungs, saliva, and sweat.

SOURCES OF EXPOSURE

Occupational

The principle routes of occupational exposures to cyanides are mainly from inhalation, yet dermal exposures are also probable to a lesser degree. Occupations with the highest risk of cyanide exposures include blacksmithing, metal cleaning, metallurgy, firefighting, pesticide applications, photography or photo engraving and the manufacturing and processing of cassava, plastic, rubber, paper, textiles, fumigants, insecticides, pesticides, steel, pharmaceuticals, chelating agents, the preparation and decomposition of cyanides, the synthesis of acrylonitrile and nitriles (ATSDR, 2006). The National

Occupational Exposure Survey (NOES) has estimated the numbers of workers potentially exposed to the following cyanides: 4005 to hydrogen cyanide; 66,493 to sodium cyanide; 64,244 to potassium cyanide; 3215 to potassium silver cyanide; 3606 to calcium cyanide; 22,339 to copper (I) cyanide; and 1393 to cyanogen chloride (ATSDR, 2006). It has also been suggested that medical and emergency personnel may be exposed to higher levels of cyanides during resuscitation efforts, gastric content removal or postmortem examinations (Andrews et al., 1989; Curry, et al., 1967; Nolte and Dasgupta, 1996). More recently, cyanide has been recognized as a hazardous toxic gas that can be generated in fires. Victims of smoke inhalation have been shown to have toxic levels of both carbon monoxide and hydrogen cyanide (Baud et al., 1991). Firefighters are an occupational group at significant risk of this source of cyanide exposure (Silverman et al., 1988). Exposure to hydrogen cyanide (prussic acid) most often occurs in connection with the fumigation of ships, workshops, and dwellings, but this gas is also encountered in fumigation intended to kill agricultural pests, in chemical laboratories, in blast furnace gas, in the manufacture of illuminating gas, and in the gas from burning nitrocellulose. The presence of HCN in various industrial gases results from an incomplete combustion of nitrogen-containing organic compounds, and its presence are often not suspected until an accident occurs. Many cases of fatal poisoning occurred during World War I because of the extensive use of hydrocyanic acid to destroy vermin, for which it is still used. HCN fumes are formed by combining dilute sulfuric acid and sodium cyanide.

A study of Nigerian cassava processing plants compared levels of urinary and serum thiocyanate (cyanide metabolite) in cassava processing workers versus frequent (once a day) and infrequent (occasionally) consumers of cassava foods (Okafor et al., 2002). Mean urinary thiocyanate concentrations in cassava processors ($154 \pm 25 \mu\text{mol/l}$) were double those of frequent consumers ($70 \pm 22 \mu\text{mol/l}$) and almost three times higher than the infrequent consumers ($59 \pm 17 \mu\text{mol/l}$). Similar levels and trends were observed in the serum. Moreover, cyanide levels in ambient air and natural water sources near the cassava processing facilities ranged from 20 to 46 mg/m^3 and 1.6 to 7.9 mg/l , respectively (Okafor and Maduagwu, 2000; Okafor et al., 2001).

Environmental

Environmental exposures of cyanides include ambient air, water, soil, and food. Cyanide in ambient air is found typically as hydrogen cyanide which is released at the surface and has a mean tropospheric photochemical lifetime of approximately 2.5 years for HCN with concentrations in the troposphere ranging from 180 to 190 ng/m^3 ; Mahieu et al., 1995). Enhancements of HCN in the atmosphere have been associated with biomass fires (Rinsland et al., 1998). Hydrogen cyanide from

fire smoke is considered the most common cause of acute cyanide poisoning in developed countries (Anseeuw et al., 2013; Alarie, 2002). The concentration of cyanide in unpolluted air averages 0.160–0.166 ppm (ATSDR, 2006). Smoke from U.S. cigarettes also contains cyanide levels ranging from 10 to 400 µg/cigarette for mainstream smoke and 0.006 to 0.27 µg/cigarette for sidestream smoke (Chepiga et al., 2000). Non-filtered cigarettes contain between 400 and 500 µg of HCN per cigarette (Hoffmann, 1997). Similarly, European cigarettes had hydrogen cyanide concentrations in the range of 280–550 µg/cigarette for mainstream smoke (Guerin et al., 1987).

In 1993, 390 of 1300 hazardous waste sites listed on the National Priority List of the Environmental Protection Agency were identified as being contaminated with cyanide (Harper et al., 1993). Many of these locations must be monitored closely to prevent public exposure through drinking water. As these sites undergo remediation, “hazmat” (hazardous material) workers constitute another occupational group at risk of cyanide exposure.

Near a large-scale cassava processing facility in Nigeria, levels of cyanide in ambient air and natural water sources ranged from 20 to 46 mg/m³ and 1.6 to 7.9 mg/l, respectively (Okafor and Maduagwu, 2000; Okafor et al., 2001). The maximum contaminant level (MCL) for cyanide in drinking water is set at 0.2 mg/l (USEPA, 2013). A survey of 35 water utilities across the United States found cyanogen chloride concentrations in drinking water varies depending on the treatment processes used (Krasner et al., 1989). For instance, median cyanogen chloride concentrations measured in water treated with free chlorine were 0.4 µg/l compared to 2.2 µg/l in water prechlorinated and postammoniated. Cyanide levels up to 100 g/l have been reported for waste water from plating industries (Chen et al., 1994; Grosse, 1986).

Cyanide compounds released to soil are primarily the result of anthropogenic activities such as the disposal of cyanide wastes in landfills, the use of cyanide containing road salts and industrial facilities (Shifrin et al., 1996; Simeonova and Fishbein, 2004). Mean cyanide concentrations at manufactured gas plants (MGP) are below 2000 ppm, although concentrations >20,000 ppm have been reported (Shifrin et al., 1996). However, it is important to note in terms of the potential toxicity of cyanides in soils, there has been no evidence of soil containing free cyanides. Iron-complexed cyanides (i.e., ferrocyanide ion) comprise over 97% of the total cyanides in weathered or unweathered soils at MGP sites (Theis et al., 1994; Shifrin et al., 1996).

Food is another important source of environmental exposures to cyanogenic glycosides. Cyanogenic glycosides are major constituents in variety of staple foods with levels ranging from <1 mg/kg in cereal grains to 7700 µg/g in bamboo shoots (ATSDR, 2006). Cassava is a major source of calories for over 500 million people in tropical regions and total cyanogens can range from 91 to 1515 µg/g in fresh roots

(O’Brien et al., 1992; Okafor et al., 2002). Hydrogen cyanide in soy protein products, soybean hulls, and lima beans have levels measuring 0.07–0.3, 1.24 ± 0.26, and 43 ± 0.26 µg/g, respectively (Honig et al., 1983). Cyanide concentrations have also been reported for apricot pits (89–2170 µg/g), black cherries (78 µg/seed), and canned unpitted fruits (0–4 µg/g) (Lasch and El Shawa, 1981; Swain et al., 1992; Voldrich and Kyzlink, 1992).

INDUSTRIAL HYGIENE

In spite of the highly toxic nature of cyanide, there have been relatively few acute accidental poisonings (Hirsch, 1964). Acute inhalation, ingestion, or dermal exposures of hydrogen cyanide may be rapidly fatal. As such, the Occupational Safety and Health Administration (OSHA) have set a permissible exposure limit (PEL) for HCN of 10 ppm (11 mg/m³) averaged over an 8 h work shift (OSHA, 1978). The National Institute for Occupational Safety and Health (NIOSH, 1994) and the American Conference of Governmental Industrial Hygienists (ACGIH) recommended an exposure limit (REL) and a threshold limit value (TLV) of 4.7 ppm (5 mg/m³) for dermal exposure (ACGIH, 1996). Exposures to 50 ppm or greater are considered Immediately Dangerous to Life or Health Limit (IDLH). The current standard guidelines applied to all cyanides (i.e., KCN, NaCN) are 5 mg/m³ for the OSHA PEL (8 h TWA) and the NIOSH PEL (10 min period).

Prevention remains the best approach to eliminating the potential for cyanide poisoning. However, in the work place engineering controls should be used wherever possible. Ventilating equipment should be used and workers should be provided personal protective equipment, including protective impervious clothing. When liquid hydrogen cyanide is in use, employees should be provided splash proof safety goggles and an emergency eyewash station and shower should be in the immediate vicinity of use. Workers should be informed of the exposure routes and risks (i.e., skin absorption, ingestion, and inhalation) and visible warning signs should be prominent in areas of potential exposure. Although there is no information available concerning the odor threshold for either KCN or NaCN, workers should be trained to recognize the odor of hydrogen cyanide and to evacuate the area immediately. A first-aid antidote kit should be readily available, and workers should be instructed to its use. If exposure to cyanide is possible, p-aminopropiophenone may be taken as a pretreatment antidote (Baskin and Fricke, 1992).

MEDICAL MANAGEMENT

The lack of rapid assays and blood tests to confirm cyanide poisoning has resulted in presumptive diagnosing based on

index of suspicion, clinical presentations, and background information (e.g., occupation and mental status) (Borron, 2006). An odor of bitter almonds is typical of cyanide, but up to 40% of the population is unable to detect cyanide by odor. A cherry red color of venous blood (more likely seen in children and, in general, is not a reliable indicator of cyanide toxicity), arising from poor oxygen utilization, unexplained metabolic acidosis, and the absence of cyanosis are clues to the diagnosis. Cyanide is a normal human metabolite which the body can be detoxified and may be produced *in vitro* by blood or *in situ* by organs after death (Dries and Endorf, 2013). Background blood levels in a normal, nonsmoking individual is 0.3 mg/l and increases to 0.5 mg/l in smokers. Normal plasma lactate concentrations range from 0.5 to 2.2 mmol/l, concentrations \geq 8 mmol/l suggests the possibility of cyanide poisoning; however, it is not specific and therefore not definitive (Borron, 2006). Fatal cyanide blood levels are typically seen at 3 mg/l, although levels as low as 1 mg/l and as high as 5 mg/l have been reported (Barillo, 2009). Cyanide blood levels of fire survivors or ingestion and inhalation have ranged from 0.02 to 6.5 and 7 to 9 mg/l, respectively (Curry et al., 1967; Barillo et al., 1994; Caravati and Litovitz, 1988; Barillo, 2009). Blood cyanide levels are useful in guiding treatment; however, the majority of cyanide in the bloodstream resides in red blood cells thereby underestimating plasma levels of free cyanide. Nonetheless, laboratory tests confirming an elevated cyanide level are not usually available in a timely manner, and successful treatments must begin early.

Treatment of acute cyanide poisoning involves decontamination, antidotal therapies, and supportive care. Decontamination may include removing the victim from the site of exposure, removing contaminated clothing, rinsing dermal exposures, gastric lavage, and activated charcoal (Borron, 2006). Cyanide antidotes are classified into three groups based on their mechanism of action: sulfur detoxification, methemoglobin formation, and direct combination (Beasley and Glass, 1998). The most important naturally occurring detoxifying mechanism involves the addition of a sulfur atom to form the less toxic thiocyanate ion (Beasley and Glass, 1998). To facilitate this process, various synthetic compounds have been used as additional sources of sulfur (i.e., sodium thiosulfate). Methemoglobin (metHb) formation increases the source of circulating ferric ions to counteract the critical cyanide binding to the ferric ion of cytochrome oxidase. This leads to the formation of cyanmethemoglobin, which has a low toxicity. Cyanide is detoxified by conversion to thiocyanate, and this reaction is enhanced by combined use of nitrite and thiosulfate. Continued or repeated treatment may be required because of liberation of cyanide ions from cyanmethemoglobin and from thiocyanate. Formation of metHb, through the use of nitrites and supplemental thiosulfate, which is excreted via the kidneys, was the primary antidote for acute cyanide poisoning in the United States

(Baskin et al., 1992). Direct combination antidotes previously combined cobalt compounds with cyanide; has a wide therapeutic index and, all factors being equal, would be the preferred cyanide antidote. Although dicobalt edetate is still available in Britain and France to treat cyanide poisoning, significant toxic effects have been observed (Jillman et al., 1974; Beasley and Glass, 1998). It has been suggested that this chelating agent should be reserved for cases of severe poisoning because of its ominous side effects, which include nausea, vomiting, profuse diaphoresis, crushing retrosternal pain, cardiac arrhythmia, facial and palpebral edema, and loss of calcium and magnesium ions (Nagler et al., 1978; Graham et al., 1977). The use of hydroxocobalamin (vitamin B12a) has been used successfully as a direct combiner (Bain and Knowles, 1967; Yacoub et al., 1974; Forsyth et al., 1993). Hydroxocobalamin binds strongly with cyanide to form cyanocobalamin (vitamin B12) and clinical trials suggest it is a safe, effective agent for preventing and treating nitroprusside-induced cyanide toxicity with few toxic effects (Zerbe et al., 1993). Intravenous hydroxocobalamin along with thiosulfate to enhance the antidotal effect is recommended (Evans, 1964; Graham et al., 1977; Beasley and Glass, 1998). However, hydroxocobalamin and thiosulfate need to be given in separated IV lines so as not allow the sodium thiosulfate to bind with hydroxocobalamin thus rendering the hydroxocobalamin inactive.

Hydroxocobalamin is currently used in both the United States and Europe for acute cyanide poisoning; however, Europe's approach is much more aggressive. The amount available in the U.S. (1 mg/ml) limits its usefulness as antidote as 10 l of material would be needed to neutralize a fatal cyanide dose (Barillo, 2009; Dries and Endorf, 2013).

Debate continues over the treatment of concurrent carbon monoxide and cyanide poisoning in victims of smoke inhalation. The carboxyhemoglobin that occurs in these patients reduces the availability of oxygen at the tissue level. The methemoglobinemia induced by the treatment of cyanide poisoning with amyl nitrite and sodium nitrite can worsen tissue hypoxia. In contrast, hydroxocobalamin treatment rapidly neutralizes cyanide without interfering with oxygen use. A study involving mice injected with potassium cyanide and exposed to carbon monoxide, followed by treatment with amyl nitrite, revealed an increase in mortality of 25% compared with the untreated control group (Moore et al., 1987). Breen et al. (1995) suggest that supportive therapy alone should be sufficient in all but those patients who continue to exhibit persistent lactic acidosis. Kirk et al. (1993) reported that seven critically ill victims of smoke inhalation were successfully treated with sodium nitrite. Supportive therapy using the administration of oxygen has also been proven successful. Oxygen itself has a specific antidotal activity by accelerating the reaction of cytochrome oxidase. Hyperbaric oxygen, when available, is advocated in the treatment of acute cyanide toxicity.

TABLE 46.3 Recommended Cyanide Antidote Dosage Regimes for Adults. (Doses of Cyanide Antidotes for Children are Lower and are weight based)

Antidote	Dosage
Sodium thiosulfate	50 ml of 25% solution (12.5 g) IV over 10–30 min
Sodium nitrite	10 ml of 3% solution (300 mg) IV over 5–20 min
4-DMAP	5 ml of 5% solution (250 mg) IV over 1 min
Dicobalt edentate	20 ml of 1.5% solution (300 mg) IV over 1 min
Hydroxocobalamin	12.5 ml of 40% solution (5 g) IV over 15 min in 100 ml of normal saline

Source: Beasley and Glass, 1998.

In summary, there is no single therapy or antidote for all poisoning situations. The choice of an antidote should be influenced by several factors, including (1) the nature of the cyanide compound and exposure scenario; (2) poisoning severity; (3) presence of certain risk factors for antidote toxicity; (4) the number of victims involved, and (5) proximity to medical facilities (Beasley and Glass, 1998). Nitrites or other metHb formers are not recommended for fire victims, because of the risk of concomitant exposure to carbon monoxide, or those with certain enzyme deficiencies which increase susceptibility. Nitrites can be used in children, but care and attention must be given to the dose (0.2 ml/kg of 3% sodium nitrite, not to exceed 10 ml or 300 mg) so as not to cause an excessive and adverse level of methemoglobin. It is also important to consider both the risk of antidote-induced toxicity and risks of withholding antidote treatment during decisions to administer an antidote based on presumptive cyanide poisoning (Beasley and Glass, 1998; Borron, 2006). Borron (2006) outlined dosage regimes (Table 46.3) and the following recommendations for mild, moderate, and severe poisoning. Mild poisonings may only require rest and oxygen treatment; however, if symptoms worsen, amyl nitrite treatment may be needed. In moderate poisonings (unconsciousness, convulsions, or cyanosis) intravenous antidotes may be indicated with sodium thiosulphate as the first choice. Severe poisonings (deep coma, dilate non-reacting pupils, and decrease in cardiorespiratory function) additional intravenous antidotes should be administered. Hydroxocobalamin is highly recommended over methaemoglobin formers and kelocyanor based on considered risks.

HALOGENS

JOSEPH A. PUCCIO

CHLORINE

Target organ(s): Respiratory system, eyes, skin, and mucous membranes

Occupational exposure limits:

OSHA: Permissible exposure limit PEL (ceiling): 1 ppm/3 mg/m³ (29 CFR 1910.1000)

NIOSH: Recommended exposure limit (REL): 0.5 ppm/1.45 mg/m³ for a maximum of 15 min

ACGIH: Threshold limit value (TLV) (8-h TWA) 0.5 ppm/1.5 mg/m³ and a short-term exposure limit (STEL) (15 min TWA) 1 ppm/2.9 mg/m³)

Reference values:

Reference dose (RfD): 1E-1 mg/kg-day

Reference concentration (RfC): Not available at this time

TDI: 150 µg/kg of body weight

BACKGROUND AND USES

Chlorine (Cl) is not found freely in nature since it is a highly reactive gas. Chlorine in its gaseous state is produced through the industrial process of electrolysis of alkali chlorides such as sodium chloride (Teitelbaum, 2001). It has many industrial uses particularly in the manufacturing of chlorinated organic chemicals. It has been widely used as a bleaching agent in the manufacturing of paper and textiles. It is also used in the manufacturing of many household items such as bleaches, detergents, antifreeze, plastics, refrigerants and pesticides,

as well as being used for metal extraction, water purification, and sanitation of sewage wastes.

It reacts explosively or forms explosive compounds with many common substances such as ether, turpentine, ammonia, acetylene, and fuel gas. It has been used as a warfare agent because of its toxic and explosive properties (Beswick, 1983; Winder, 2001).

PHYSICAL AND CHEMICAL PROPERTIES

Chemical formula: Cl₂

Structural formula: Cl-Cl

Molecular weight: 70.906

CASRN 7782-50-5

Physical properties

Color: Greenish yellow

State/form: Gas

Description:

Melting point: -101 °C (-149.8 °F)

Boiling point: -34.1 °C (-29.3 °F)

Relative density (specific gravity): 1.467 at 0 °C and 368.9 kPa (saturated liquefied gas) 0.0032 at 0 °C (gas) (water = 1)

Solubility in water: Slightly soluble (0.73 g/100 g water at 20 °C) (reacts)

Solubility in other liquids: Very soluble in dimethylformamide; soluble in benzene, chloroform, carbon tetrachloride, tetrachloroethane, chlorobenzene, glacial acetic acid (99.84%), sulfonyl chloride, phosphoryl chloride, silicon tetrachloride, and metal chlorides such as chromyl chloride, titanium tetrachloride, and vanadium oxide chloride.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute toxicity data have largely come from accidents involving the leakage of chlorine cylinders (Chasis et al., 1947). Tracheobronchitis, pulmonary edema, and pneumonia have been reported with severe overexposure. Exposure may cause burning of the eyes and nose, lacrimation, rhinorrhea, respiratory distress, nausea, and vomiting. All of the immediate signs and symptoms typically subside within 24 h, except for cough, substernal pain, and respiratory distress persisting for up to 2 weeks. High concentrations at approximately 400 parts per million (ppm) can be fatal over a 30 min duration, while a 1000 ppm concentration can cause fatality within minutes (White, 2010).

Beach et al. (1969) studied seven chemical workers exposed to chlorine gas in separate accidents. The usual symptoms of cough, dyspnea, and chest pain started within 10 min of exposure and lasted 2–8 days. Congestion, consolidation, and nodulation were seen on chest X-rays, and pulmonary edema was present in a severe case. Hypoxemia was corrected by oxygen therapy. This treatment had to be continued for 4 days in a one severe case. All recovered completely.

Postmortem changes after fatal massive exposure to chlorine include destruction of the mucous membranes lining the bronchi and bronchioles, focal and confluent areas of edema in the alveoli, patchy superimposed pneumonia, hyaline membrane formation, multiple recent fibrinocellular thromboses of the pulmonary vessels, and ulcerative tracheobronchitis (Dixon and Drew, 1968; Adelson and Kaufman, 1971). Some of the pulmonary damage was attributed to the use of high pressure oxygen in the treatment.

The effects of different levels of chlorine exposure are presented in Table 47.1. In a recent study of chemically related respiratory disease in Michigan, chlorine was one of the most common causative agents (Reilly and Rosenman, 1995).

TABLE 47.1 Effects of Exposure to Chlorine

Concentration, ppm	Effect
0.03–3.5	Range of reported odor thresholds
1	TLV, PEL ceiling
1–3	Slight irritation
3–6	Stinging or burning of eyes, nose, and throat; lacrimation; sneezing, coughing; bloody nose or sputum
5	Severe irritation of eyes, nose, and respiratory tract that becomes intolerable after a few minutes
14–21	Dangerous if exposure lasts 30–60 min
35–50	Lethal in 60–90 min

TLV, threshold limit value; PEL, permissible exposure limit.

Construction workers employed at a pulp mill reported eye and throat irritation, cough, congestion, headache, fatigue, and shortness of breath (Courteau et al., 1994). Victims of another acute industrial exposure reported watering eyes, sneezing, cough, production of sputum, retrosternal burning, dyspnea, anxiety, and vomiting (Abhyankar et al., 1989). Formerly healthy subjects with normal lung function had signs of tracheobronchitis that lasted 3–7 days.

Acute exposure to chlorine gas happens quite regularly at homes and in industries. In a review of 97 cases of acute chlorine inhalation reported to a poison control center, 91 patients were adults and 6 were children. The cases were a mixture of home poisonings (74%) and industrial exposures (26%). Chlorine gas was released after mixing sodium hypochlorite bleach and an acidic descaler in 68 cases and during handling of swimming pool tablets in 22 cases. In total 91 patients had symptoms, including cough (71% of symptomatic cases) or cough and dyspnea (26%). Only 26 victims were admitted to the hospital and 15 of these had a preexisting respiratory condition (2 asthma, 3 chronic bronchitis, 2 allergy, 8 smoking). Of these 26 patients, 21 had dyspnea and 5 had expiratory wheeze. X-rays were taken in 9 cases and only 1 was abnormal. Only 2 patients had hypoxemia with an oxygen saturation of 88–90%. Spirometry was performed in 4 cases and 1 patient had an obstructive airway syndrome. Treatment included bronchodilators in 7 patients, corticosteroids in 4 patients, and 15 patients were treated with both. The average stay in the hospital was 24 h. One patient, a 76-year-old female, required mechanical ventilation for 24 h because of an acute respiratory distress. Follow-up by telephone 3 months later found 2 patients with symptoms suggestive of reactive airways dysfunction syndrome (RADS) (Guerrero et al., 2003). Female C57BL/6N mice were given 4.8–5.8 mg/kg of body weight/day of hyperchlorinated tap water, which resulted in a reduction of macrophages.

Acute chlorine exposure has resulted at sites of bomb explosions, as chlorine is released following the use of homemade chemicals bombs (CDC, 2003).

Chronic Effects

Chronic exposure to low levels of chlorine does not appear to have any lasting effects. Patil et al. (1970) studied 600 diaphragm cell workers in 25 North American chlorine-manufacturing plants. The exposure level generally was below 1 ppm, and the time-weighted average (TWA) ranged from 0.006 to 1.42 ppm. No statistically significant correlations were found between exposure and signs, symptoms, or abnormal chest X-rays, electrocardiogram results, or pulmonary function tests.

Chronic effects have been reported subsequent to acute overexposure. A group of longshoremen were accidentally exposed when the main valve of a cylinder of liquid chlorine

ruptured. Fifty-nine of these workers were studied over a 3-year period after the accident. Eleven heavily exposed individuals showed evidence of alveolocapillary injury and gradually developed increasing airway resistance. Lung function studies of the 59 workers followed showed a decreased vital capacity and diffusing capacity and an increase in the elastic work of breathing (Kowitz et al., 1967).

The effects of chlorine on the mucous membranes were once attributed to the formation of hydrochloric acid and later to the toxic effects of nascent oxygen released by the oxidative action of the gas. This effect of nascent oxygen has since been explained to be the result of a complex series of reactions in which unstable oxidizing agents (e.g., hypochlorous acid and perchloric acid) cause damage by forming stable hydrates of organic chlorine (Chester et al., 1977).

Acute single overexposure to chlorine has been reported to cause RADS, which may persist for several years (Donnelly and FitzGerald, 1990; Malo et al., 1994). This has not been a consistent finding and is concentration and effect dependent.

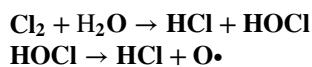

Pulp mill workers exposed to chlorine or chlorine dioxide in "exposure incidents" had a reduced 1-min forced expiratory volume (FEV₁) and forced vital capacity (FVC) and were more likely to have chest symptoms, such as tightness and wheezing (Enarson et al., 1984; Salisbury et al., 1991). Another study found no significant differences between FEV₁, FVC, the FEV₁/FVC ratio, or midmaximal flow (MMF) among a pulp mill worker cohort and a railroad worker control cohort (Kennedy et al., 1991). However, pulp mill workers exposed to chlorine during "gassing incidents" who were not smokers or were ex-smokers had a significantly lower MMF and FEV₁/FVC ratio.

Wolf et al. (1995) exposed male and female mice and rats to chlorine gas for 6 h a day, 5 days a week. They noted concentration-dependent lesions and respiratory tract irritation. Male mice and female rats were the most susceptible. There was no evidence of carcinogenicity.

Chronic exposure to low levels of chlorine gas can lead the affected individual to develop a dermatitis known as chloracne, tooth enamel corrosion, coughing, severe chest pain, sore throat, hemoptysis, and an increased risk for developing tuberculosis (Genium, 1992).

Mechanism of Action(s)

Chlorine has low solubility in water and penetrates deep into the lungs (Winder, 2001). Tissue damage is caused by the products of its chemical reaction with water: hydrochloric acid (HCl) and hypochlorous acid (HOCl). Hypochlorous acid is unstable and further breaks down to hydrochloric acid and oxygen free radicals:

The acids cause irritation and the oxygen free radicals mediate tissue necrosis (HSDB, 2007; Traub et al., 2002). Hypochlorous acid has been known to penetrate the cell wall that can disrupt the integrity and permeability; it can also react with enzymes through the sulphydryl groups in cysteine (HSDB, 2007). The severity of the injury depends on the duration of exposure, the concentration, and the water content of the exposed tissues (Winder, 2001). The hydrolysis to hydrochloric and hydrochloric acids increases the solubility of chorine.

It has also been suggested that hypochlorous acid could interact with nitrite (the end auto-oxidation product of nitric acid) to form an intermediate, nitryl chloride (Cl⁻NO₂) orchlorine nitrate (Cl⁻ONO), which could nitrate, chlorinate, or dimerize aromatic amino acids (Evans, 2005).

Chemical Pathology

The immediate effect of exposure to chlorine gas is acute inflammation of conjunctivae, nose, pharynx, larynx, trachea, and bronchi. In severe cases this can result in effects on the respiratory mucosa with arterial and capillary hyperemia. The plasma exudate can fill the alveoli resulting in pulmonary edema. There is hypersecretion of the seromucoid glands. Mucosal sloughing occurs and exfoliated cells show chromatolysis and multi-nucleation owing to chemical injury. Muco-purulent exudates may cover the areas of sloughing. Chemical pneumonitis may result with the risk of secondary infection. Recovery occurs with epithelial repair and regeneration. This manifests as basal cell hyperplasia in subjects with injury restricted to the surface epithelium. Subjects with erosive tissue damage have fibroblastic and capillary proliferation and repair by fibrosis. Chronic respiratory incapacity following chlorine exposure may be due to fibrosis.

INDUSTRIAL HYGIENE

Chlorine is produced by the electrolysis of sodium chloride (fused or in brine) in diaphragm cells or in mercury cells and by the chemical oxidation of chloride. Production of chlorine via the mercury process may result in exposure to inorganic mercury and associated symptoms (Smith et al., 1970). Environmental monitors for chlorine gas are unnecessary because this compound has excellent warning properties that alert workers to its presence. Ruth (1986) reported a low odor detection value for chlorine of 0.03 mg/m³ (10 ppb). Workplace personal protective equipment is recommended, including respirators, and adequate training is necessary for workers involved in handling chlorine to avoid overexposure and explosion.

The National Institute for Occupational Safety and Health (NIOSH) has set the recommended exposure limit (REL) for chlorine at a ceiling value of 0.5 ppm for a maximum of

15 min (NIOSH, 2005). The Occupational Safety and Health Administration (OSHA) has set a ceiling value for chlorine at 1 ppm (3 mg/m^3). The American Conference of Governmental Industrial Hygienists (ACGIH) has set the threshold limit value (TLV) for chlorine at 0.5 ppm with a 15-min short-term exposure limit (STEL) of 1 ppm (ACGIH, 2006).

MEDICAL MANAGEMENT

Diagnosis and Treatment

Treatment of acute chlorine gas inhalation includes intermittent positive pressure oxygen, use of nebulized bronchodilators, and administration of mild sedatives and a cough medication containing codeine (Kramer, 1967; Noe, 1963). Administration of humidified oxygen is required for most cases of overexposure to a respiratory irritant. Chester et al. (1977) suggested the possible beneficial effects of intramuscular and oral corticosteroid therapy, although these treatments have not proven to be effective in every patient. Arterial blood gas levels are useful in managing patients after chlorine gas exposure (Traub et al., 2002). Intubation of the lungs may be required in some cases in which suctioning to remove fluid is necessary. Anoxia may lead to cardiac and respiratory arrest.

Severe acute exposure to chlorine can result in residual pulmonary dysfunction, particularly RADS, asthma, and low residual volumes in some patients. Sequelae can persist for years, although in most cases pulmonary function tests return to normal within a few months.

Treatment of other effects of chlorine exposure should be supportive and symptomatic.

Dermal and ocular exposure should be immediately treated by flushing the affected surfaces copiously with water. Contact with compressed liquid gas can cause frostbite or burns.

HYDROGEN CHLORIDE

Target organ(s): Tissues immediately in contact with the compound: Eyes, skin, and the respiratory system

Occupational exposure limits:

OSHA: PEL (ceiling): 5 ppm or 7 mg/m³ (29 CFR 1910.1000)

NIOSH: REL: 5 ppm as a ceiling

ACGIH: TLV 5 ppm which should not be exceeded during any part of the working exposure

Reference values:

RfD: Not established

RfC: 0.02 mg/m³

Risk/safety phrases: Hazardous: Ignitability, corrosivity, reactivity, or toxicity

BACKGROUND AND USES

Hydrochloric acid is used frequently in the production of chlorides. In addition, it is used for refining the ore in the production of tin and tantalum, for pickling and cleaning of metal products; in electroplating, in removing scale from boilers; for the neutralization of basic systems; as a laboratory reagent; as a catalyst and solvent in organic syntheses, in the manufacture of fertilizers and dyes; for hydrolyzing starch and proteins in the preparation of various food products; and in the photographic, textile, and rubber industries. Small amounts of hydrogen chloride are released from waste incinerators (Shy et al., 1995).

PHYSICAL AND CHEMICAL PROPERTIES

The synonyms for an aqueous solution of hydrogen chloride include chlorohydric acid, hydrochloric acid, and muriatic acid.

Chemical properties:

Chemical formula: HCl

Structural formula: H-Cl

Molecular weight is 36.47 g/mol (1,3)

CASRN 7647-01-0

Physical properties:

Color: Colorless to slightly yellow gas

Odor: Pungent, irritating

Water solubility: 67% by weight at 30 °C (86 °F)

Vapor pressure: 40.5 atm at 20 °C (68 °F).

State/form: Nonflammable aqueous solution or gas (1,3,4)

MAMMALIAN TOXICOLOGY

Acute Effects

Exposure to HCl almost always involves the hydrochloric acid aerosols because of the hygroscopic nature of the anhydrous form. These aerosols irritate the mucous membranes of the nose, mouth, and respiratory tract. The concentrations of acute exposure and their likely health effects are listed in Table 47.2. Two workers were exposed to high concentrations of HCl in the degradation products of paint, which were produced by high welding temperatures. These workers complained of fever, dyspnea, fatigue, and respiratory discomfort. The final diagnosis of toxic alveolitis and obstructive lung disease was linked to this exposure (Sjogren et al., 1991). Overheated polyvinyl chloride (PVC) in a fabricating factory is believed to have been the cause of the brief hospitalization of 63 individuals who complained of headache, dizziness, and dyspnea. Hydrogen chloride and inhalation of carbon monoxide were concluded to be the cause of this outbreak of illness (Froneberg et al., 1982).

Dermal exposure to liquid hydrochloric acid can result in severe chemical burns and scarring. Permanent ocular damage may occur if the liquid is splashed into the eyes.

In recent years concern has arisen over increases in the levels of irritant air pollutants and their potential to increase the incidence of asthmatic attacks. The potential effect of HCl was studied in 10 young adult asthmatics (Stevens et al., 1992).

TABLE 47.2 Effects of Exposure to Hydrogen Chloride

Concentration, ppm	Effect
0.067–0.134	Threshold for odor detection and change in respiratory pattern
5	No organic damage
10	Irritation but work undisturbed
10–50	Work difficult but possible
35	Throat irritation after short exposure
50–100	Intolerable; work impossible
1000–2000	Brief exposure dangerous; laryngospasm
13,000–20,000	Lethal after a few minutes

Volunteers were exposed to 0.8–1.8 ppm of HCl during 45-min sessions. Researchers reported no effect on forced expiratory volume, peak flow rate, or total respiratory flow.

Children exposed to the same levels of hydrogen chloride as adults may receive a larger dose because they have greater lung surface area:body weight ratios and increased minute volumes:weight ratios. In addition, they may be exposed to higher levels than adults in the same location because of their short stature and the higher levels of hydrogen chloride found nearer to the ground.

Chronic Effects

Chronic or prolonged exposure to hydrogen chloride gas (above the OSHA PEL) or to mist has been associated with changes in pulmonary function, chronic inflammation of the bronchi, nasal ulceration, and symptoms resembling acute viral infection of the upper respiratory tract as well as inflammation of the skin, discoloration and erosion of dental enamel, and inflammation of the eye membrane. However, these effects were not corroborated in another worker population upon physical examination (Patil et al., 1970).

The reproductive hazards of hydrogen chloride to humans are unknown. Few studies have been directed at the reproductive effects in experimental animals exposed to hydrogen chloride. No data were located pertaining to maternal transfer of hydrogen chloride through the placenta or in breast milk. Hydrogen chloride is not included in the Reproductive and Developmental Toxicants, a 1991 report published by the U.S. General Accounting Office (GAO) that lists 30 chemicals of concern because of the widely acknowledged reproductive and developmental consequences.

No information is available on the carcinogenic effects of hydrochloric acid in humans. In one study, no carcinogenic response was observed in rats exposed via inhalation (HSDB, 1993). The Environmental Protection Agency (EPA) has not classified hydrochloric acid with respect to potential carcinogenicity (Bond et al., 1991).

INDUSTRIAL HYGIENE

Hydrogen chloride is a pyrolysis product of PVC and is considered the principal toxic component of PVC smoke (Barrow et al., 1979). Thus it often is encountered by fire-fighters responding to structure fires and has been implicated as the cause of death in one case (Dyer and Esch, 1976). A positive-pressure, self-contained breathing apparatus (SCBA) is recommended as the respiratory protection in response situations that involve exposure to potentially unsafe levels of hydrogen chloride (Treitman et al., 1980). Chemical-protective clothing is recommended as the appropriate skin protection because hydrogen chloride can cause skin irritation and burns.

MEDICAL MANAGEMENT

There is no antidote for hydrogen chloride poisoning.

The treatment consists of support for respiratory and cardiovascular functions. Victims who are able may assist with their own decontamination. Remove contaminated clothing while flushing exposed skin and hair with water for 3–5 min, wash thoroughly with soap and water. Use caution to avoid hypothermia when decontaminating children or the elderly. Use blankets or warmers when appropriate. Double bag contaminated clothing and personal belongings.

Flush exposed or irritated eyes with tepid plain water or saline for 15 min. Eye irrigation should be carried out simultaneously with other basic care and transport. Remove contact lenses if easily removable without additional trauma to the eye.

Be certain that victims have been decontaminated properly. Victims who have undergone decontamination or who have been exposed only to gas and who have no symptoms of skin or eye irritation pose no serious risk of secondary contamination. In such cases, first responder personnel require no specialized protective gear.

Quickly access for a patent airway. If trauma is suspected, maintain cervical immobilization manually and apply a cervical collar and a backboard when feasible. Ensure adequate respiration and pulse. Administer supplemental oxygen as required and establish intravenous access if necessary. Place on a cardiac monitor.

In cases of respiratory compromise, secure airway and respiration via endotracheal intubation. If not possible, perform cricothyroidotomy if equipped and trained to do so.

Treat patients who have bronchospasm with aerosolized bronchodilators. The use of bronchial-sensitizing agents in situations of multiple chemical exposures may pose additional risks. Consider the health of the myocardium before choosing which type of bronchodilator should be administered. Cardiac-sensitizing agents may be appropriate; however, the use of these agents after exposure to certain chemicals may pose enhanced risk of cardiac arrhythmias (especially in the elderly). Sympathomimetic bronchodilators generally will reverse bronchospasm in patients exposed to hydrogen chloride.

Consider a racemic epinephrine aerosol for children who develop stridor. Administer a dose of 0.25–0.75 ml of 2.25% racemic epinephrine solution in 2.5 cc water, and repeat every 20 min as needed.

Patients who are comatose, hypotensive, or are having seizures or cardiac arrhythmias should be treated according to advanced life support (ALS) protocols.

In cases of ingestion, do not induce emesis. Do not administer activated charcoal or attempt to neutralize stomach contents. Victims who are conscious and are able to swallow should be given 4–8 ounces of water or milk (children's dose is 2–4 ounces).

CHLORINE DIOXIDE

Target organ(s): Eyes and the respiratory system

Occupational exposure limits:

OSHA: PEL: 0.1 ppm (0.3 mg/m³) as an 8-h TWA concentration (29 CFR 1910.1000, 2006)

NIOSH: REL: 0.1 ppm (0.3 mg/m³) as a TWA for up to a 10-h workday and an hour workweek and a STEL of 0.3 ppm (0.9 mg/m³)

ACGIH: TLV: (8-h TWA 0.1 ppm mg/m³) as a TWA for a normal 8-h workday and a 40-h workweek and an STEL of 0.3 ppm (0.83 mg/m³) for periods not to exceed 15 min. Exposures at the STEL concentration should not be repeated more than four times a day and should be separated by intervals of at least 60 min

Reference values:

RfD: 3×10^{-2} mg/kg-day

RfC: 2×10^{-4} mg/m³

TDI: 30 µg/kg of body weight

Risk/safety phrases: [list information for classification and labeling]

BACKGROUND AND USES

Chlorine dioxide has been used to bleach cellulose, flour, beeswax, leather, paper pulp, oils, and textiles. It is used as a common compound for water disinfection and in the antimicrobial gel Alcide, and in other bactericides, antiseptics, and deodorizers. It is used in water purification as a taste and odor control agent (HSDB, 2005). Recently, ClO₂ has been shown to inactivate the human immunodeficiency virus (HIV) in medical waste disposal processes (Farr and Walton, 1993).

PHYSICAL AND CHEMICAL PROPERTIES

The synonyms for chlorine dioxide include chlorine oxide, anthium dioxide, chlorine peroxide, chlorine (IV) oxide, chloroperoxyl, chloryl radical, alcide, doxcide 50. Chloride dioxide decomposes when heated and emits toxic fumes of hydrogen chloride (HSDB, 2005). It is unstable in light but will remain stable in dark if it is pure (HSDB, 2005). However, chlorides can catalyze even in the dark. Chloride dioxide reacts only by oxidation, while it is an efficient disinfectant because it does not vary with pH (HSDB, 2005).

Chemical properties:

Chemical formula: ClO₂

Molecular weight is 67.5 g/mol.

CASRN 10049-04-4

Physical properties:

Color: A yellow or reddish-yellow gas at room temperature. The solid is a yellowish-red crystalline mass. The liquid is reddish-brown in color.

Odor: Unpleasant chlorine-like odor

Boiling point: (at 760 mmHg): 11 °C (51.8 °F)

Specific gravity: 1.64 at 0 °C (32 °F) (liquid)

Vapor density: (air = 1): 2.4

Melting point: -59 °C (-74.2 °F)

Vapor pressure: Greater than 760 mmHg at 20 °C (68 °F)

Solubility: Soluble in water (with decomposition), alkalies, and sulfuric acid

MAMMALIAN TOXICOLOGY

Acute Effects

In general, most effects noted from occupational exposure to ClO₂ are irritation responses to dermal and inhalation exposure. The unpleasant odor at high concentrations can irritate mucous membranes and the upper respiratory tract. Inhalation can produce coughing, wheezing, respiratory distress, and congestion in the lungs. In a group of workers who reported

at least one instance of overexposure to chlorine or chlorine dioxide, or both, significant changes were noted in the FEV₁/FVC ratio and chest symptoms increased (Salisbury et al., 1991). No distinction was made between the two gas exposures. Eye irritation may occur and some workers may see halos around lights for a short time after exposure.

Chronic Effects

Ingestion of water with 5 ppm ClO₂ did not have any measurable effect in a group of healthy human volunteers (Lubbers et al., 1984). There has been some concern about chlorine dioxide ingestion and the formation of a thyroid inhibitory substance by means of a redox interaction with iodine and nutritional biochemicals, but this has not been verified (Bercz and Bawa, 1986). ClO₂ is considered not classifiable as to its carcinogenicity in humans.

Workers exposed for 5 years to average chlorine dioxide concentrations below 0.1 ppm but with excursions to higher concentrations had symptoms of eye and throat irritation, nasal discharge, cough, and wheezing; on bronchoscopy, bronchitis was observed in 7 of the 12 workers. Concentrations of 0.25 ppm and less have been reported to worsen mild respiratory ailments. Two adults who ingested 250 ml of a 40 mg/l solution of chlorine dioxide experienced headache, nausea, abdominal discomfort, and lightheadedness within 5 min of ingestion. The symptoms disappeared within another 5 min.

Animal studies have reported the effects of ClO₂ exposure in young laboratory animals. There appears to be some effect on thyroid function and the development of the central nervous system in rats prenatally or postnatally exposed to chlorine dioxide (Orme et al., 1985; Toth et al., 1990).

Mechanism of Action

The metabolism of chlorine dioxide yields a number of different compounds, including chlorite, chlorate, chloramine, and chlorine. These metabolites are of similar low toxicity. There may be some relationship between the endogenous formation of chloroform and ClO₂ exposure, as demonstrated in rats (Suh et al., 1984).

SOURCES OF EXPOSURE

The sources of exposure to chlorine dioxide are as follows:

In the manufacture and transportation of chlorine dioxide.

During its use as a bleaching agent for paper and wood pulp, textiles, cellulose, beeswax, and leather; used to bleach mature flour.

During its use in swimming pool and municipal water treatment for purification and to remove tastes and odors by oxidation; use as a wastewater disinfecting agent; use in

bleaching fats and oils; use in the cleaning and de-tanning of leather.

INDUSTRIAL HYGIENE

The reactions used to manufacture ClO₂ include sodium chlorate and sulfuric acid with sulfur dioxide and an alternate mechanism of methanol reacted with HClO₃. The primary routes of occupational exposure are inhalation and dermal contact. The general population may be exposed to ClO₂ through residues in ClO₂-treated drinking water. This compound is flammable and combustible and should be treated with caution around flame, heat, and reactive compounds. Protective gear should prevent skin and inhalation exposure. Simon et al. (1987) tested a variety of available respirator cartridges and found all of them to be efficient in removing chlorine dioxide gas. Some situations may require the use of respirators to control exposure. Respirators must be worn if the ambient concentration of chlorine dioxide exceeds prescribed exposure limits. Concentrations of the gas in the workplace can be detected by diffusive samplers followed by nonsuppressed ion chromatography (Bjorkholm et al., 1990; Hekmet et al., 1994; Poovey and Rando, 1995).

The NIOSH, OSHA, and ACGIH have set the allowable exposure limits for ClO₂ at 0.1 ppm (0.3 mg/m³) with a ceiling value of 0.3 ppm (0.9 mg/m³) (NIOSH, 1994; ACGIH, 1996). Conveniently, the regulatory guideline for ClO₂ corresponds with the low odor detection limit reported by Ruth (1986). For most workers, odor detection will serve as a warning to possible overexposures.

If chlorine dioxide contacts the skin, workers should immediately wash the affected areas with soap and water. Clothing contaminated with chlorine dioxide should be removed immediately, and provisions should be made for the safe removal of the chemical from the clothing. Persons laundering the clothes should be informed of the hazardous properties of chlorine dioxide, particularly its potential for causing severe irritation.

A worker who handles chlorine dioxide should thoroughly wash hands, forearms, and face with soap and water before eating, using tobacco products, using toilet facilities, applying cosmetics, or taking medication. Workers should not eat, drink, use tobacco products, apply cosmetics, or take medication in areas where chlorine dioxide or a solution containing chlorine dioxide is handled, processed, or stored.

MEDICAL MANAGEMENT

Some populations are more at risk when exposed to ClO₂; individuals with a glucose-6-phosphate dehydrogenase deficiency are sensitive to ClO₂, which can affect the capacity for maintaining significant levels of glutathione (HSDB, 2005).

Remove an incapacitated worker from further exposure and implement appropriate emergency procedures. If the eyes were involved they should be irrigated with water immediately. The skin should be washed with soap and water.

If respiratory irritation occurs, respiratory support should be given including oxygen and aerosolized bronchodilators. In cases of respiratory compromise, secure the airway and respiration via endotracheal intubation. If not possible, perform cricothyroidotomy if equipped and trained to do so.

Rinse out the mouth and drink a few glasses of water or milk immediately, but only if the person is fully conscious. Do not induce vomiting. Seek hospital treatment if more than a minimal amount has been swallowed.

HYDROGEN FLUORIDE

Target organ(s): Bones, eyes, respiratory system, skin, and teeth

Occupational exposure limits:

OSHA: PEL: 3 ppm; 2 mg/m³ TWA

NIOSH: REL: 3 ppm; 2.5 mg/m³ TWA and a ceiling: 15 min of 6 ppm, 5 mg/m³ (NIOSH, 1994)

ACGIH: TLV: 0.5 ppm TWA with a 2 ppm ceiling

Reference values:

RfD: 8×10^{-2} mg/kg/day

RfC: Not established

Minimal risk level (MRL): 0.02 ppm

Risk/safety phrases: Toxic by inhalation, in contact with skin and if swallowed. Do not breathe dust. Avoid contact with skin and eyes.

BACKGROUND AND USES

Fluoride is used in preventing tooth decay by adding it to drinking water, tooth paste, and mouth washes. The dentist also directly provides fluoride therapy on children’s teeth. Fluoride in the form of a pill increases bone mineral density in osteoporosis and is showing promise in rheumatoid arthritis and Crohn’s disease. Hydrogen fluoride is manufactured from calcium fluoride; it is mainly used in the production of synthetic cryolite, aluminium fluoride (AlF_3), motor gasoline alkylates, and chlorofluorocarbons (IPCS, 2002). Production of chlorofluorocarbons is decreasing due to the restrictions on their effect on the environment (IPCS, 2002). Hydrogen fluoride may also be found in commercial rust removers (IPCS, 2002).

PHYSICAL AND CHEMICAL PROPERTIES

The synonym of hydrogen fluoride is anhydrous hydrofluoric acid: HF-A.

Chemical properties:

Chemical formula: HF

Molecular weight is 20.01 g/mol

CASRN 7664-39-3

Physical properties:

Color: Colorless gas or fuming liquid

Odor: Strong, irritating odor

Boiling point: (at 760 mmHg): 19.4 °C (67 °F)

Specific gravity: 0.987 at 0 °C (32 °F) (liquid)

Melting point: -83.3 °C (-118 °F)

Vapor density: 0.92

Vapor pressure at 2.5 °C (36.5 °F): 400 mmHg

Solubility: Very soluble in water, in alcohol, and in most organic solvents; slightly soluble in ether

Evaporation rate: Data not available

MAMMALIAN TOXICOLOGY

Exposure to hydrogen fluoride and its aqueous solution can occur through inhalation, ingestion, and eye or skin contact (Sittig, 1991).

Acute Effects

Exposure to HF or fluorine can produce mucosal, respiratory, and ocular irritation. Acute and chronic conjunctivitis and eczema of the eyelids have been reported. In one case, repeated overexposure to hydrogen fluoride vapor was associated with cartilaginous changes and osteomalacia of the nasal septum and nasal mucosa (Miszke et al., 1984). The authors concluded that repeated irritation of the nasal mucosa by hydrofluoric acid can cause hypertrophic inflammation. In addition, exposure to high concentrations of the vapors of hydrofluoric acid characteristically results in ulcerative tracheobronchitis and hemorrhagic pulmonary edema; this local reaction is equivalent to that caused by gaseous hydrogen chloride (Gosselin et al., 1984).

From accidental, occupational, and volunteer exposures, it is estimated that the lowest lethal concentration for a 5-min human exposure to hydrogen fluoride is in the range of 50–250 ppm. Significant exposures by the dermal or inhalation route may cause hypocalcemia and hypomagnesemia; cardiac arrhythmias may follow. Acute renal failure has also been documented after an ultimately fatal inhalation exposure (Hathaway et al., 1991).

Gaseous F₂ reacts violently with the skin to produce thermal burns. Burns resulting from an exposure to hydrogen fluoride or fluoride may be life threatening and require immediate medical attention. Although actual damage to

the skin may be minor, the systemic effects of hydrogen fluoride exposure may quickly create a life-threatening situation. Death typically is the result of respiratory failure or ventricular arrhythmia. An exposure of as little as 2.5% of the body surface to pure hydrogen fluoride has reportedly resulted in death caused due to hypocalcemia (Bertollini, 1992). Tissue injury may increase for days after exposure (Anderson and Anderson, 1988). Exposures to weak solutions of hydrofluoric acid (<20%) may cause considerable pain, erythema, and edema but do not result in long-term morbidity (Upfal and Doyle, 1990). Pain may be delayed for 2–24 h. Although less serious, an exposure to dilute forms of hydrofluoric acid is much more common.

Chronic Effects

Fluorosis is characterized by increased bone density of the spine and pelvis, calcification of ligaments, and hyperostosis. These skeletal changes were first noted in workers exposed to fluoride during cryolite processing as early as the 1930s (Møller and Gudjonsson, 1932). Industrial hygiene practices have since prevented any cases of fluorosis of the crippling severity reported early in this century. However, some skeletal changes may still be noted in workers exposed to fluoride. In one report of a fluorspar processing facility, 22% of the workers had radiological changes indicative of fluorosis (Desai et al., 1983).

Fluorosis of the trabecular bone tissue may be reversible. Grandjean and Thomson (1983) examined 17 cases of skeletal fluorosis 8–15 years after exposure ended. They found that trabecular sclerosis had faded extensively, whereas cortical bone thickening and the calcification of muscle insertions and ligaments remained relatively unchanged.

Grandjean et al. (1992) and Grandjean et al. (1993) detected an excess of lung, larynx, and urinary bladder cancer in a cohort of 522 workers exposed to fluorite during cryolite processing. The higher incidence of respiratory and urinary cancers was especially pronounced in men who were under 35 years of age at first employment. There was no consistent relationship between the length of employment and incidence of cancer, but the highest number of incidences occurred after 10–19 years of employment.

Ingestion of an estimated 1.5 g of hydrofluoric acid produces sudden death; however, repeated ingestion of small amounts of hydrogen fluoride may cause fluoride osteosclerosis (Gosselin et al., 1984).

Mechanism of Action(s)

Hydrogen fluoride can pass easily through the cell membranes by nonionic diffusion. It is absorbed almost completely through the digestive tract (IPCS, 2002). It binds to magnesium and calcium, making them unavailable for various biological functions (Greco et al., 1988; Reinhart, 1992).

Calcium is only weakly buffered in the body by protein-bound and bone stores. Small amounts of fluoride can drastically disrupt metabolism. Fluoride inhibits several enzymes that can diminish tissue respiration and anaerobic glycolysis (HSDB, 2007).

Several investigations demonstrated that fluoride can induce oxidative stress and modulate intracellular redox homeostasis, lipid peroxidation and protein carbonyl content, as well as alter gene expression and cause cellular apoptosis (Barbier et al., 2010).

INDUSTRIAL HYGIENE

Methods that are effective in controlling worker exposures to hydrogen fluoride include process enclosure, local exhaust ventilation, general dilution ventilation, and the use of personal protective equipment.

Medical Surveillance

A study of the Swiss aluminum industry concluded that screening for early detection of fluorosis is more cost effective than allowing employees to progress to a disabling condition (Morabia et al., 1989). This benefit would be realized even if the prevalence of fluorosis in the workforce is <10%.

MEDICAL MANAGEMENT

Hydrofluoric acid burns should be immediately irrigated and the person transported immediately to an emergency care facility, even if he or she is asymptomatic for systemic effects. A subscleral injection of 10% calcium gluconate should be given to manage severe burns (Anderson and Anderson, 1988; Sheridan et al., 1995). Calcium supplementation should be monitored to ensure that hypercalcemia does not result (Greco et al., 1988). Hydrofluoric acid burns are usually treated by traditional means, but severe cases may require surgery and skin grafts (Buckingham, 1988). When treating victims of hydrogen fluoride burns, medical personnel must protect themselves with latex or vinyl gloves and plastic aprons. Oral administration of a high dose of CaCl₂ or MgSO₄ is an effective method for treating severe oral fluoride poisoning (Kao et al., 2004).

IODINE

Target organ(s): Cardiovascular system, CNS, eyes, respiratory system, and skin

Occupational exposure limits:

OSHA: PEL: 0.1 ppm; 1 mg/m³ TWA.

NIOSH: REL: 0.1 ppm; 1 mg/m³ TWA (NIOSH, 1994).

ACGIH: TLV: 0.1 ppm TWA with a 1 mg/m³ ceiling.

Reference values:

RfD: Not established

RfC: Not established

MRL: 0.01 mg/kg/day

Risk/safety phrases: Corrosive

BACKGROUND AND USES

Iodine is the largest molecular weight halogen of any industrial significance. Although I₂ itself is not used extensively, salts and other inorganic compounds containing iodine, such as potassium iodide and iodine monochloride, are used in a variety of settings. A large number of I₂ uses are found in the medical setting, where it is used as an antiseptic and biocide in such compounds as USP tincture and Lugol's solution, so named to identify the percent of I₂ in a solution. Other salts are used in photography and explosives and as reaction intermediates and catalysts.

PHYSICAL AND CHEMICAL PROPERTIES

Synonyms include hydrogen fluoride, anhydrous hydrofluoric acid; HF-A

Chemical properties:

Chemical formula: I₂

Molecular weight is 253.8 g/mol

CASRN 7553-56-2

Physical properties:

Color: Violet solid noncombustible

Odor: Sharp, characteristic odor

Boiling point: (at 760 mmHg): 185 °C (365 °F)

Specific gravity: 4.93 at 0 °C (32 °F)

Melting point: 133.3 °C (236 °F)

Vapor density: 0.92

Vapor pressure at 25 °C (77 °F): 0.3 mmHg

Solubility: 0.01%.

Evaporation rate: Data not available

MAMMALIAN TOXICOLOGY

Acute Effects

Acute toxicity typically occurs at dosages of more than 1 g of iodine, according to the Linus Pauling Institute. Acute iodine toxicity may cause symptoms such as diarrhea, nausea and vomiting, as well as a burning sensation in the stomach, throat, and mouth. A weak pulse and coma are also potential complications of acute toxicity.

Dermal exposure occurs primarily in settings where cleaners containing iodine are used. Skin eruptions, fever, and hypersensitivity reactions are commonly reported during overexposure. Occupational contact dermatitis was reported in a butcher who used povidone-iodine as an antibacterial solution for cuts (Lachapelle, 1984). A fisherman exposed to seaweed that contained iodine had extensive lesions on the exposed skin (Van der Willigen et al., 1988). Systemic effects from dermal exposure are rare but have been reported.

Chronic Effects

A case of thyrotoxicosis was observed in a woman who was a beautician and was chronically exposed to cosmetics containing iodine (DelGuerra et al., 1992). A persistent remission was noted after exposure to the cosmetics was discontinued. Iodine monochloride (CASRN 7790-99-0) is harmful to the skin and may cause burns with dark, painful patches.

Inhalation exposure to iodine is irritating to the mucous membranes and may also result in congestion, throat irritation, bronchitis, headache, and other symptoms. The vapor can also irritate the eyes and skin.

An examination of an operating room revealed high concentrations of iodine as a result of scrubbing with surgical cleansing agents containing iodine and of hospital waste and spills of iodine-containing solutions (Morris et al., 1986). The authors suggest that susceptible individuals may experience systemic effects, such as thyrotoxicosis, at estimated intake levels. Thyroid and metabolic disturbances may be possible after an occupational exposure to iodine, but they have not been reported.

Chronic toxicity may develop when intake is >1.1 mg/day. The vast majority of people who ingest excess amounts of iodine remain euthyroid. Occasionally, iodine-deficient individuals who ingest excess amounts of iodine develop hyperthyroidism (Jod-Basedow phenomenon). Excess uptake of iodine by the thyroid may inhibit thyroid hormone synthesis (called Wolff-Chaikoff effect). Thus, iodine toxicity can eventually cause iodide goiter, hypothyroidism, or myxedema. Very large amounts of iodide may cause a distinct taste in the mouth, increased salivation, gastrointestinal irritation, and skin lesions. Patients exposed frequently to large amounts of radiographic contrast dyes or the drug amiodarone need to have their thyroid function monitored (Johnson, 2012).

Mechanism of Action(s)

Ingested iodine not used by the thyroid but is excreted in the urine and other bodily fluids. Inhaled iodine is converted to the less toxic iodide and subsequently excreted. The toxic effects of iodine in high concentrations result from fluid loss in the affected tissues.

INDUSTRIAL HYGIENE

The primary manufacturing procedure for the preparation of iodine is the purification and extraction by acidification with sulfuric acid and precipitation with chlorine. Compounds that contain iodine are considered more hazardous than those that contain chlorine and bromine, but iodine compounds are not used as extensively for industrial applications. The primary route of exposure in most settings is dermal contact, although inhalation of the vapor may occur when the solid is heated or reacted. The use of iodine in some hand cleansers allows for some exposure by both routes when a scrubbing action is required. Protective clothing and gloves should be worn during prolonged exposure. Respirators are recommended for use when airborne concentrations are likely to exceed 1–2 ppm (Ruth, 1986).

MEDICAL MANAGEMENT

In the event of exposure to radioactive iodine, there are several techniques to help protect the patient from too much intake of the radioactive iodine, which can cause the development of thyroid nodules and thyroid cancer. Potassium iodide is a nonradioactive form of iodine, which binds to thyroid receptors to compete with the radioactive iodine. The radioiodine that does not bind to thyroid receptors is eventually cleared from the body in the urine. Potassium iodide isn't a cure-all and is most effective if taken within a day of exposure.

Prussian blue is a type of dye that binds radioactive elements known as cesium and thallium. These radioactive particles are then excreted in the feces. This treatment speeds up the elimination of the radioactive particles and reduces the amount of radiation that cells may absorb.

Diethylenetriamine pentaacetic acid (DTPA) binds to particles of the radioactive elements plutonium, americium, and curium. The radioactive particles pass out of the body in urine, reducing the amount of radiation absorbed.

BROMINE

Target organ(s): Cardiovascular system, CNS, kidneys, and respiratory system

Occupational exposure limits:

OSHA: PEL: 0.1 ppm; 0.7 mg/m³ TWA.

NIOSH: REL: 0.1 ppm TWA, 0.7 mg/m³; 0.3 ppm, 2.0 mg/m³ STEL (NIOSH, 1994).

ACGIH: TLV: 0.1 ppm, 0.66 mg/m³ TWA; 0.2 ppm, 1.3 mg/m³ STEL (ACGIH, 1996).

Reference values:

RfD: Not established

RfC: Not established

MCL: 0.01 ppm

Risk/safety phrases: Strong oxidizer, corrosive

BACKGROUND AND USES

Bromine compounds are a major component of fire retardants and are also used in gold extraction, drilling fluids (calcium bromide), sanitation, and agriculture (methyl bromide), as laboratory reagents and intermediates, and in ethylene dibromide, an antiknock component of gasoline. The elemental form of this compound is an alternative for chlorine used in swimming pools. A natural element, bromine is found in abundance in the earth's crust and in seawater in a variety of inorganic salts and organic compounds. It is the only halogen that is a liquid at room temperature.

PHYSICAL AND CHEMICAL PROPERTIES

Synonyms include molecular bromine

Chemical properties:

Chemical formula: Br₂

Molecular weight is 159.8 g/mol

CASRN 7726-95-6

Physical properties:

Color: Dark reddish-brown fuming liquid with suffocating fumes
 Boiling point: (at 760 mmHg): 59.4 °C (139 °F)
 Specific gravity: 3.12 at 0 °C (32 °F)
 Melting point: -7.2 °C (19 °F)
 Vapor pressure: 172 mmHg
 Solubility: 4%
 Evaporation rate: Data not available

MAMMALIAN TOXICOLOGY

Acute Effects

Bromine is corrosive to human tissue in a liquid state and its vapors irritate the eyes and throat. Bromine vapors are very toxic upon inhalation (Table 47.3). The most important health effects that can be caused by bromine-containing organic contaminants are the malfunctioning of the nervous system and disturbances in genetic materials.

Organic bromines can also cause damage to organs such as liver, kidneys, and lungs. Bromine can cause stomach and gastrointestinal malfunctioning. Some forms of organic bromines, such as ethylene bromine, can even cause cancer.

Acute inhalation exposure to bromine gas can be hazardous, depending on the duration and concentration. An exposure to a lower concentration for a longer period can have the same health effects as an exposure to a higher concentration for a shorter period (Withers and Lees, 1986).

Inflammation of the tongue and palate may be seen as well. Some of the symptoms developed after the individual had a seemingly healthy period of time, and others were reported and treated immediately. More severe respiratory responses to bromine exposure have included case reports of chemical pneumonitis and pneumomediastinum (Kraut and Lilis, 1988; Lossos et al., 1990).

Brief dermal contact with the vapor and liquid form may cause severe chemical burns, manifesting as pustules and vesicles. Prolonged contact with bromine can result in painful, deep ulcers.

TABLE 47.3 Effects of Exposure to Bromine

Concentration, ppm	Effect(s)
0.05–3.5	Odor threshold
0.1	TLV–TWA limit
>1.0	Irritation level
40–60	Toxic pneumonitis and pulmonary edema
1000	Fatal within a few minutes

Chronic Effects

Human studies have not identified bromine as a carcinogenic compound. Some brominated compounds, such as potassium bromate, have been reported to have carcinogenic effects in animal studies (Kurokawa et al., 1990). Inorganic bromines are found in nature. But more bromine has been included in daily life through common use in water and in pesticides. These bromines can damage the nervous system and thyroid gland after prolonged low level exposure. Bromine is potentially capable of extensive damage to the lower respiratory tract. Limited studies have reported diffuse interstitial pulmonary fibrosis, emphysema, and/or airway hyperreactivity secondary to acute exposure to bromine (Kraut and Lilis, 1988; Lossos et al., 1990).

Mechanism of Action(s)

Absorbed bromine can be excreted in the urine or stored in the tissue as bromide. This accounts for the cumulative effect of some bromine exposures. Due to its reactivity, bromine does not persist as an element in living tissue but quickly forms bromide. In this form, it may be deposited in the tissues, displacing other halogens (Sticht and Kaferstein, 1988).

INDUSTRIAL HYGIENE

As with other halogens, bromine can be extracted from brine solutions, first oxidized with chlorine, and then vaporized with air or steam. Many brominated compounds can react violently and form explosive mixtures with a variety of compounds, such as acetylene, ammonia, and organic substances such as rubber and cork. Inhalation and dermal exposures are most common with bromine. Workers should be protected from high concentrations of bromine with proper engineering controls and protective gear. Pool service personnel using elemental bromine should wear gloves and goggles to protect themselves from an accidental splashing exposure. The low odor threshold of this chemical is reported to be 0.392 mg/m³ (50 ppb), with an irritating concentration of 2 mg/m³ (0.3 ppm) (Ruth, 1986). This would indicate an inadequate irritation warning of concentrations exceeding the regulatory guidelines.

MEDICAL MANAGEMENT

Acute contact with bromine liquid or vapor requires removal from the source of bromine contamination. An exposure of bromine to the eyes should be irrigated with copious amounts of tepid water for at least 15 min. If irritation, pain, swelling, lacrimation, or photophobia persist, further medical evaluation is recommended. In instances when bromine comes in

contact with clothing or the skin, it is necessary to remove the contaminated clothing and thoroughly wash the affected area with copious volumes of water for 20 min. Since the effects may be delayed, close observation for blistering and discoloration of the skin is required for the next 24 h (Sagi et al., 1985).

An exposure to bromine vapors can cause respiratory symptoms and should receive respiratory support in accordance with symptomatology, including maintenance of an adequate airway, oxygen, antibronchospasm therapy, including inhaled beta adrenergic agonist and a short course of corticosteroids and antibiotics if there is evidence of infection. Assisted or supported ventilation with tracheal intubation and positive pressure ventilation may be needed.

PHOSGENE

BENJAMIN WONG, MICHAEL W. PERKINS, AND ALFRED M. SCIUTO

First aid:

Eye: Immediately wash (irrigate) the eyes with large amounts of water, occasionally lifting the lower and upper lids. Get medical attention immediately.

Skin: Immediately flush the contaminated skin with water. Remove contaminated clothing and flush the skin with water. Get medical attention promptly.

Inhalation: Move the exposed individual to fresh air at once. Keep the affected person calm and at rest in a half-upright position. Monitor and maintain the airway and blood pressure. If breathing has become difficult administer oxygen; if breathing has stopped, perform artificial respiration. Get medical attention as soon as possible.

Target organ(s): Eyes, skin, respiratory system

Occupational exposure limits:

OSHA PEL: 0.1 ppm (0.4 mg/m³)

American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV): 0.1 ppm (0.4 mg/m³)

NIOSH REL: 0.1 ppm (0.4 mg/m³) TWA, 0.2 ppm (0.8 mg/m³) 15-min ceiling

Reference values:

RfC: $3 \times 10^{-4} - 5 \times 10^{-4}$ mg/m³

Risk/safety phrases:

R26: Very toxic by inhalation

R34: Causes burns

S1/2: Keep locked up and out of the reach of children

S9: Keep container in a well-ventilated place

S26: In case of contact with eyes, rinse immediately with plenty of water and seek medical advice

S36/37/39: Wear suitable protective clothing, gloves, and eye/face protection

S45: In case of accident or if you feel unwell, seek medical advice immediately (show the label where possible)

BACKGROUND AND USES

Phosgene was first synthesized by John Davy (1790–1868) in 1812 when he exposed a mixture of carbon monoxide and chlorine to sunlight (Davy, 1812). During the nineteenth century, phosgene was slowly integrated into the chemical industry but gained particular notoriety as the most heavily used chemical warfare agent (CWA) of World War I (WWI) (NAS/NRC Board on Environmental Studies and Toxicology, 1984; Tuorinsky and Sciuto, 2008). Although banned from use in warfare by the Geneva Protocol in 1929, phosgene was used again during World War II (WWII). Today, phosgene is an important intermediate in the production of polyurethanes and other chemicals and is commercially prepared by passing chlorine and excess carbon monoxide over activated carbon (Via et al., 2002).

As a CWA in WWI, phosgene was used offensively by both Allied and Axis powers to produce mass casualties. Some reports suggest that phosgene alone was responsible for nearly 80% of all gas casualties, numbering approximately 71,000 in total between 1914 and 1918 (Gilchrist and Matz, 1933; Elsayed and Salem, 2006). The intent of CWAs is not solely to exterminate the opposition, but also to incapacitate the enemy, thus removing soldiers from the battlefield. Phosgene gassing during WWI caused men to

lose 311,000 days to hospitalization, an astonishing 852 man-years (Jackson, 1933). After the Geneva Protocol was established in 1929, prohibiting the use of chemical and biological weapons, the only documented use of phosgene as a CWA was by the Imperial Japanese Army against the Chinese during the Second Sino-Japanese War/WWII, with 375 separate occasions occurring during the battle of Wuhan from August to October of 1938 (Tanaka, 1988; Yoshimi and Matsuno, 1997).

Since WWII, phosgene has gained importance in the chemical industry as a reactive chemical intermediate and is used to help supply chlorine groups to reaction products in phosgenation reactions (Babad and Zeiler, 1973). The principal use of phosgene is in the polyurethane industry, which consumes over 85% of the world's phosgene output. The polycarbonate industry accounts for approximately 10% of phosgene used, and the remaining 10% is used in the production of aliphatic diisocyanates, monoisocyanates, chloroformates, agrochemicals, and intermediates for dye-stuffs and pharmaceuticals (NAS/NRC Board on Environmental Studies and Toxicology, 1984). Estimated annual worldwide consumption of phosgene ranges from 5 to 10 million tons (Via et al., 2002; Cotarca and Eckert, 2004; U.S. Environmental Protection Agency, 2005), with U.S. production alone around 1 million tons (Bast and Bress, 2002). Production estimates are difficult to obtain because synthesis of phosgene is almost entirely captive, meaning that more than 99% is used in the manufacture of other chemicals within a plant boundary. In the United States, this is the case for the overwhelming majority of phosgene generation (Cotarca and Eckert, 2004); and only one company sells phosgene in the merchant market.

While phosgene has been a military and terrorist threat for many years due to its low cost and ease of production, it is also an occupational and an environmental hazard. Although phosgene is nearly completely consumed during industrial use, it can be released through failed processes. Phosgene is an environmental pollutant and has been detected worldwide in ambient air samples (Singh, 1976; U.S. Environmental Protection Agency, 2005). It can also be formed by the thermal decomposition of chlorinated hydrocarbons, posing a threat for welders, refrigeration mechanics, and car repairmen (Brown and Birk, 1980). Of recent note in the United States, on January 23, 2010, an operator working at a DuPont chemical plant in the phosgene cylinder storage area was sprayed in the face and upper torso with phosgene when a flexible hose suddenly ruptured. Although exposed to a significant amount of phosgene, he did not exhibit immediate signs of respiratory distress. However, approximately 3 h later, after he had arrived at the hospital, his condition deteriorated and he died the following night (U.S. Chemical Safety and Hazard Investigation Board, 2011). Phosgene gas has been and

TABLE 48.1 Physical Properties of Phosgene

CASRN:	75-44-5
Structural formula:	COCl_2
Formula weight:	98.92
Boiling point:	8.2 °C
Liquid density, 0 °C:	1.4187 g/ml
Gas density, 20 °C:	4.39 g/l
Specific gravity, gas, 20 °C:	3.4
Vapor pressure:	1180 mmHg at 20 °C
Solubility:	Slightly soluble in water (5940 mg/l at 25 °C); hydrolyzes to hydrochloric acid and carbon dioxide. Soluble in carbon tetrachloride, chloroform, acetic acid, benzene, and toluene
Color:	Colorless
Odor:	Sweet in low concentrations; sharp, pungent (odor of moldy hay) in higher concentrations
Odor threshold:	0.4–1.5 ppm
Irritation threshold:	3 ppm
Conversion factors:	1 ppm = 4.05 mg/m ³ 1 mg/m ³ = 0.247 ppm (25 °C, 760 mmHg)

continues to be a potentially serious and occasionally fatal substance (Polednak and Hollis, 1985).

PHYSICAL AND CHEMICAL PROPERTIES

Phosgene, also known as CG, carbon dichloride oxide, carbonic dichloride, carbon oxychloride, carbonyl chloride, carbonyl dichloride, and chloroformyl chloride, is a colorless, volatile, synthetic irritant and asphyxiating gas. In aqueous solution, hydrolysis of phosgene is extremely rapid (Manogue and Pigford, 1960; Schneider and Diller, 1989) producing carbon dioxide and hydrochloric acid ($\text{COCl}_2 + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 2\text{HCl}$). Some of the physical and chemical properties are listed in Table 48.1 (NAS/NRC Board on Environmental Studies and Toxicology, 1984; National Institute for Occupational Safety and Health, 2005; U.S. Environmental Protection Agency, 2005).

ENVIRONMENTAL FATE AND BIOACCUMULATION

The production and use of phosgene as an intermediate in organic synthesis, especially of isocyanates, polyurethane and polycarbonate resins, carbamates, organic carbonates, and chloroformates may result in its release to the environment through various waste streams (Lewis, 2007). The

potential environmental threat of phosgene is compounded by its additional uses in dye and plastics manufacturing, in acid chlorination processes, as a phosgenation reagent, and as a CWA compound (Klaassen, 1995; O'Neil, 2001).

Phosgene is produced in the earth's atmosphere from the degradation of a variety of chlorinated compounds, including tetrachloroethylene, trichloroethylene, chloroform, methyl chloroform, and carbon tetrachloride (Kindler et al., 1995). With a vapor pressure of 1180 mmHg at 20°C, phosgene will exist solely in the gaseous phase in the atmosphere, where it is slowly degraded by reacting with photochemically produced hydroxyl radicals. The half-life for this reaction in air is estimated to be 44 years (Hazardous Substances Data Bank [Internet], 2008). Phosgene does not absorb at wavelengths above 290 nm and therefore is not expected to be susceptible to direct photolysis by sunlight. If released to soil, phosgene is expected to have very high mobility based upon an estimated soil organic carbon–water partitioning coefficient (*K_{oc}*) of 2.2. Volatilization from moist soil surfaces is expected to be an important fate process based upon the Henry's Law constant (*H_{cc}*) of 17 l·atm/mol and its vapor pressure. If released into water, phosgene is not expected to adsorb on the suspended solids and sediment based upon the estimated *K_{oc}*; and like for soil, its *H_{cc}* indicates that volatilization from water surfaces is expected to be an important fate process. Complete hydrolysis of a 1% solution of phosgene in water occurs within 20 s at 0°C, suggesting that bioconcentration will not be an important environmental fate process. No biodegradation data are currently available (Hazardous Substances Data Bank [Internet], 2008).

ECOTOXICOLOGY

No information has been reported on either the acute or chronic effects of phosgene on the environment. However, the levels of phosgene currently found in the general environment would not be expected to result in significant effects to aquatic or terrestrial life. Damage to plants and aquatic organisms could result in areas where accidental release of phosgene has occurred, owing its rapid hydrolysis to hydrochloric acid (World Health Organization, 1988).

MAMMALIAN TOXICOLOGY

Acute Effects

In mammals, inhalation or contact (skin or ocular) exposure to phosgene results in a range of symptoms dependent on the dose and time of exposure. An inhaled concentration of phosgene above 3 parts per million (ppm) causes pain and

irritation to the mucous membranes of the eyes, nose, throat, and bronchi. Higher concentrations (>200 ppm) of phosgene can cause apnea, bronchoconstriction, inflammation, and thickening of the bronchioles (Banister et al., 1949).

Exposure to high concentrations (>200 ppm) of phosgene results in a reflex, a symptom-free latent, and a terminal phase of injury (Borak and Diller, 2001). The reflex phase results in vagal reflex actions that may cause shallow respiration due to the decrease in the arterial partial pressure, blood pH, vital lung capacity and volume. This phase can last for up to 4 h and is followed by the latent phase. The latent phase initially lacks clinical symptoms and lasts for several hours before the development of early signs of pulmonary edema. In the final terminal or clinical phase, fluid rapidly accumulates in the lungs and gas exchange decreases, resulting in severe pulmonary edema and lobular pneumonia, which peaks at 24 h postexposure (Hamilton et al., 1983). Mortality may occur between 24 and 48 h following phosgene exposure as a result of respiratory and circulatory failure.

Chronic Effects

The chronic effects of phosgene exposure consist of various symptoms that may include emphysema, fibrosis, dyspnea, reduced physical fitness, and alterations in pulmonary function (Diller, 1985; Wyatt and Allister, 1995). An evaluation of six patients who were exposed to an acute dose of phosgene showed that they suffered from cough, tightness of the chest, shortness of breath, and abnormalities in pulmonary function for at least 1 year after the exposure (Galdston et al., 1947a). The author suggested that the abnormalities in pulmonary function were a reflection of the myriad physiological and biochemical changes in the lungs and direct damage to the bronchioles similar to that observed in the early stages of emphysema. Unfortunately, the chronic symptoms resulting from these changes in pulmonary function could not be correlated with the severity of the phosgene intoxication. Another study evaluated five workers who were exposed to multiple occupational doses of phosgene for up to 18 months (Galdston et al., 1947b). These individuals developed symptoms similar to those previously mentioned and included coughs, tightness of the chest, and shortness of breath, all of which gradually improved once the individual was no longer exposed to phosgene.

Victims of phosgene exposure may require months to years to fully recover. It is recommended that all victims of phosgene exposure have yearly medical checkups, including pulmonary function tests (Borak and Diller, 2001). Victims with preexisting lung damage, with pulmonary conditions such as chronic bronchitis, or who are tobacco users may experience more severe and prolonged toxic effects following phosgene exposure (Diller, 1985).

Chemical Pathology

The most prominent symptom of phosgene poisoning is pulmonary edema resulting from increased water permeability of the alveolar capillaries and swelling of lung tissue. It has been reported that the terminal airways, alveolar lining, and alveolar epithelial layer are affected first by the inhalation exposure to phosgene (Gerard, 1948). Damage to the terminal bronchi and alveoli increases the permeability of the blood-air barriers and results in movement of excess fluid and protein into interstitial spaces. Flooding of the interstitial spaces is initially cleared by increased lymphatic drainage, but once fluid volumes exceed the clearance capacity, fluid leaks into the alveolar epithelium, flooding the alveoli. Gas exchange is drastically reduced as a result of both the death of the cells comprising the bronchiolar mucous membranes and migration of leukocytes into the bronchi and alveoli (Mehlman and Fensterheim, 1985). Damage resulting from phosgene exposure is primarily respiratory, but other effects, including cardiovascular, hematological, renal, ocular, and cutaneous toxicities, have also been observed (Borak and Diller, 2001).

Mode of Action(s)

Phosgene is a highly reactive gas that reacts with biological molecules and tissues primarily through acylation and/or hydrolysis of hydrochloric acid. Acylation occurs when amino, hydroxyl, and sulphydryl groups on biological molecules attack the electrophilic carbon molecule in phosgene (Babad and Zeiler, 1973), and can result in membrane structural changes, protein and lipid denaturation, and irreversible alteration of membrane, enzyme, and cellular functions. The highly reactive nature of phosgene with constituents present in the alveolar lining fluids causes direct damage to the lung surfactant through peroxidation of lipids (Guo et al., 1990; Jugg et al., 1999; Duniho et al., 2002). Phosgene-induced damage leads to the downstream changes in redox enzyme activity and release of arachidonic acid mediators (Sciuto et al., 2003; Sciuto et al., 2005). Exposure to phosgene also depletes and oxidizes lung nucleophiles, particularly glutathione, which has been implicated in alleviating phosgene-induced effects (Sciuto et al., 2003; Sciuto and Hurt, 2004). Phosgene exposure also causes pulmonary cellular glycolysis and oxygen uptake to decrease that results in decreased adenosine triphosphate and cyclic adenosine monophosphate levels (Currie et al., 1987; Schroeder and Gurtner, 1992; Sciuto et al., 1996). These alterations in cellular activity combined with increase in water uptake by epithelial, interstitial, and endothelial cells result in alveolar leakage and pulmonary edema.

Phosgene is hydrolyzed into hydrochloric acid following contact with water and may cause irritation and damage to the eyes, nasopharynx, and respiratory tract. Considering the

low water solubility of phosgene, only limited amounts of hydrochloric acid would be produced under normal physiological conditions as a result of phosgene exposure to biological tissues.

SOURCES OF EXPOSURE

Occupational

Occupational exposure to phosgene may occur through inhalation and dermal contact with this compound at workplaces where phosgene is manufactured and/or used. Monitoring data indicate that the general population may be exposed to phosgene via inhalation of ambient air, although the concentrations are low (U.S. Environmental Protection Agency, 2005). Phosgene can be formed by the thermal decomposition of chlorinated hydrocarbons, posing a threat for welders, refrigeration mechanics, and car repairmen (Brown and Birk, 1980). Commonly used industrial degreasers contain chlorinated hydrocarbons such as perchloroethylene, which can form phosgene when heated. Industrial workers, firemen, military personnel are at increased risk for accidental or occupational exposure to phosgene.

Environmental

The only natural source of phosgene in the environment documented to date is from volcanic activity. However, calculations indicate that the preeminent chlorinated species in volcanic gases is HCl and that the concentration of phosgene is roughly 15 orders of magnitude less (Ryan et al., 1996). Nonetheless, phosgene is an environmental pollutant and has been detected in ambient air samples (Singh, 1976; U.S. Environmental Protection Agency, 2005). The source of such pollutants most likely stems from the errant release of phosgene and its precursors during manufacturing processes, as well as the degradation of chlorinated compounds in the atmosphere, as previously described (Kindler et al., 1995). In Poland, the proximity of heavy industrialization to densely populated areas has resulted in the identification of phosgene as one of the most significant threats in the environment in those areas (Krajewski, 1997).

INDUSTRIAL HYGIENE

Recommended personal protective equipment (PPE) for liquid phosgene includes impervious clothing, full facepiece respirator, gloves, face shields (8-inch minimum), splash-proof safety goggles, and the availability of quick-drenching facilities, and eye-wash stations. Table 48.2 shows exposure limits as set forth by several different organizations (National Institute for Occupational Safety and Health, 2005).

TABLE 48.2 Phosgene Exposure Limits

Immediately Dangerous to Life or Health IDLH	2 ppm (8.1 mg/m ³)	
National Institute for Occupational Safety and Health (NIOSH) recommended exposure limits (REL)	Time-weighted average TWA 0.1 ppm (0.4 mg/m ³)	15-m C 0.2 ppm (0.8 mg/m ³)
Occupational Safety and Health Administration (OSHA) permissible exposure limits (PEL)	TWA 0.1 ppm (0.4 mg/m ³)	

RISK ASSESSMENTS

Phosgene is a gas at room temperature, is highly reactive, and hydrolyzes rapidly in water to CO₂ and HCl. As such, oral exposure to phosgene is exceedingly unlikely. The most likely route of phosgene exposure is through inhalation, and the acute effects of inhalational phosgene exposure have been well studied. Exposure results in the development of pulmonary edema and these symptoms increase in severity with both concentration (*C*) and time (*t*), as described by Haber's Law. At relatively high concentrations (>200 ppm), irritation of the eyes and alterations in respiratory parameters may occur, and at sufficiently high *Ct* levels, death may occur as a result of hypoxia or cardiac failure, both believed to be secondary responses resulting from the severe pulmonary edema associated with high levels of inhaled phosgene (U.S. Environmental Protection Agency, 2005). The effects of phosgene inhalation for sub-chronic or chronic durations are less defined, as limited human data and very few animal studies are available. The respiratory tract and the lungs are identified as the primary target organ in all species, and immunotoxicity has been observed in a few animal studies. However, the relevance of these findings to human hazard cannot be addressed at this time. Currently, information to assess the carcinogenic potential of phosgene is inadequate (U.S. Environmental Protection Agency, 2005).

NITROGEN COMPOUNDS

KATHLEEN T. JENKINS

First aid: *Inhalation exposure:* Nitrogen is a simple asphyxiant. Remove the victims to fresh air. Immediately eliminate exposure and prevent repeated exposure by removal from exposure. *Dermal/eye exposure:* Nitrogen oxides are irritating to eyes, mucous membranes, lungs, and skin. Nitrogen oxides and acids are skin irritants and corrosive. The hair, skin, and eyes should be irrigated for 20 min and then referred to a physician

Cardiovascular: Nitrogen oxides can cause weak rapid pulse and circulatory collapse. **Hematologic:** High dose exposure can lead to formation of methemoglobinemia and impaired oxygen transport. Methylene blue may be used for treatment

Target organs: Skin, respiratory, cardiovascular, and hematologic

Occupational exposure limits: Nitrogen is a simple asphyxiant and was not assigned a TLV because of the limiting factor of available oxygen

Nitric oxide: OSHA PEL: 25 ppm over 8 h shift, NIOSH IDLH 100 ppm

Nitrogen dioxide: OSHA PEL 5 ppm (9 mg/m^3) ceiling, NIOSH PEL1 ppm (1.8 mg/m^3) STEL, ACGIH TLV 3 ppm (5.6 mg/m^3), STEL, 5 ppm, NIOSH IDLH 50 ppm, Rfd-withdrawn

Nitrous oxide: OSHA, not regulated, NIOSH REL 25 ppm (45 mg/m^3) TWA, ACGIH 50 ppm (90 mg/m^3) TWA

Nitric Acid: OSHA PEL, 2 ppm TWA, NIOSH: REL 2 ppm TWA, NIOSH: IDLH 100 ppm

Risk/safety phrases: Most of the nitrogen oxides are irritants to the eyes, lungs, and skin. Nitrogen oxides are not classified as carcinogenic by IARC, EPA, or DHHS

BACKGROUND AND USES

Nitrogen (CASRN 7727-37-9) is the most abundant element in the atmosphere. It makes up 78% of the atmosphere by volume. It is essential to living systems, including a plant nutrient and utilized by most living systems. Humans and other life forms require the reactive form of nitrogen for a variety of physiological processes. Nitric oxide (NO) is acknowledged as an important endogenous second messenger within several organ systems. It is a ubiquitous signaling molecule produced through metabolism and l-arginine by nitric oxide synthases. Its formation is crucial for the control of blood pressure, blood flow, and other bodily functions (Kovalchin et al., 1997). Nitrogen does not exert a direct toxicological effect and has no toxicological profile. Nitrogen is only safe for humans and animals when mixed with oxygen. Nitrogen is considered a simple asphyxiant and displaces oxygen, which can cause immediate and serious health effects. To improve safety, the commercial use of nitrogen is an inerting agent to keep material free of contaminants, including oxygen. Since oxygen can corrode equipment or cause a fire or explosion hazard; nitrogen is also used to purge air from equipment prior to introducing materials.

Reactive nitrogen includes all forms of nitrogen that are biologically, photochemically, and radioactively active. Compounds of nitrogen that are reactive include the following: nitrous oxide (N_2O), nitrate (NO_3^-), nitrite (NO_2^-), ammonia (NH_3), and ammonium (NH_4^+). The nitrogen oxides include elemental nitrogen in five different oxidation states, +1 through +5. Because of its multiple oxygenation states, nitrogen is commonly found in all of the above forms. However, nitric acid (HNO_3), NO, and NO_2 are the forms of greatest interest to medicine and occupational health. The

oxides of nitrogen can best be described as an important group of irritant gases in both industry and the environment. Exposure to these compounds has been reported in a variety of occupational settings and in some cases has been associated with fatal respiratory complications.

Nitric oxide (CASRN 10102-43-9) is a colorless gas with 5% solubility in water and a vapor pressure of 34.2 atm. It is a nonflammable gas that accelerates the burning of combustible materials.

Nitrogen dioxide (CASRN 10102-44-0) may be present in the form of a yellowish-brown liquid or a reddish-brown gas above 21.1 °C (70 °F) with a pungent acrid odor. It reacts with water to form nitric and nitrous acid and has a vapor pressure of 720 mmHg. It is also a noncombustible liquid or gas that accelerates the burning of combustible materials. Nitrogen dioxide is more toxic than nitrogen oxide.

Nitrous oxide (laughing gas) is a colorless gas with a slightly sweet odor and taste. It is transported as cryogenic liquid and used as anesthetic and foaming agent in whipped cream.

Nitric acid (CASRN 7697-37-2) is commonly used as a strong oxidizing agent. The main use of nitric acid is the production of fertilizers. Other industrial uses include explosives, nylon precursors, and specialty organic compounds. Nitrous acid is also used as an oxidizer in liquid-fuel rockets. In electrochemistry, nitric acid is used as a chemical doping agent for organic semiconductors. It is also used in the purification process for raw carbon nanotubes. During the wood working process, nitric acid is used to artificially age pine and maple. It is also used for etching and pickling metals due to corrosive properties. The food and dairy industry uses nitric acid in combination with other chemicals for cleaning equipment (Safety Bulletin, 2003).

Two of the most toxicologically significant nitrogen oxides are nitrogen oxide and nitrogen dioxide. Nitrogen dioxide (NO_2) is the most abundant and toxic. Nitrogen oxide inhalation is 1/5 as toxic as nitrogen dioxide. Human exposure to nitrogen dioxides varies from indoors to outdoors, from countryside to cities, and the time of day and season. Reactive forms of nitrogen impact the environment through smog, acid rain, and biodiversity loss. Oxides of nitrogen in combination with sunlight may promote the formation of ozone. The formation of ozone may cause coughing, shortness of breath, aggravation of asthma, and other chronic lung diseases.

Nitrogen oxides form naturally during oxidation of nitrogen containing compounds such as coal, diesel, fuel, and silage. It is formed during the burning of fuels in furnaces and internal combustion engines. It is also a component of tobacco smoke. Nitrogen oxides are intermediates in the production of lacquers, dyes, and other chemicals and are important components of photo-oxidant smog. It is used in rocket fuel in nitration production, which is used in nitro-explosives, gun cotton, dynamite, and Trinitrotoluene (TNT).

Nitric acid is used to produce ammonium nitrate in fertilizer. It is also used to dissolve noble metals, etching, and cleaning metals.

Nitric oxide (10–20 ppm) is used to treat pulmonary hypertension (Ichinose et al., 2004).

PHYSICAL AND CHEMICAL PROPERTIES

Nitrogen is a colorless, odorless, and tasteless gas. It is often used under refrigeration as a cryogenic liquid. The boiling point is –195.8 °C and –320 °F. Nitrogen is not combustible. Nitrogen can combine with oxygen at high temperatures to form oxides and may form ammonia in contact with hydrogen at elevated temperatures. Cyanides can form if nitrogen is heated with carbon in presence of alkalies or barium oxide. If nitrogen comes in contact with ozone, nitrogen can oxidize explosively.

The nitrogen oxides include elemental nitrogen in five different oxidation states, +1 through +5. Nitroxyl anion (NO^-) and the anesthetic gas nitrous oxide (N_2O) contain nitrogen in the +1 oxidation state. Nitric oxide (NO) contains nitrogen in the +2 oxidation state. The weak base nitrite (NO_2^-) and its corresponding acid, nitrous acid (HNO_2), the nitrosonium cation (NO^+), dinitrogen trioxide (N_2O_3), and the peroxy nitrite anion (ONOO^-) all contain nitrogen in the +3 oxidation state. Nitrogen dioxide (NO_2) and its dimer, dinitrogen tetroxide (N_2O_4), are present in equilibrium in the +4 oxidation state. And finally, nitrate (NO_3^-), its corresponding acid, nitric acid (HNO_3), and dinitrogen pentoxide (N_2O_5) contain nitrogen in the +5 oxidation state. Nitrogen dioxide has a strong harsh odor and is a liquid at room temperature, becoming reddish-brown gas above 70 °F. Nitric oxide is a sharp sweet smelling gas at room temperature. Nitrogen oxide and dioxide are nonflammable gases or liquids; however, they can accelerate combustible materials.

Nitric acid is a highly corrosive strong mineral acid. Most commercially available nitric acid has a concentration of 68%. Fuming nitric acid contains more than 86% of HNO_3 . This grade is used in the explosives industry. It is an inorganic acid that is miscible in water and has a vapor pressure of 48 mmHg. It can be a colorless, yellow or red liquid with an acrid, suffocating odor. It is noncombustible but increases the flammability of combustible materials.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Nitrogen oxides are a key component of the formation of ground level ozone or smog. Nitrogen dioxide is a ubiquitous product of combustion, emitted from the exhaust of motor vehicles and emissions from stationary fuel sources such as coal, oil, natural gas, and other industrial sources. In the

environment, nitrogen oxides are broken down rapidly in the atmosphere by reacting with substances commonly found in the air. Molecular nitrogen is also modified via discharge of lightening. The electrical discharges of lightening break strong bonds between the nitrogen atoms and cause nitrogen to react with oxygen. The reaction of nitrogen dioxide with chemicals produced by sunlight leads to the formation of nitric acid, which is a major component of acid rain.

ECOTOXICOLOGY

The Environmental Protection Agency (EPA) regulates nitrogen dioxide as a criterion air pollutant. Outdoor sources of nitrogen dioxide include emissions from power plants, oil refineries, and automobile exhaust systems. Indoor sources include emissions from gas stoves and furnaces, kerosene space heaters, and cigarette smoke. Nitrogen dioxide does not exist in water, since it reacts instantaneously with water to form nitric acid and nitrous acids. Nitrogen cycle acceleration affects the environment through eutrophication of terrestrial and aquatic systems and global acidification. Eutrophication is defined as a natural and artificial addition of nutrients to bodies of water. The addition of artificial nitrogen to bodies of water I considered part of water pollution (Gruber and Galloway, 2008). Nitrogen dioxide plays an important role in the formation of photochemical smog, giving it a characteristic brown color. Nitrogen oxides are also major contributors to the formation of acid rain ($\text{NO}_x + \text{H}_2\text{O} \rightarrow \text{HNO}_3$). The formation of acid rain, smog, and biodiversity loss occur from reactive forms of nitrogen in the environment.

Acute Effects

The initial symptoms of exposure to nitrogen oxides include cough, burning of the throat and chest, nausea, fatigue, and shortness of breath. Severe exposure can cause drowsiness, hypoxemia, methemoglobinemia causing blue discoloration of the skin and lips, pulmonary edema, mental confusion, unconsciousness, and death. Exposure to liquid nitrogen can cause rapid, severe frostbite to the fingers, hands, and other tissues. The freezing temperature of nitrogen can lead to amputation of fingers despite wearing protective equipment.

MAMMALIAN TOXICOLOGY

The toxicological database for nitric oxide is small, relative to nitrogen dioxide. It is often difficult to obtain pure nitric oxide in air without some contamination with nitrogen dioxide. Most of the experimental animal studies available focused on the therapeutic use of nitric oxide in an animal model of human disease. Lethality studies in dogs, rats, and mice lacked complete concentration-response information,

are confounded by possible NO_2 contamination, or were secondary citations, in which the original source could not be obtained. From these studies, it appears that in the absence of lung injury, the mechanism of toxicity of nitric oxide is methemoglobin formation (IRIS, 2006). There are no apparent species differences in the toxic response to acute inhalation exposure to nitric acid. Nitric acid fumes cause immediate irritation of the respiratory tract, pain, and dyspnea, which are followed by a period of recovery that may last for several weeks. Relapses may occur due to bronchopneumonia and/or pulmonary fibrosis, which may result in death. With chronic exposure, emphysematous lesions were produced in mice after exposure to 10 ppm of nitrogen dioxide for various periods up to 30 weeks (Patty's, 1981).

Acute Effects

Nitrogen oxides are skin irritants and corrosives. Reaction with skin moisture can lead to formation of nitric acids, causing second- and third-degree burns. Nitric acid is a highly corrosive, strong oxidizing acid. Nitric acid may also cause yellowing of the skin and dermal erosion. Nitrogen oxides are respiratory irritants, which cause an immediate response, including cough, fatigue, nausea, choking, headache, abdominal pain, and difficulty breathing. After 3–30 h, pulmonary edema may develop with anxiety, mental confusion, lethargy, and loss of consciousness. Bronchiolitis obliterans (fibrous obstruction of the bronchioles) may occur several weeks later. For exposure to nonlethal concentrations, allergic, or asthmatic individuals appear sensitive to acidic atmospheres. High dose exposure may cause formation of methemoglobin and impaired oxygen transport. Cardiovascular effects include weak, rapid pulse, dilated heart, chest congestion, and circulatory collapse.

Chronic Effects

Victims of inhalation exposure of nitrogen oxides can suffer reactive airway dysfunction (RADS) after a single acute high exposure. Children have an increased risk of respiratory infections. Permanent restrictive and obstructive disease from bronchiolar damage may occur.

Nitrogen oxides are not classified as carcinogenic by IARC, EPA, or DHHS.

Chemical Pathology

Nitrogen dioxide (NO_2) is thought to cause damage to the lungs by three ways. NO_2 is converted into nitric and nitrous oxides in distal airways, which directly damages certain structural and functional lung cells. Nitrogen dioxide initiates free radical generation that causes cell membrane damage; it alters macrophage and immune function by decreasing the resistance to infection. NO_2 is characterized by denudation

followed by compensatory proliferation. The persistent injury and remodeling include the development of fibrosis (Persinger et al., 2002) Nitric acid is known to be a highly corrosive inorganic and strong oxidizing acid.

Evidence suggests that nitrogen oxide in the presence of oxygen at physiological pH can produce mutations in *Salmonella* species by the conversion of cytidine to thymidine. These reactions have been proposed as one mechanism by which cigarette smoke causes lung cancer (Wink et al., 1991; Nguyen et al., 1992).

Mode of Action(s)

Nitric oxide is a low molecular weight, lipophilic molecule that has a rapid onset of action and a very short half-life (i.e., seconds). Nitric oxide is an endogenous ubiquitous substance that acts as a biological messenger in the regulation of numerous organ systems. Nitrogen oxide plays central roles in the regulation of vascular smooth muscle tone. Nitric oxide gas is utilized in medicine to selectively dilate the pulmonary vessels by increasing blood flow to areas in the lung and improves oxygen levels in the body (ventilation-perfusion V/Q matching). After NO is inhaled in the lungs and into the blood stream, its effects are quickly deactivated. In recent years, the beneficial effects of inhaled NO to reduce intrapulmonary shunting and oxygenation have been demonstrated in patients with acute respiratory syndrome and pulmonary hypertension (Ichinose et al., 2004). Nitrogen oxide exposure to the skin and eyes causes inflammation and irritation. Nitrogen oxides are deposited in the lower airways. Sixty percent of the nitrogen dioxide is deposited in the centriacinar region. The amount of exposure increases with exercise. Approximately, 15 times more NO₂ would be delivered to the pulmonary tissue at maximum tidal volume that would occur during heavy exercise. (Bauer, 1986) Nitric oxide has an affinity for heme-bound iron, which is two times higher than that of carbon monoxide. This affinity leads to the formation of methemoglobin and stimulation of guanylate cyclase. Furthermore, nitric oxide reacts with thio-associated iron in enzymes and eventually displaces the iron. This is the possible mechanism for the cytotoxic effects of nitric oxide (WHO, 1997).

SOURCES OF EXPOSURE

Occupational

It has been estimated that more than 1.5 million workers in the United States may be exposed to nitrogen oxides. Nitrogen oxides (NO and NO₂) are formed when nitric acid reacts with reducing agents, as well as by combustion of nitrogen-containing materials. Nitrogen dioxide may be encountered in a wide variety of industrial settings, including: production

of nitric acid (by catalytic oxidation of ammonia), manufacture of explosives, in the exhaust of metal cleaning processes, in underground blasting operations, decomposition of agricultural silage, by ice arena resurfacing machines, the exhaust of diesel engines, and burning of gun cotton and cordite. Nitrogen dioxide is also a component of rocket fuels. There were 80 deaths and 50 workers were injured in the industry, between the years 1992 and 2002, from nitrogen asphyxiation hazards. Sixty-two percent occurred in chemical plants, refineries, food processing and storage facilities, and metal and manufacturing sites, including nuclear plants. The majority of workers were working in confined spaces containing nitrogen-enriched air (US Chemical Safety, 2003). Nitric acid is an important industrial acid used in the production of ammonium nitrate fertilizer and explosives. All commonly used explosives, with the exception of gunpowder, are made by the action of nitric acid on cellulose, glycerin, phenol, benzol, toluene, and similar substances. Nitrocellulose is used for lacquers, photographic film, and celluloid. Nitrobenzols and nitrophenols are used in the production of dyes and drugs as well as explosives. Metal etching and photoengraving both require nitric acid, which, in its dilute form, also is used to clean copper and brass.

Nitric oxide has been utilized in the medical field for over 20 years. It is being used worldwide to treat both adult and pediatric patients from pulmonary hypertension and acute respiratory distress syndrome. It is utilized in pulmonary hypertension and congenital heart diseases in newborns. Inhaled gas is delivered via face mask, nasal cannula or through an endotracheal tube (Ichinose et al., 2004).

Environmental

Nitric oxide is formed and combines with oxygen to form nitrogen dioxide. When released to soil, small amounts of nitrogen oxides may evaporate into the air. Most of it is converted into nitric acid and other compounds. The nitrogen dioxide dissolves in water to form nitric and nitrous acids. Nitrogen dioxide compound undergoes direct photolysis in the environment leading to the formation of ozone and smog conditions in the troposphere. Human exposure to nitrogen oxides varies indoors, outdoors, urban, and rural with the time of day and season. Nitrogen dioxide can be mixed with the nitric oxide exposures because nitric oxide is oxidized to nitrogen dioxide.

At certain levels, inhaled nitric oxide concentrations can cause vasodilatation in pulmonary circulation without affecting systemic circulation. Relatively high concentrations have been used in clinical applications for brief periods without adverse effects. The lowest effect concentration of NO has not been established. On 01/22/10, EPA strengthened the health-based ambient air standard for NO₂ by setting the standard of 100 parts per billion (ppb). The standard is

intended to protect the health of sensitive populations such as people with asthma, children, and elderly.

INDUSTRIAL HYGIENE

Workers should wear personal protective equipment (PPE) when utilizing liquid nitrogen to prevent skin contact due to below freezing temperature. The selection of appropriate PPE is based on the extent of exposure to nitrogen and nitrogen compounds. Safety showers and eye wash stations should be located close to the operations using liquid nitrogen. Engineering controls are the most effective way of reducing nitrogen liquid and gas exposure. The best protection is to enclose operations and or provide local exhaust ventilation at the site of chemical release. In confined spaces where nitrogen is present, sufficient oxygen levels (19%) should be checked prior to entry. Oxygen and nitrogen gases are odorless and not detected by sense of smell. Nitrogen enriched environment, which depletes oxygen can only be detected with special instruments. Asphyxiation can occur if a worker is exposed to a high concentration of nitrogen. Nitric oxide produced in welding arcs and other flame operations, such as glassblowing, is oxidized in air to nitrogen dioxide. It has been reported that the levels of nitrogen dioxide in welding areas can be as high as 7 ppm during flux arc welding. The levels inside the welder's eye protection mask were lower at 2 ppm, illustrating some protection in the breathing zone. Contact between nitric acid and organic matter produces nitrogen oxides. The inhalation effects of nitric acid cannot be separated from those of the nitrogen oxides because they invariably occur together. It is recommended that those working in high concentrations of nitrogen oxide gases wear proper respirators to prevent serious or fatal respiratory injury. Ventilation needs to be adequate in all processes in which nitrogen oxides are formed.

Nitrogen does not have exposure levels listed; it is a simple asphyxiant and was not assigned a TLV, because of the limiting factor of available oxygen (Table 49.1).

HEALTH EFFECTS

Acute overexposure to nitrogen gases may result in death almost immediately. An example of this would be the 1929 fire at the Cleveland Clinic, in which burning nitrocellulose radiographs generated NO, CO, and HCN gases. Ninety-seven workers died immediately from this exposure, and 26 people died within the next month, probably from the effects of nitrogen oxide (Gregory et al., 1969). Individuals who survive acute overexposure often develop delayed symptoms within 48 h, including pulmonary edema, the most common form of occupational injury associated with nitrogen dioxide. In 1975, the presentation of disease

TABLE 49.1 Occupational Exposure Limits for Nitrogen Compounds

Agency	Compound	Exposure Guideline	Parameter
OSHA	Nitrogen dioxide	5 ppm (9 mg/m ³)	PEL
	Nitrogen oxide	25 ppm	PEL
	Nitrous oxide	Not Regulated	
	Nitric acid	2 ppm (5 mg/m ³)	PEL
	Nitric acid	4 ppm (10 mg/m ³)	STEL
	Nitrogen dioxide	5 ppm (9 mg/m ³)	PEL
NIOSH	Nitrogen dioxide	1 ppm (1.8 mg/m ³)	STEL
	Nitrogen dioxide	20 ppm	IDLH
	Nitric oxide	25 ppm (30 mg/m ³)	REL
	Nitric oxide	100 ppm	IDLH
	Nitrous oxide	25 ppm (45 mg/m ³)	REL
	Nitric acid	4 ppm (10 PPM)	STEL
ACGIH	Nitrogen dioxide	2 ppm (5 mg/m ³)	REL
	Nitrogen dioxide	3 ppm (5.6 mg/m ³)	TLV
	Nitrogen dioxide	1 ppm (1.8 mg/m ³)	REL
	Nitrogen dioxide	5 ppm (9.4 mg/m ³)	STEL
ACGIH	Nitrogen dioxide	50 ppm	IDLH
	Nitric acid	2 ppm (5.2 mg/m ³)	TLV
	Nitric acid	4 ppm (10 mg/m ³)	STEL
	Nitric acid	100 ppm	IDLH
ACGIH	Nitric oxide	25 ppm (31 mg/m ³)	TLV
	Nitrous oxide	50 ppm (90 mg/m ³)	TLV

ACGIH: American Conference of Governmental Industrial Hygienists

OSHA: Occupational Safety and Health Administration

NIOSH: National Institute for Occupational Safety and Health

TLV-TWA: Threshold limit value, time-weighted average—average exposure on the basis of an 8 h/day, 40 h/week-work schedule

PEL: Permissible exposure limit based on an 8 h-TWA exposure

REL: Recommended exposure limit based on a time-weighted average exposure of up to 10 h/day and 40 h/week

STEL: 15 min TWA exposure that should not be exceeded at any time during the workday even if the 8 h TWA is within TLV-TWA. Exposures above the TLV-TWA up to STEL should not be longer than 15 min and should not occur more than 4 times per day. There should be at least 60 min between successive exposures in this range

occurred when three American astronauts on the Apollo-Soyuz aircraft were inadvertently exposed to nitrogen tetroxide for approximately 4–5 min. They developed pulmonary edema the day after splash down. All of the crew members recovered after 13 days of medical observation.

Several studies have linked air pollution by nitrogen dioxide (NO₂) with increased admissions for asthma in children. Exacerbations of asthma in children are often precipitated by upper respiratory infections. It is therefore, possible for NO₂ to increase the risk of airway obstruction when children develop upper respiratory infections (Linaker et al., 2000). There is evidence that children who live in households where gas stoves are used, develop more infections before two years of age and have diminished lung function compared with matched controls. Further evaluation is required (Florey et al., 1982). Ambient NO₂ and SO₂ may be important risk factors for sudden infant death syndrome. One study found increases

in both NO₂ and SO₂ associated with a 17.72% increase in SIDs incidence in Canada (Dales et al., 2004).

Exposure to liquid nitrogen or liquefied nitrous oxide can cause skin burns or frostbite to exposed areas of the body.

DIAGNOSIS AND TREATMENT

The correct diagnosis is dependent on an accurate detailed occupational and medical history. The most hazardous of the nitrogen oxides are nitric oxides and nitrogen dioxide. Nitrogen oxides (NO₂, N₂O₄, N₂O₃, and N₂O₅) are irritating to the upper respiratory tract and lungs even at low concentrations. Severe toxicity may occur after a brief period of exposure. It is important for the clinician to be aware of the pattern of illness caused by exposure to the nitrogen oxides. Because of the delayed onset of symptoms, people suspected of high dose exposure should be observed for approximately 48 h. The victim could show signs of lung injury such as hypoxemia or rapid respiratory rate. Chest X-rays may not be diagnostically helpful initially, but abnormalities maybe seen after several days or weeks later. Laboratory studies may reveal an elevation in white cell count. The presence of methemoglobinemia is helpful in diagnosing exposure to nitrogen oxides. Treatment involves administration of oxygen, possibly assisted ventilation, hemodynamic monitoring, and use of corticosteroids. Children exposed to the gas are more vulnerable to exposure due to the greater lung surface area: body weight ratios and minute volumes: weight ratios. Since nitrogen dioxide is heavier than air, children may have an increased exposure due to its short stature. The clinical presentation of all the above categories is similar. Since nitrogen dioxide is relatively insoluble in water and moist membrane surfaces, it has little effect on mucous membranes of the eyes and throat. There is no immediate recognition of exposure, and workers or others may remain in the area for several minutes before coughing and chest congestion alert them to leave. Respiratory symptoms are delayed for 3–30 h after exposure, at which time cough, shortness of breath, fever, and elevated white blood cell count may develop. Chest X-rays initially may be negative and over time may reveal pulmonary edema. For this reason, chest X-rays may not be diagnostic in patients evaluated early after initial exposure, and observation may be prudent. Most patients recuperate without sequelae. However, some patients may develop lung disease and die from exposure. Pathologically, the appearance of the lungs in fatal cases reveals hemorrhagic edema and patches of pneumonia. In patients who do not succumb initially, but rather a few weeks after exposure, small, palpable nodules are seen within the lung as well as hemorrhagic areas. Microscopically, there is extensive damage and sloughing of the respiratory epithelium into the bronchioles. Diffuse infiltration of the alveolar walls and

numerous macrophages within the alveolar spaces also can be seen, as can numerous areas of bronchiolitis obliterans in various stages of the organization. Bronchiolitis obliterans is characterized by inflammation and fibrosis in and around the small bronchi and bronchioles.

Another clinical manifestation of nitrogen oxide poisonings is development of methemoglobinemia. The nitrogen oxide binds to hemoglobin, causing a sharp leftward shift in the oxygenation dissociation curve resulting in limited delivery of oxygen to tissues. The affinity of nitrogen oxide for hemoglobin renders it incapable of binding oxygen.

Nitric acid spill on the skin should be irrigated with large quantities of water because of the corrosive properties. If nitric acid is accidentally splashed onto the skin or into the eyes, the area should be irrigated immediately and washed with water or saline until all burning sensations cease. Wash the area for 10–15 min to cool surrounding tissue and prevent secondary damage. Contaminated clothing should be removed immediately. Because of its corrosive properties, concentrated nitric acid can injure tissues on direct contact. It can cause a yellow burn to the skin, the result of the formation of denatured colored proteins.

Treat dermal irritation or burns with standard local therapy. Patients developing dermal hypersensitivity may require treatment with systemic or topical steroids or antihistamines.

More important, when nitric acid is splashed in the eye it can cause immediate opacification of the cornea; when severe, this accident may result in blindness. The patient will need to be evaluated by a physician. To prevent such accidents, eye protection and protective clothing should be worn when concentrated nitric acid is used.

If skin is exposed to liquefied nitrogen or nitrous oxide, the skin or area can burn or develop frostbite. The skin should be immersed into warm water to increase the temperature. Medical attention is warranted to evaluate tissue damage.

TARGET ORGANS AND MECHANISM OF ACTION

The severity of the effects of nitrogen oxides depends on the concentration of the agent and the duration of exposure. Because of their relatively low solubility in water, nitrogen oxides have little effect on the oropharyngeal mucosa, which allows the gases to be transmitted to the lower airways. Approximately 80–90% of nitrogen oxides are absorbed by the respiratory epithelium during normal ventilation in healthy subjects. In the lower airways, nitrogen oxides react with water to form nitric acid. The nitrates and nitrites that result from the dissociation of nitric acid can induce direct local tissue inflammation and destruction and also may initiate peroxidation of lung lipids by forming oxygen free radicals. This damage causes noncardiogenic pulmonary edema, which is seen clinically. After inhalation exposure

to the lungs, the nitrogen oxides are absorbed into the bloodstream. Most of the absorbed nitrogen dioxide enters the blood as nitrite because of the previous reaction with water, in which nitric acid was formed. The absorbed nitrogen oxide enters the blood unreacted. Both combine with hemoglobin, in the presence of oxygen, and methemoglobinemia results (Gosselin et al., 1984).

BIOLOGICAL MARKERS

Nitrogen oxides have been evaluated as potential biological markers. Because of the turnover of the extracellular matrix of the lungs after exposure to irritant gases, the levels of hydroxyproline and hydroxylsine, collagen breakdown products, in the urine may reflect collagen turnover secondary to lung damage.

A cross sectional study was carried out on two groups of subjects differently exposed to nitrogen dioxide in order to test the urinary hydroxyproline ratio (UHP/mg/24 h/sq m) use as a biomarker of effect after exposure to this pollutant. The UHP was higher in subjects training in polluted areas vs. nonpolluted areas. (Perdelli et al., 2002) Studies in glassworkers exposed to nitrogen oxides have shown increased urinary excretion of nitrate and hydroxyproline compared with controls. (Azari et al., 1994a). However, collagen is found in nearly all organ systems and is not specific for the lung. An increase in the level of lipid peroxidation in the respiratory system, resulting in higher concentrations of pentane in expired air, also was seen (Azari et al., 1994b).

Exhaled nitric oxide is a marker for asthma and utilized as a research tool in evaluation of asthma. It may prove to be a diagnostic tool in the diagnosis of primary ciliary dyskinesia syndromes. The clinical utility of nitric oxide for other lung diseases remains to be established (American Thoracic Society, 2006).

SILO FILLERS' DISEASE (SFD)

Silo fillers' disease (SFD) occurs in workers who enter unopened grain silos. In the United States, SFD is prevalent among farmers during the harvest months of September and October. It is an occupational disease that results from pulmonary exposure of oxides of nitrogen. It is a preventable occupational hazard that can be eliminated by proper work practices. Nitrogen dioxide is formed within hours at toxic and lethal levels after corn and grains are placed in the silos. Nitrogen dioxide gas is heavier than air and is present after the silos are entered or near open hatches. The concentration of nitrogen dioxide in the air partly depends on the nitrate content of the grain. Both carbon dioxide and nitrogen

dioxide are heavier than air and accumulate just above the level of the grain, especially within lower uneven surfaces of the grain itself. If the silo has remained unopened, dangerous amounts of gas may be present after a few days to months later. To enter the silo, a worker enters through a chute door and jumps onto the surface of the silage a few feet below. The respiratory rate of the farm worker will increase because of the low levels of oxygen and carbon dioxide causing an elevated amount of nitrogen dioxide to be inhaled into the lungs. If the concentration of gas is high, the worker may be physically unable to get out. Special prevention measures must be taken with forage silos: (1) the tower should be ventilated by means of a blower for at least half an hour before the silo is entered; (2) workers should wear safety harnesses and ropes, and additional workers should be in attendance outside the tower; (3) if the silo must be entered during filling, this should be done after the last load and not the next day, when gases may have evolved. Exposure is usually mild and self-limiting; however, severe exposure can lead to pulmonary edema, bronchiolitis obliterans or asphyxia (Kamanger, 2012).

OXYGEN AND OZONE

ROBERT A. KLOCKE

OXYGEN

First Aid: Removal from environment with abnormal oxygen level

Target organ(s): Lungs, central nervous system

Occupational exposure limits: OSHA PEL: 19.5% oxygen minimal oxygen percentage; consensus: ACGIH TLV 3.0 ATA maximum pressure breathing 100% oxygen

Reference values: None

Risk/safety phrases: R8: Contact with combustible material may cause fire; S2 keep out of the reach of children; S17 keep away from combustible material

BACKGROUND AND USES

Oxygen is the most abundant element in the outer layer of the earth, largely the result of its combination with hydrogen and silica to form water and sand. It is ubiquitous and is present in the same fractional concentration (0.2094) throughout the earth's atmosphere. However, its partial pressure varies with altitude because of the effect of altitude on barometric pressure. Oxygen is necessary for respiration in all mammals. In medicine, oxygen is the most used pharmaceutical agent and is usually administered under normobaric conditions. However, there is a gradually increasing use of hyperbaric oxygen treatment for a variety of medical illnesses.

Oxygen supports combustion and is frequently used as an oxidizing agent. It is used throughout the industry for processing metal and petroleum products, fabrication of chemicals and pharmaceutical agents, and welding.

PHYSICAL AND CHEMICAL PROPERTIES

Oxygen is a diatomic element (molecular weight 32) normally present in a gaseous form but does exist as a liquid at very low temperatures (boiling point -183°C) and as a solid (melting point of -218°C). It is normally used in its gaseous form but liquid oxygen also has some medical and industrial applications. It is relatively insoluble in aqueous solutions with a solubility of 0.0311 and 0.0239 ml/ml at 20 and 37°C , respectively, at 1.0 atmospheres absolute pressure (ATA) (Battino et al., 1983). As a result, mammalian species and some vertebrates require a protein in blood, such as hemoglobin, to transport adequate quantities of oxygen to support life. Oxygen supports combustion, especially at pressures above 0.21 ATA. The risk increases with increasing oxygen pressure, and avoidance of fire risk is essential at elevated oxygen pressures. Materials that normally do not burn in air may become combustible at elevated oxygen pressures.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Carbon dioxide is the final end product of many biological and industrial processes, thereby depleting atmospheric oxygen and increasing carbon dioxide concentration. Oxygen in the atmosphere is maintained constant through plant photosynthesis in the oxygen–carbon dioxide cycle. Plants use chlorophyll to form carbohydrates through reduction of carbon dioxide and release oxygen into the atmosphere. In addition to the trees and plants that produce oxygen, green algae are also a major natural source of oxygen.

Oxygen is used to support combustion of carbon fuels to produce carbon dioxide. As a result of increasing industrial activity, atmospheric carbon dioxide has risen from 300 to 400 parts per million (ppm) in the last century. Incomplete combustion of carbon fuels produces carbon monoxide, a common atmospheric pollutant in urban areas.

ECOTOXICOLOGY

Oxygen concentration in air is essentially constant in the overall environment, and toxic effects have not been observed.

MAMMALIAN TOXICITY

Toxicity caused by oxygen is dependent on its duration of exposure and chemical activity. The latter is commonly estimated by the partial pressure of oxygen in absolute atmospheres. At elevated levels, oxygen principally affects the lungs and central nervous system. Survival data of mammals, especially rodents, when breathing 100% oxygen at 1.0 ATA are limited to several days, but extrapolation of these data to humans has a dubious value (Clark and Lambertsen, 1971). It appears that primates are more resistant to oxygen exposure; monkeys with exposure to pure oxygen have survived as long as 3 weeks. Animal data indicate that the usual cause of mortality is pulmonary edema. There are no comparable studies in humans breathing 100% oxygen at 1.0 ATA for such long periods.

Pulmonary oxygen toxicity is found to be nonexistent in humans at exposures <0.5 ATA (Clark and Lambertsen, 1971), although limited data are available to support a definite threshold. Variability in susceptibility to increased oxygen exposure is substantial in humans. Small changes (4%) in the vital capacity (VC), the volume of gas that can be exhaled after a maximal inhalation, are noted in subjects breathing oxygen at 1.0 ATA for 24 h (Bitterman, 2004). With exposure to oxygen at greater than normal barometric pressure, the time required to produce progressive decrements in VC, as well as symptoms (chest pain, cough, shortness of breath), decreases exponentially (Figure 50.1) (Clark et al., 1999).

Changes in VC following exposures in these experiments returned to normal within 24–30 h. Surprisingly, these changes did not impair pulmonary oxygen exchange, but it must be noted that great care was taken to limit the duration of exposure at higher inspired oxygen levels to prevent serious health threats to the subjects.

In healthy individuals undergoing surgical anesthesia, increased oxygen concentrations (0.6–1.0 ATA) at normal barometric pressure can result in the development of absorption atelectasis, i.e., collapse of pulmonary exchange units

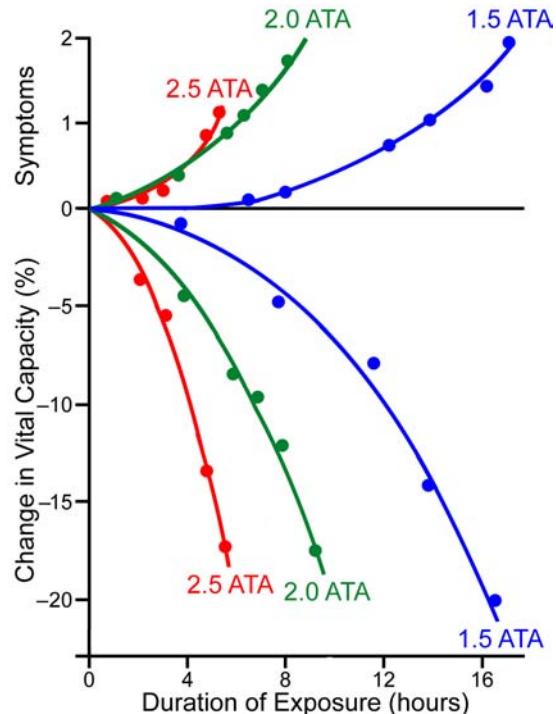

FIGURE 50.1 Mean values of development of symptoms and reductions in vital capacity of young (mean 24.3 years), healthy subjects exposed to 100% oxygen at 1.5 ($n=9$), 2.0 ($n=25$) and 2.5 ($n=8$) ATA for varying periods of time. Curves of responses compared to baseline (0 h) determined while breathing air at 1.0 ATA were fitted empirically. Pulmonary symptoms were self-rated on a 0–3 scale (absent, mild, moderate, severe). Figure redrawn with permission from Clark et al. (1999).

(Edmark et al., 2011). However, this is not a truly toxic effect of oxygen per se. Nitrogen is not absorbed in the lung, and the presence of nitrogen in gas exchange units inhibits the collapse of the units. As oxygen concentration is increased, nitrogen concentration in gas exchange units decreases, and the units are more prone to collapse as oxygen is absorbed into the blood. For this reason, and the likelihood that diseased lungs are more prone to oxidant damage, oxygen is administered at the lowest concentration necessary to maintain acceptable oxygen concentrations in the blood in clinical settings.

Premature infants are more sensitive to increased oxygen pressures than adults. Exposure to increased oxygen levels for prolonged periods is accompanied by a risk of developing a chronic respiratory condition (bronchopulmonary dysplasia). In addition, increased oxygen in the blood of premature infants can cause retinopathy with permanent impairment of vision. This complication is minimized by limiting oxygen administration to the least amount necessary to achieve normal arterial blood oxygenation. The damage to sight can be reduced further by keeping blood oxygenation slightly below normal levels. However, a large controlled study has indicated that this

treatment is associated with a small, but significant, increase in neonatal mortality (SUPPORT Study Group, 2010). Current recommendations are to maintain blood oxygenation within the normal range in premature infants.

Oxygen exposure at elevated atmospheric pressures (>2 ATA) causes central nervous system abnormalities ranging from muscular twitching (particularly facial muscles), blurred or tunnel vision, apprehension, dizziness, aphasia to grand mal seizures (Bitterman, 2004). These extreme exposures are limited principally to commercial diving and medical hyperbaric oxygen treatments.

During the World War II era, Donald (1947) investigated the effects of varying oxygen exposures and conditions that precipitated neurological symptoms. With exposure to 3.7 ATA of oxygen in a hyperbaric chamber, 50% of the 36 resting subjects experienced neurological symptoms within 20 min, and all were affected in <100 min. Five of the subjects had grand mal seizures. Anecdotal reports suggest that oxygen-induced convulsions result in no permanent damage, although there have been no long-term, detailed studies of individuals who have suffered this complication. Certainly, convulsions during deep water dives could result in death. In Donald's report (1947), the time required to experience neurological symptoms was reduced by approximately one half if the subjects were submerged in water inside the hyperbaric chamber, simulating wet diving conditions. The mechanism of increased susceptibility to occurrence of neurological symptoms while immersed in water has not been elucidated. Physical labor also reduced the time of exposure prior to the onset of symptoms. Oxygen fractions in inspired gas mixtures are reduced in dives of great depth to prevent neurological and pulmonary toxicity. Since compressed air is used in usual scuba diving, inspired oxygen pressures do not reach a critical level at maximum depths (50–100 ft) associated with recreational dives. This avoids oxygen toxicity but not other pressure-related problems.

In recent years there has been an increasing medical use of hyperbaric oxygenation in the treatment of a wide variety of diseases. The classic uses are treatment of carbon monoxide poisoning and diving-related decompression illness. Short-term (<2.0 h) hyperbaric oxygenation also has been used in the treatment of diabetic ulcers, anaerobic tissue infections, radiation-induced injury, and severe brain trauma. Oxygen exposure is usually limited to a maximum of 3.0 ATA to minimize toxicity, but this does not completely avoid complications (Hampson and Atik, 2003).

Despite extensive studies on the incidence and effects of oxygen toxicity, the actual mechanisms involved remain uncertain. The most common hypothesis postulates production of reactive oxygen species (ROS), including hydrogen peroxide, hydroxyl radicals, and superoxide radicals. These powerful oxidizing agents have important biological functions such as bacterial killing in infectious diseases. Yet, in excess, these agents increase cellular damage and death.

There is a delicate balance between these oxidizing agents and body antioxidant defenses. Oxygen administration can increase the production of ROS and upset the normal balance, leading to toxicity (Auten and Davis, 2009).

Reduced oxygen in inspired air can be fatal. Symptoms and signs of oxygen deprivation are nonspecific and include shortness of breath, increased heart and respiratory rates, fatigue, agitation, cyanosis (bluish discoloration of the lips, finger nails, and skin), and coma. Oxygen uptake in the lungs is dependent on its pressure. Healthy individuals breathing air are exposed to reduced oxygen pressures when flying or residing at an altitude. Federal Aviation Administration regulations limit the exposure in commercial flight to no less than an absolute pressure of 0.75 ATA, equivalent to the reduction in barometric pressure present at an altitude of 8000 ft. Healthy humans tolerate this exposure without any symptoms or difficulty, but individuals with lung disease may require supplemental oxygen during flight. The Occupational Safety and Health Administration (OSHA) has set a minimum of 19.5% oxygen concentration in industrial circumstances. This produces an oxygen pressure in inspired air that is equivalent to an elevation of 2000 ft. This is well above the limit tolerated by healthy humans but is a preventative limit since further fatal reduction can occur rapidly in closed occupational environments.

SOURCES OF EXPOSURE

Normally oxygen at 1.0 ATA does not constitute a risk unless breathed for periods of hours to days, essentially ruling out accidental exposures. At pressures >1.0 ATA, there is an increasing risk as the oxygen partial pressure increases. This limits the risk to hyperbaric chambers (for medicinal or experimental purposes), use of underwater breathing apparatus, or work in caissons.

INDUSTRIAL HYGIENE

There are no National Institute of Occupational Safety and Health (NIOSH) or OSHA permissible exposure limits (PELs) for oxygen. The OSHA limits minimum oxygen concentration to 19.5% in work environments. At lower oxygen concentrations, OSHA mandates the use of a self-contained breathing apparatus. Half-face or full-face respirators should not be used for atmospheres with reduced oxygen concentrations. No personal protective equipment (PPE) are required for oxygen exposure to 1.0 ATA. At higher pressures encountered in commercial diving and work in caissons, it is necessary to reduce the inspired oxygen concentration to avoid the absolute oxygen rising above 3.0 ATA. The U.S. Navy has published data sheets with limits for safe oxygen exposure at increased pressures.

Atmospheres containing increased oxygen concentrations, even at total pressures <1.0 ATA, are hazardous not for inhalational toxicity but as a result of the increased risk of supporting combustion.

RISK ASSESSMENTS

None available.

OZONE

First aid: Removal from contaminated atmosphere

Target organ(s): Eyes, skin, upper respiratory tract, lungs, heart, vasculature

Occupational exposure limits: OSHA PEL 100 ppb TWA; NIOSH PEL 100 ppb ceiling, IDLH 5000 ppb; CAL/OSHA PEL 100 ppb TWA; ACGIH: TLV 50 ppb heavy work, 80 ppb moderate work, 100 ppb light work, 200 ppb 2-h TWA at all work intensities

Reference values: NAAQS 75 ppb (annual fourth-highest daily maximum 8-h concentration, averaged over 3 years)

Risk/safety phrases: Oxidizer; lung irritation, damage; increases mortality/keep away from skin, eyes; avoid low level chronic inhalation; avoid high level short-term inhalation

BACKGROUND AND USES

Ozone is distributed throughout the earth's atmosphere in both the stratosphere and the troposphere. The vast majority of ozone (~90%) is located in the stratosphere where it has the critical function of absorbing ultraviolet (UV) light, particularly in the UVC bandwidth (<290 nm) (Crutzen et al., 1999). This prevents profound, deleterious effects on both plants and animals. The remainder of the atmospheric ozone is located in the lower troposphere. Excessive concentrations of ozone in the boundary layer surrounding the surface of the earth can cause significant human mortality and morbidity as well as inhibit vegetative growth. However, ozone in the troposphere also has the beneficial effect of oxidizing potentially dangerous organic compounds that arise from both natural and human sources.

Ozone is a potent oxidizing agent. It is increasingly replacing chlorine as an oxidizing agent in industrial processes. It is used in the disinfection and purification of water, sewage, and food products. Its oxidant properties are also used as a bleaching agent in the paper, textile, and chemical industries. Extracting ozone from the atmosphere is difficult,

and in the industry, it is generated by passing an alternating high voltage electric current through a dry stream of air or oxygen. Although ozone is widely used in industrial applications, these potential sources do not contribute significantly to atmospheric contamination because the highly reactant ozone is confined and has a short half-life. Ozone is produced through electrical discharges occurring in lasers printers, copying machines, and similar equipment, but its concentration is low unless the equipment is operated in a confined environment. In general, indoor air contains ozone concentrations that are only 10–40% of the outdoor ozone concentrations (U.S. EPA, 2013), but the indoor concentration varies widely depending on the type of building construction, heating/cooling systems, and the use of open windows for ventilation in a warmer weather when atmospheric ozone levels are usually greater. Ozone generators have been advertised and sold to "purify" indoor air but can produce indoor concentrations well in excess of National Ambient Air Quality Standards (NAAQS) limits. State and federal agencies strongly recommend against their use.

PHYSICAL AND CHEMICAL PROPERTIES

Ozone (O_3) is composed of three oxygen atoms and has a molecular weight of 48. Its boiling point is -114°C and melting point is -193°C . Compared to oxygen, ozone is approximately an order of magnitude more soluble (0.2605 ml/ml at 21°C) in water at pH 7 and 1.0 ATA (Cremasco and Mochi, 2012). Ozone in air has a relatively short half-life (3 days at 20°C). In water at pH 7, its half-life is brief (20 min at 20°C). These estimates of longevity are quite variable because ozone is a highly reactive agent. For example, its half-life is highly pH dependent, decreasing with increasing pH. Contaminants in a water solution also decrease its longevity since ozone is highly reactive. In addition, its half-life is inversely related to ambient temperatures and the half-life in solution cannot be measured accurately above 40°C .

ENVIRONMENTAL FATE AND BIOACCUMULATION

At present, the average overall background concentration of ozone in the troposphere is 20–40 parts per billion (ppb). Background ozone concentrations have doubled with the advent of industrialization in the last 100–150 years, although the rate of increase has slowed modestly in the late twentieth century (Fuhrer, 2009). Ozone concentrations can be substantially greater in locales with fossil fuel energy sources utilized in motor vehicles and industry. Prior to the realization of the deleterious effects of ozone and initiation of environmental controls, ozone levels reached extremely high

levels in some areas. In 1955, an ozone level of 680 ppb was recorded in Los Angeles (Bachman, 2007).

Relatively little ozone is created directly from the oxygen in the troposphere. However, substantial ozone can be created in the presence of oxides of nitrogen (NO_x) and volatile organic compounds (VOCs). The principal NO_x involved in ozone generation are nitric oxide (NO) and nitrogen dioxide (NO_2). The atmospheric concentration of NO is much greater than NO_2 , and the NO/NO_2 ratio is usually 10:1 or greater (Jenkin and Clemitshaw, 2000). The NO/ NO_2 reaction catalyzes the generation of an ozone molecule. When NO_2 is exposed to UV radiation in sunlight (<420 nm), it dissociates into NO and an oxygen atom (Crutzen et al., 1999; Jenkin and Clemitshaw, 2000)

The oxygen atom reacts with oxygen in the atmosphere to form ozone

where M is an energy-absorbing substance, usually nitrogen or oxygen. The mean life of an NO_2 molecule in the presence of UV radiation during daylight is estimated to be only a few minutes (Jenkin and Clemitshaw, 2000).

Numerous volatile carbon compounds, such as those present in gasoline, can contribute to ozone generation in the atmosphere. The interaction of NO and VOCs is initiated by a hydroxyl radical attacking a VOC molecule to form an organic peroxy radical (RO_2), where R represents an intermediate in the photochemical oxidation of a VOC (Figure 50.2). Then, the peroxy radical reacts with NO to

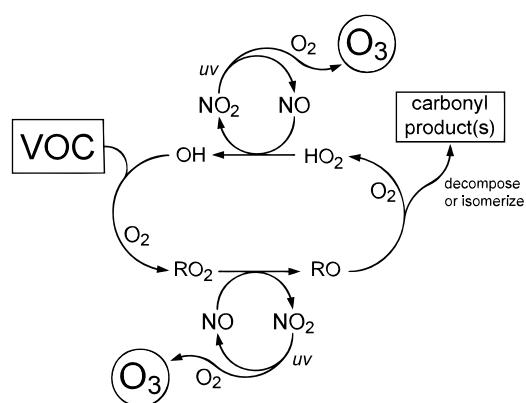

FIGURE 50.2 Role of nitric oxides (NO and NO_2) in the production of ozone (O_3) from a volatile organic compound (VOC). Hydroxyl radical (OH), organic peroxy radical (RO_2), organic oxy radical (RO), and hydroperoxy radical (HO_2) are involved in the cyclical autocatalytic cycle of oxidation. The breakdown of NO_2 requires ultraviolet (UV) radiation and the presence of oxygen (O_2). Figure redrawn from Jenkin and Hayman (1999).

produce an RO radical and NO_2

In the presence of UV radiation and oxygen, the NO_2 molecule breaks down to form an ozone molecule and NO via Equations (50.1) and (50.2). The RO radical further reacts to form a hydroperoxy radical (HO_2) and carbonyl products, which may decompose or isomerize. The hydroperoxy radical reacts with NO to produce an NO_2 molecule and a hydroxyl radical

This NO_2 degrades to NO in the presence of UV radiation in sunlight and oxygen, producing another molecule of ozone via Equations (50.1) and (50.2). The hydroxyl radical proceeds to initiate the autocatalytic cycle again with another VOC (Jenkin and Hayman, 1999).

Ozone molecules formed with this interaction between VOCs and NO_x can remain free, oxidize particles or chemicals in the atmosphere, or react with NO to regenerate NO_2 .

The actual level of ozone in the atmosphere is a complex function of the atmospheric concentrations of NO_x and VOCs, the type of VOCs, ambient temperature, the amount of UV radiation provided by sunlight, humidity, wind, and the rates of ozone removal during both day and night (Crutzen et al., 1999; Jenkin and Clemitshaw, 2000). An example of the interaction of VOC and NO_x concentrations in ozone generation is shown in Figure 50.3. The isopleths in the figure depict the level of atmospheric ozone produced by different combinations of VOC and NO_x . The ratios of VOC/ NO_x are indicated by the dashed lines. In circumstances of low NO_x , there is an insufficient catalytic generation of ozone to maximize its net production even when the VOCs are plentiful. Similarly, low VOC concentrations result in limited production of ozone even when NO_x concentrations are elevated. Maximum ozone production occurs when the ratios of VOCs and NO_x are optimal. The figure serves as an example of the effects of VOC and NO_x on ozone production, but the production also depends on a number of other variables cited above. Sunlight and temperature have dominant effects on ozone levels, and the cited levels are much lower in winter than summer in urban areas with large seasonal changes in these factors. Maximum generation of ozone may occur 10–20 miles downwind of the sites of release of the primary pollutant precursors of ozone.

Outside urban areas, natural sources of ozone contribute to the background level of ozone. Massive electrical

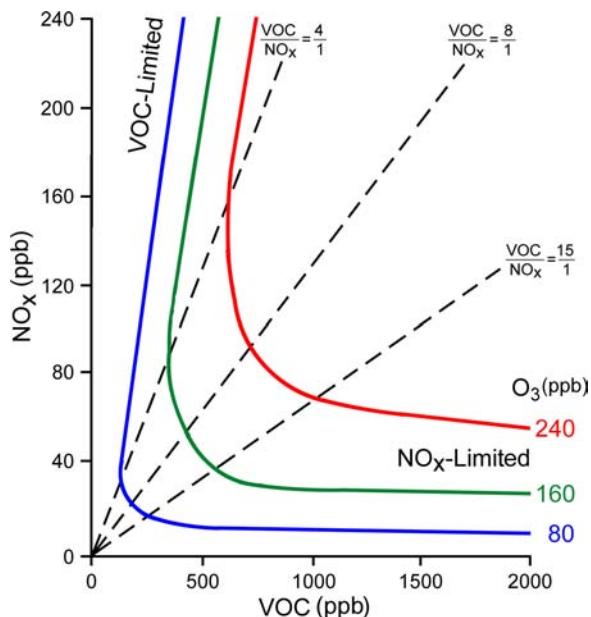

FIGURE 50.3 Example of the relationship between concentrations of nitric oxides (NO_x) and volatile organic compounds (VOC) in determining the levels of ozone (examples of 80, 160, 240 ppb) in the atmosphere under a given set of environmental factors. Ozone production is maximal at the optimal VOC/NO_x ratio and increases relatively little as VOC concentration increases (NO_x -Limited), indicated by the quasi-horizontal lines of production at higher VOC concentrations. Ozone production remains relatively constant (VOC-Limited), indicated by the quasi-vertical lines of production, as increasing NO_x concentration alters the optimal VOC/NO_x ratio. Ozone production and the VOC/NO_x relationship are also affected by a number of other factors, including sunlight, temperature, and humidity. Modified from Jenkin and Clemitshaw (2000). Original diagram from Dodge (1977).

discharges occurring with lightning produce ozone directly; this leads to markedly elevated, but localized, ozone levels. Biomass combustion occurring in wildfires increases atmospheric NO_x and some trees naturally release VOCs that stimulate ozone production. While these sources contribute to ozone levels, the increase noted in the background levels of ozone in the last century is the result of increased human activity. Ozone is widely dispersed in the troposphere by wind and weather patterns and can be transported throughout the earth's atmosphere (WHO Regional Office for Europe, 2008). In spring, the minor contribution of stratospheric ozone to the troposphere may increase with violent storms having a strong vertical component, particularly at high altitudes.

ECOTOXICOLOGY

Even in rural areas, ozone in the atmosphere can affect vegetative growth. Some crops will have reduced yield in

regions with ozone levels that are within Environmental Protection Agency (EPA)-approved limits (Morgan et al., 2003). Wheat, corn, and soybean are the major food crops most sensitive to ozone. There is evidence that the yield of these crops in East Asia and Europe has been reduced by as much as 20–25% during the years of severe ozone pollution in the 1990s (Fuhrer, 2009). Other crops, such as rice, are moderately sensitive, but any reduction in rice productivity would be considered serious in view of the importance of this source of nutrition in many countries.

The effect of ozone on plants not only is a factor of the level of exposure, but also depends on the uptake and detoxification of ozone by the particular plant species (Fuhrer, 2009). Ozone is predominantly absorbed by diffusion through the leaf stomata and leads to production of reactive oxygen species (ROS). Stomatal conductance not only varies with different species but is also a complex function of environmental conditions, including solar radiation, temperature, humidity, and carbon dioxide concentration as well as the stage of plant growth. The detoxification of ROS in plants is principally accomplished by reducing agents, e.g., ascorbate. Reactive oxygen species that are not scavenged cause decreased photosynthesis, increased rate of leaf senescence and degradation of proteins and chlorophyll.

Morgan et al. (2003) conducted a meta-analysis of 53 studies of the impact of ozone on soybean growth using the open-top chamber technique. With this methodology, the plants are exposed through the top of the enclosure to prevailing sun and rain. The atmosphere surrounding the plants is maintained constant by continuous ground-level release of a gas with the desired composition. The mean ozone concentration in the experimental group in these studies was 70 ppb and was compared with plants exposed to air free of ozone. At the completion of the growing season, dry plant mass in the ozone-exposed plants had decreased by 38% and seed yield decreased by 24% compared to the control. Other reductions from normal values included photosynthetic rate (20%), leaf chlorophyll concentration (14%), green leaf area (32%) and total leaf area (10%). Interestingly, addition of CO_2 to the gas mixture significantly reduced the damage caused by ozone, most likely the result of a CO_2 -induced decrease in stomatal conductance (27%) (Morgan et al., 2003). However, carbon dioxide exposure did not completely eliminate the deleterious effects of ozone.

The influence of ozone on tree growth as opposed to that of ground-level plants presents a more complicated situation. Extrapolating conclusions from juvenile trees grown in exposure chambers does not necessarily correlate with mature tree growth in the field. Matyssek et al. (2008) has criticized this methodology because significant gradients in ozone concentration, sunlight exposure, and humidity occur between the leaf canopy and ground levels in mature trees. These authors argue that conclusions regarding ozone and other air pollutants must be reached by understanding the mechanisms involved in

pollutant uptake and detoxification as well as the effect of different species in resistance to pollutant effects. Clearly much more progress has been achieved in the study of ground-level plants compared to trees.

MAMMALIAN TOXICITY

Experimental studies utilizing animal models, principally rodents, have demonstrated that acute, high level exposure to ozone results in mortality through the induction of severe pulmonary edema. Last et al. (2010) have described the pathologic and functional changes in animals exposed to high doses of ozone as well as lesser exposures in humans. In general, reported animal studies are less pertinent to humans, since the levels of exposure in animal work are rarely encountered in current human exposures to ozone. Early experimental studies in humans were conducted with ozone concentrations that no longer occur in developed countries and are present only in a few urban areas in developing countries. Recently, investigations have focused on more pertinent ozone levels and its interaction with other air pollutants, especially particulate matter (PM) less than 2.5 microns in diameter (PM_{2.5}).

Ozone has relatively mild irritant effects on the eyes and skin at the current levels of exposures, but these effects are transient without permanent residua. However, ozone produces significant cardiopulmonary morbidity and mortality.

Substantial progress has been achieved in the last decade in defining the effect of ozone exposure on human mortality. Previously published investigations reported time-series studies of mortality, usually performed in a single city or region. The results were variable with both positive and negative findings. Several earlier meta-analyses had suggested an increase in mortality but considerable uncertainty persisted. In 2003 the EPA commissioned three different epidemiological teams to analyze available studies contained in a large database of ozone reports. The teams performed meta-analyses independently using different methodologies (Bell et al., 2005; Ito et al., 2005; Levy et al., 2005). Wherever possible, primary data were analyzed. All three groups reached the conclusion that acute ozone exposure increased mortality within a few days by approximately 0.89% for each 10 ppb increase. Using studies reporting seasonal data, a higher mortality was noted during warmer months when ozone levels are greater. With the limited data available in these primary sources, no significant effect of confounding pollutants could be discerned. One of these three meta-analyses suggested that the calculated mortality rates could partially be due to publication bias that tended to favor studies with positive results (Bell et al., 2005).

A more conclusive approach to investigate the effect of tropospheric ozone is to utilize the data collected from multiple cities in a single uniform study. The National

Morbidity, Mortality and Air Pollution Study (NMMAPS) provided 14 years (1987–2000) of information collected in a uniform fashion in 95 large urban areas throughout the United States. Bell et al. (2004) used a distributed-lag model of mortality adjusted for PM, weather, seasons, and long-term trends in each urban area. Individual regional mortalities were combined to calculate an average national mortality that accounted for statistical uncertainty and heterogeneity in each community. The overall national mortality increase was 0.52%/10 ppb increase in a daily average ozone exposure during the previous week. Age (~50% of those dying were ≥75 years) and increased respiratory and cardiovascular mortality were major contributors to the overall mortality. Particulate matter (PM₁₀) did not correlate with ozone levels and inclusion of specific community PM₁₀ levels in the model did not affect the calculated ozone mortality. Exclusion of days with temperatures >29 °C. (85 °F.) also did not affect the calculated ozone mortality.

Bell and Dominici (2008) extended their previous study utilizing the data from the NMMAPS study, as well as data from the National Center for Health Statistics, National Climatic Data Center, and EPA, to determine the role of specific community-level characteristics on mortality. This work included data from 40% of the total U.S. population. There was no demonstrable effect of PM, either PM_{2.5} or PM₁₀, on short-term ozone-associated mortality. The highest mortality rates were (1.44 and 0.73%/10 ppb increase in ozone) in the Northeast and Industrial Midwest regions, respectively. The lowest mortalities (essentially no increased risk) were in the Southwest and urban Midwest. A major difficulty in interpreting any ozone-associated effects is the determination of actual exposure, since outdoor ozone concentrations correlate poorly with indoor concentrations. The latter concentration can be much lower than that of outdoors depending upon the extent of air exchange between the two environments (U.S. EPA, 2013).

A study of 48 U.S. cities investigated the timing and factors involved in ozone-associated mortality rates (0.5%/10 ppb increase) during the months of May through September (Zanobetti and Schwartz, 2008a). The increase in ozone-associated mortality started in the springtime and peaked in July. Mortality rates decreased in August and the authors calculated a null association in September even though ozone levels were elevated in the latter 2 months. The authors hypothesized that susceptible persons developed biological resistance to ozone, an observation noted in some acute laboratory experiments (Folinsbee et al., 1994). However, this observation also would be compatible with the concept that the susceptible individuals died when first exposed to the elevated ozone levels in the spring and early summer. As noted in earlier studies, the increased mortality was prominent in older individuals (>50 years) in this study.

The influence of PM on ozone-associated mortality has been investigated, but the exact composition of particulate

pollutants can vary widely with time and geography. Anderson et al. (2012) studied the effect of the seven major components of PM_{2.5} on ozone-associated mortality in 57 U.S. communities and found no effect of local components of PM, including sulfate. These seven components studied comprise the great majority of small particulate mass in the atmosphere. In addition, levels of particulate pollutants are relatively constant throughout the year while ozone levels and its associated mortality vary substantially throughout the year depending upon the season and ambient temperatures.

The use of advanced statistical analyses and large multicity databases has convincingly described an effect on short-term mortality at ozone levels present in many urban areas. More recent attention has been paid to its role in the morbidity of specific diseases. Patients with asthma, a common and widespread disease, are likely to experience morbidity with pollutant exposure. There are numerous studies relating exposure to automotive air pollution to hospital or emergency room admissions for asthma exacerbation, symptoms such as wheezing and shortness of breath, and the need for acute or chronic asthmatic medications. Despite this large body of evidence that exacerbations of asthma can be precipitated by components of automotive air pollution, especially ozone and small PM, it is still uncertain whether this pollution causes the actual development of asthma rather than only precipitating exacerbations (Ryan and Holguin, 2010). The role of ozone in exacerbations of asthma is still not completely defined due to the lack of many large multicity studies, measurements of only a few of the multiple components of automotive pollution in some studies, the high correlation among some components of atmospheric pollution that obscure individual roles, and the use of retrospective review of medical records to obtain diagnoses. Overall, recent studies are supportive of the concept that ozone itself is a factor in exacerbations of asthma.

Silverman and Ito (2010) analyzed 69,735 non-ICU hospital admissions for asthma to 74 New York City hospitals in the months April through August for the period 1999–2006. They reported an overall increased relative risk of hospital admission (1.06, 95% confidence interval (CI), 1.03–1.10) for an increase in ozone exposure of 22 ppb and an increased relative risk (1.07, 95% CI, 1.05–1.10) for an increased exposure of PM_{2.5} of 12 µg/m³ in a two-pollutant, 0–1 day lag model. The age effect was greatest in the age group 6–18 years (1.15 and 1.16, respectively, for ozone and PM_{2.5}). The correlation (0.59) between ozone and PM_{2.5} increases the uncertainty of which pollutant, or possibly their combination, was responsible for the effect. However, the simultaneous inclusion of both the pollutants in the analytic model argues strongly for both the pollutants having causative roles in exacerbations of asthma, especially in young individuals.

In an analysis of 91,386 emergency room visits for asthma treatment for over 12 years (1993–2004) in 41 hospitals in

metropolitan Atlanta, Georgia, Strickland et al. (2010) studied the effects of 11 different ambient air pollutants. In preliminary univariate analysis, 10 of the 11 pollutants had significant positive associations with patient visits. Of these 10 pollutants, ozone had the strongest association with patient visits during the warm weather (relative risk 1.082 for an interquartile change in concentration). Case-crossover and time-series models only reduced significant associations of one and three pollutants, respectively, of the original 10 associations. The association between ozone and emergency room visits for asthma persisted when the data were analyzed in several two pollutant models. In these models carbon monoxide had the strongest association with emergency department visits. Ozone and nitrogen dioxide also exhibited positive associations with visits. The authors concluded that the two-pollutant models support the conclusion that ozone and traffic-related primary pollutants independently contribute to the frequency of exacerbations of asthma.

Investigators have attempted to define the effects of ozone per se in the absence of other pollutants by performing controlled chamber studies in which the same subjects are exposed to filtered air and known concentrations of ozone in air on separate occasions. Since subjects act as their own controls, this approach enables the detection of small decrements in lung function that would not be appreciated in large-scale epidemiological studies investigating the effects of mixed pollutant exposures. Initial studies employed inspired ozone levels as high as 400 ppb for short periods of time and demonstrated substantial decrements in lung function. However, this still did not answer the question of whether exposure to current urban levels of ozone carries a health risk. As urban ozone levels have decreased in most developed countries, investigations have focused on low levels of ozone that span the range currently present in urban atmospheres. A commonly used testing protocol involves a 6.6-h exposure with 50 min of exercise/h plus a 35-min lunch break. The increased ventilation (4–5 times the resting values) obviously leads to a greater overall ozone exposure than experienced by an individual who is not exercising. This serves as an estimate of the potential risk of exposure that could be expected to mimic real-life, outdoor working conditions of a moderate degree.

Using this 6.6-h protocol, Schelegle et al. (2009) studied the responses of 16 healthy females and 15 males to 5 different ozone exposures [mean measured exposure levels: 0 (filtered air), 63, 72, 81, and 88 ppb] on different days in a random order. Exposures were separated by a minimum of 7 days to avoid cumulative effects of the exposures. In this study, exposure was initiated at a level lower than the target level, peaked at 4.6 h, and then decreased to simulate the course of ozone levels during a working day. Spirometry and symptom scores were recorded at the end of each exercise period and 1 and 4 h post exposure. The

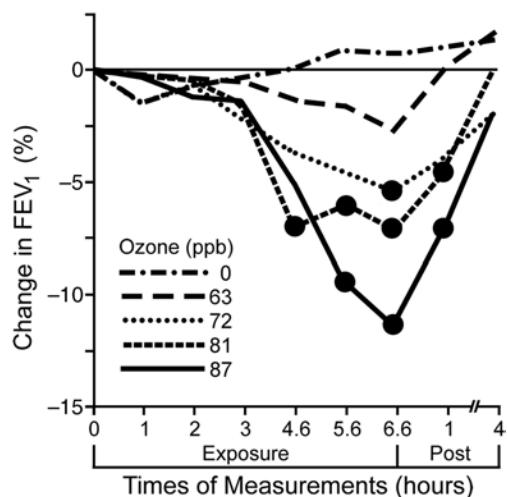

FIGURE 50.4 Mean changes in forced expiratory volume, 1.0 s (FEV₁) from baseline pre-exposure values (0 h) with continuing exposure to mean levels of ozone (0, 63, 72, 81, and 87 ppb) during a 6.6 h protocol. Exercise increased minute ventilation in subjects ($n = 31$, mean age 21.4 years) to a mean of 38.7 l/min during 50 min of exercise per hour with a 35 min rest period for food at hour 4. Postexposure values were obtained at rest while breathing air without ozone. The filled circles indicate statistically significant changes ($p < 0.05$) compared with the FEV₁ breathing ozone-free inspired air at the same time point. Figure redrawn with permission from Schelegle et al. (2009).

average forced expiratory volume in 1.0 second (FEV₁), the most common clinical measurement of airflow obstruction, decreased significantly during the three highest levels of ozone exposure compared to the FEV₁ measured during the exposure to filtered air (Figure 50.4). The decrease in the group mean of the FEV₁ did not reach statistical significance during exposure to 63 ppb ozone. However, the response to ozone exposure is heterogeneous, and at this level of exposure, 11 of the 31 subjects had decrements in the FEV₁ that were significantly greater than the measurement error of the FEV₁. Increases in symptom scores of the subjects followed the same pattern as the FEV₁ and reached a statistical significance during exposures of 72, 81, and 88 ppb. Reductions in the forced vital capacity (FVC) were less than those of the FEV₁ and reached statistical significance only during the exposures to 81 and 88 ppb. Most abnormalities returned to control values by 4 h after the termination of exposures.

A larger study of 59 young (25.0 ± 0.5 SEM years) healthy subjects exposed to a constant level of 60 ppb ozone with the same 6.6-h exercise protocol demonstrated small, but statistically significant, decrements in both FEV₁ (-1.7%) and FVC (-1.2%) compared to control experiments breathing ozone-free air (Kim et al., 2011). In addition, the

mean percentage of neutrophils in sputum, an indicator of airway inflammation, was 15% greater than the control percentage 18 h post exposure ($p < 0.002$).

These two studies (Kim et al., 2011 and Schelegle et al., 2009) indicate that exposure to ozone levels that are within the current NAAQS during outdoor exercise can result in decrements of pulmonary function and increases in lung inflammation. While the mean values of functional loss are small, of greater concern is the larger loss of function in a subset of subjects with greater sensitivity to ozone.

Relatively short-term experimental challenges demonstrate loss in function, but this reverts to normal shortly after the termination of the exposure. Long-term effects of modest ozone exposure on lung function and the inflammatory response have not been defined. In fact, repeated exposures to higher levels of ozone (120–200 ppb), over the course of several days, suggest that the initial loss in lung function and the delayed inflammatory response are ameliorated, but not resolved, despite continued exposure (Folinsbee et al., 1994).

The effect of ozone on cardiovascular health is less clear than its influence on respiratory morbidity and mortality. Most epidemiologic data regarding the effect of ozone on the incidence of myocardial infarction, hypertension, emergency department visits, and hospital admission for cardiovascular events do not support an association (U.S. EPA, 2013). Earlier studies investigating a possible association of cardiovascular mortality with ozone exposure were inconsistent, but more recent studies with large populations support a causative association. Jerrett et al. (2009) reviewed data collected from 1.2 million people in an American Cancer Society study. The authors found associations between cardiovascular mortality and exposure to both ozone and PM_{2.5} in single-pollutant analyses, but in a two-pollutant model, only PM_{2.5} had a significant association. Stafoggia et al. (2010) analyzed data from 10 Italian cities, which included both ozone and PM₁₀ data. They found increased all-cause and cardiovascular mortalities of 1.5 and 2.3% with an increase of 5 ppb ozone in both single- and two-pollutant models, supporting the role of both the pollutants in total and cardiovascular mortalities. Other investigators (Samoli et al., 2009; Zanobetti and Schwartz, 2008b) also have found significant associations between ozone exposure and cardiovascular mortalities in large studies of multiple European and U.S. cities, respectively. However, neither of these two studies included PM data in the analyses. All of these studies were conducted on data obtained during summer months when ozone levels are the highest. Because of the large effect of PM on cardiovascular mortality and its correlation in many regions with ozone levels, it is difficult to separate completely the effects of both the pollutants on cardiovascular mortalities.

A concern regarding the findings of increased total mortality with ozone exposure is the possibility that the

individuals who died were already severely ill and the exposure only hastened inevitable death by a short time. In an analysis of a time-series study, Zanobetti and Schwartz (2008b) investigated this possibility by comparing the number of deaths on a given day to the deaths in the ensuing 3 weeks. If the deaths were premature because of an ozone effect and these individuals were removed from the cohort earlier, then the later number of deaths would be less and the overall mortality for the period would not be increased. In their analysis, they found that the deaths consistently increased over a 3-week window throughout June through August, the time of year when ozone levels are elevated. The authors concluded that the overall mortality increases with ozone exposure. Since their analysis could only include a total period of 3 weeks, they were unable to reach any conclusion regarding longer periods of premature death. Clearly further studies are needed to investigate this possibility. Investigations of the long-term effects of ozone exposure are few in number and difficult to analyze due to the large number of variables involved.

Remaining uncertainties regarding long-term effects, the different levels of indoor and outdoor ozone, and the exact role of ozone in multi-pollutant atmospheres require further study. Air quality in developed countries has improved greatly in the last 50 years. Currently in many areas, average ozone levels are approaching the present background of 40 ppb. Further lowering of ozone levels will become increasingly more difficult and expensive (Frampton, 2011). It is possible that background levels of ozone could have health effects, either independently or in combination with other atmospheric components. Therefore, future research needs to address the most effective means of reducing adverse health effects of ozone. This may not include only an effort to reduce the level of ozone in the troposphere.

SOURCES OF EXPOSURE

Urban atmospheres are the principal sources of exposure to ozone and levels frequently exceed not only the NAAQS of 75 ppb but also the OSHA and NIOSH limits of 100 ppb. Since ozone is a potent oxidizing agent, it is generated as per industrial use and is rarely stored. However, concentrations of ozone generated with an oxygen stream can be as great as 20% weight/total weight. Ozone monitors must be present wherever ozone is generated, transported via conduits, or used, because ozone can leak through corroded valves and pipes. Personal exposures to ozone can be significant during arc welding, but source levels do not approach those occurring with industrial ozone generators. With appropriate ventilation, ozone levels generated in arc welding can be maintained at acceptable levels. Compared to these industrial circumstances, most ozone exposure levels are low. Although ozone is generated by electrostatic printing and

copying procedures, the resulting concentrations are below the current OSHA PEL.

INDUSTRIAL HYGIENE

The OSHA limits for ozone exposure are 100 ppb time-weighted average (TWA). The NIOSH ceiling is 100 ppb. The American Conference of Governmental Industrial Hygienists (ACGIH) has published a sliding scale from 50 to 100 ppb depending on work intensity and a 200 ppb 2-h TWA at all levels of work. For PPE, the Centers for Disease Control and Prevention (CDC)/NIOSH Pocket Guide recommends a chemical cartridge respirator or supplied-air respirator (assigned protection factor (APF)=10) for ozone levels above acceptable levels up to 1000 ppb; a supplied-air respirator operated in continuous-flow mode or a powered, air-purifying respirator (APF=25) up to levels of 2500 ppb; a chemical cartridge respirator with full facepiece, an air purifying, full facepiece respirator (gas mask) with chin-style, front or back-mounted canister, a supplied-air respirator with a tight-fitting facepiece operated in a continuous-flow mode, a self-contained breathing apparatus with a full facepiece or a supplied-air respirator with a full facepiece (APF=50) up to levels of 5000 ppb. For entry into unknown concentrations or Immediately Dangerous to Life or Health (IDLH) conditions, the recommendation is for a self-contained breathing apparatus that has a full facepiece and is operated in a pressure-demand or other positive-pressure mode or a supplied-air respirator that has a full facepiece and is operated in a pressure-demand or other positive-pressure mode in combination with an auxiliary self-contained, positive-pressure breathing apparatus (APF=10,000).

RISK ASSESSMENTS

The U.S. EPA (2013) published an Integrated Science Assessment for Ozone and Photochemical Oxidants (ISA-Ozone). This document concludes that there is a causal relationship between short-term ozone exposure and respiratory effects. These effects include exacerbations of asthma, respiratory-related hospital admissions, and increased respiratory symptoms. Likely causative effects of short-term ozone exposure included total mortality, cardiovascular effects, and cardiovascular mortality. The conclusion regarding cardiovascular effects was based on toxicological and animal studies. Epidemiologic data were inconsistent. Long-term exposure to ozone was identified as a likely cause of respiratory effects. Elevated ambient ozone exposure was identified as a cause of foliar injury, reduced growth of native plants, and reductions of yield and quality of agricultural crops.

The Regional Health Office for Europe of the World Health Organization (2008) issued a health impact statement that estimated that ozone levels above 35 ppb caused 21,000 premature deaths in 25 European countries in the year 2000. In terms of morbidity, ozone exposures caused an estimated 14,000 annual admissions to hospitals caused by respiratory illness, 54.9 million person-days of minor respiratory distress in adults, and 21.0 million person-days of required respiratory medications in children. In anticipation of the results of current pollution control, the predicted premature mortality in 2020 would decrease only by 5% and hospital admissions would rise by 43%, but the adult and childhood morbidities would decrease by 21 and 38%, respectively.

Berman et al. (2012) calculated the potential effects of adherence to the new NAAQS of 75 ppb that would have resulted if this had been achieved in years 2005–2007 in the United States. The annual premature deaths would have decreased between 1410 and 2480 individuals, cases of respiratory symptoms by 3 million, and days of lost school attendance by 1 million. If a lower ozone exposure limit of 70 ppb had been achieved during 2005–2007, calculated premature deaths would have decreased by an annual average between 2450 and 4130 individuals. It is unlikely that these estimated improvements would be directly applicable to the present time since ozone levels have decreased further since 2005–2007 even though the current NAAQS often is exceeded in areas within the country.

ACKNOWLEDGMENT

The author wishes to acknowledge the editorial and technical assistance of Margaret A. Simons in the preparation of this manuscript.

51

PHOSPHORUS COMPOUNDS

M. RONY FRANCOIS AND FRANK STEPHEN

First aid (white phosphorus): Inhalation: Remove casualty to fresh air and keep at rest. Seek medical advice; Skin: Treat phosphorus burns by immediate immersion under water and call for medical assistance; Eyes: Rinse with plenty of water and seek medical advice; Ingestion: Rinse mouth. Consult a doctor immediately. Do not induce vomiting. Hazards: Danger of circulatory collapse. Treatment: It may be necessary to administer oxygen. After skin contact, mechanically remove any residual attached phosphorus under water; then coat skin with a "Ben Hur" solution. Apply a sterile dressing to the wound. If swallowed, wash out the stomach and administer active charcoal together with a 0.2% solution of copper sulfate

Occupational exposure limits (white phosphorus): 0.1 mg/m³ (OSHA PEL, NIOSH REL, ACGIH TLV)

Hazard statement (white phosphorus): H250—catches fire spontaneously if exposed to air; H330—fatal if inhaled; H300—fatal if swallowed; H314—causes severe skin burns and eye damage; H400—very toxic to aquatic life

Precautionary statements (white phosphorus): P210—keep away from heat/sparks/open flames . . . /hot surfaces . . . no smoking; P222—do not allow contact with air; P260—do not breath dust/fume/gas/mist/vapors/spray; P264—wash...thoroughly after handling; P270—do not eat, drink, or smoke when using this product; P271—use only outdoors or in a well-ventilated area; P273—avoid releases to the environment; P280—wear protective gloves/protective clothing/eye protection/face protection; P284—wear respiratory protection; P285—in case of inadequate ventilation wear respiratory protection; P302+P334—if on skin, immerse in cool water/wrap in wet bandages; P304+P340—if inhaled, remove victim to

fresh air and keep at rest in a position comfortable for breathing; P310—immediately call a poison center or doctor/physician; P320—specific treatment is urgent (see . . . on label); P370+P378—in case of fire, use . . . for extinction; P403+P233—store in a well-ventilated place. Keep container tightly closed; P405—store locked up; P422—store contents under . . . ; P501—dispose of contents/container to . . . ; P301+P310—if swallowed, immediately call a poison center or doctor/physician; P321—specific treatment (see . . . on label); P301+P330+P331—if swallowed, rinse mouth. Do not induce vomiting; P303+P361+P353—if on skin (or hair), remove/take off immediately all contaminated clothing. Rinse skin with water/shower; P305+P351+P338—if in eyes, rinse cautiously with water for several minutes. Remove contact lenses, if present and easy to do. Continue rinsing; P309+P311—if exposed or if you feel unwell, call a poison center or doctor/physician; P391—collect spillage; P363—wash contaminated clothing before reuse

Risk phrases (white phosphorus): R17—spontaneously flammable in air; R26/28—very toxic by inhalation and if swallowed; R35—causes severe burns; R50—very toxic to aquatic organisms

Safety phrases (white phosphorus): S1/2—keep locked up and out of reach of children; S5—keep contents under . . . (appropriate liquid to be specified by the manufacturer); S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S38—in case of insufficient ventilation, wear suitable respiratory equipment; S45—in case of accident or if you feel unwell, seek medical advice immediately

TABLE 51.1 Exposure Limits and Threshold Limit Values for Phosphorus Compounds

Chemical Name and Synonyms	Formula	CASRN	Form	OSHA PEL (mg/m ³)	NIOSH REL (mg/m ³)	ACGIH TLV (mg/m ³)
Phosphorus (yellow), elemental phosphorus, white phosphorus	P ₄	7723-14-0	Clear, colorless liquid	0.1	0.1	0.1
Phosphoric acid, orthophosphoric acid, white phosphoric acid	H ₃ PO ₄	7664-38-2	Crystalline solid	1	1.0, 3.0 ^a	1.0, 3.0 ^a
Phosphorus oxychloride, phosphorus chloride, phosphorus oxytrichloride, phosphoryl chloride	POCl ₃	10025-87-3	Clear, colorless to yellow liquid	None	0.6, 3.0 ^a	0.6
Phosphorus pentachloride, pentachlorophosphorus, phosphoric chloride, phosphorus perchloride	PCl ₅	10026-13-8	White to pale yellow crystalline solid	1.0	1.0	0.1
Phosphorus pentasulfide, phosphorus persulfide, sulfur phosphide, phosphorus sulfide	P ₂ S ₂ /P ₄ S ₁₀	1314-80-3	Greenish gray crystalline solid	1.0	1.0, 3.0 ^a	1.0, 3.0 ^a
Phosphorus trichloride, phosphorus chloride	PCl ₃	7719-12-2	Colorless to yellow fuming liquid	3	1.5, 3.0 ^a	1.5, 3.0 ^a
Phosphorus anhydride, 1,2-benzenedicarboxylic anhydride, PAN, phthalic acid anhydride	C ₆ H ₄ (CO) ₂ O	85-44-9	White solid or clear colorless liquid	12	6	6
Phosphine, hydrogen phosphide, phosphorated hydrogen, phosphorus hydride, phosphorus trihydride	PH ₃	7803-51-2	Colorless gas	0.4	0.4, 1.0 ^a	0.4, 1.4 ^a

^a15 min short-term exposure limit.

OSHA, Occupational Safety and Health Administration; NIOSH, National Institute for Occupational Safety and Health; ACGIH, American Conference of Governmental Industrial Hygienists; PEL, permissible exposure limit; REL, recommended exposure limit; TLV threshold limit value.

(show the label where possible); S61—avoid release to the environment, refer to special instructions/safety data sheets.

HISTORY

Essential for life, phosphorus is a nonmetal that, as phosphate (PO₄) rocks, is mined for use in producing phosphate-based fertilizers for agriculture. First isolated from urine in the seventeenth century, phosphorus has had common uses in explosives, poisons and nerve agents. Ironically, because of these uses and the claim that it was the 13th element discovered, it has sometimes been referred to as “the Devil’s element” (Emsley, 2002). In its phosphate form, phosphorus is found in ATP, as a constituent of cell membrane phospholipids and part of the sugar-phosphate backbone of DNA and RNA. As a commercial product, phosphate is mainly found in fertilizers where it is used to replace phosphorus removed by growing plants. It is also used in food preservatives, ceramics, cosmetics, animal feed supplements, water treatment (softeners), and metallurgy (steel production). In its organophosphate form,

phosphorus is also used in pesticides, nerve agents, detergents, and matches. The toxicological properties of phosphorus are based upon the form in which it is found. Table 51.1 outlines exposure limits and threshold limit values (TLV) for various phosphorus compounds and definitive examples of toxicity of some compounds are discussed below.

WHITE/YELLOW PHOSPHORUS

Historically, white phosphorus was notorious because its inhalation in the matchmaking industry caused a disfiguring ailment known as *phossy jaw*. Fatal, the ailment is caused when white phosphorus fumes are absorbed through cavities in the teeth. Eventually deposited in bones and causing them to glow a greenish-white color in the dark, white phosphorus exposure can also lead to liver and other organ failure. Victims would also suffer from a foul-smelling discharge from the rotting bone. The use of yellow phosphorus in industry was discontinued early in the twentieth century after the discovery of the safer, but more expensive, red phosphorus.

White phosphorus (CASRN 12185-10-3) is found as a waxy, sometimes translucent solid. However, because it oxidizes quickly and discolors after exposure to light, it is also known as yellow phosphorus. Flammable at temperatures as little as 10 °C above room temperature, white phosphorus is stored underwater. White phosphorus is also pyrophoric and has a melting point of 44.2 °C, a boiling point of 280.5 °C, and a density of 1.823. Used mainly to produce phosphoric acid, white phosphorus has a slight garlic smell. It reacts with oxygen and water to form strong acids (H_3PO_2 , H_3PO_3).

White phosphorus can persist in air from minutes to days but may have a longer half-life when aerosolized and coated with a protective layer of oxide (Berkowitz et al. 1981). White phosphorus can exist in water as dissolved phosphorus in amounts ≤ 3 mg/l, in the colloidal state, as large particles of elemental phosphorus at concentrations > 3 mg/l, or in the particle-sorbed state (Bullock and Newlands, 1969). Bioconcentration of white phosphorus in aquatic organisms does occur. In soil, white phosphorus will rapidly oxidize as long as oxygen is able to diffuse through (Bohn et al., 1970) and at ambient temperatures, this process can take as little as 2 days (Rodriguez et al., 1972).

NIOSH (1994) and the American Conference of Governmental Industrial Hygienists (ACGIH) (1996) have set the recommended exposure limit (REL) and TLV, respectively, at 0.1 mg/m³. The Environmental Protection Agency (EPA) has derived a chronic oral reference dose (RfD) of 0.00002 mg/kg/day (IRIS, 1993) and listed white phosphorus as a group D carcinogen: not classifiable as a human carcinogen (IRIS, 1995).

PHOSPHORUS PENTACHLORIDE

Found as a white to pale-yellow, crystalline solid, phosphorus pentachloride (PCl_5 , CASRN 10026-13-8) is also known as pentachlorophosphorus, phosphoric chloride, and phosphorus perchloride. Noncombustible, phosphorus pentachloride has a very pungent, unpleasant odor with a density of 2.1 g/cm³, a melting point of 148 °C, and a sublimation point of 160.5 °C. The vapors of phosphorus pentachloride decompose in the presence of moisture with the subsequent liberation of hydrochloric and phosphoric acids (Henderson and Haggard, 1943).

Phosphorus pentachloride is used in a wide array of industrial processes. These include the manufacture of chlorophazenes, penicillin, and cephalosporin antibiotics, industrial catalyst, a mild chlorinating agent, aluminum metallurgy and as a precursor to Mustard gas and O-Mustard. In 2008, NIOSH estimated that approximately 2500 American workers are potentially exposed to phosphorus pentachloride (NIOSH, 2008). OSHA (USDOL, 2014) and NIOSH (2005)

have set the permissible exposure level (PEL) and REL at 1 mg/m³, respectively. ACGIH (2008) established the TLV time-weighted average TWA (TLV-TWA) for phosphorus pentachloride at 0.1 mg/m³. The NIOSH IDLH for phosphorus pentachloride is 70 mg/m³ (NIOSH, 2005). Occupational exposure to phosphorus pentachloride may occur through dermal contact with this compound at workplaces where phosphorus pentachloride is produced or used.

The primary effects of phosphorus pentachloride exposure are eye (conjunctiva) and respiratory passage irritation, deterioration of the mucous membranes of the mouth, throat, and esophagus. Subjects with eye exposures may also experience aversions to light (photophobia) and excessive tear production (lacrimation). Respiratory effects also include rhinitis, cough and dyspnea, mild bronchial spasm, respiratory distress, and pulmonary edema (Sullivan and Krieger, 1992). Bronchitis and bronchopneumonia can also occur. As the exposure concentration to this compound increases, gastrointestinal symptoms and central nervous system effects may develop. Extremely high vapor concentrations may cause tachypnea, tachycardia, arrhythmia, and death as a result of respiratory paralysis.

PHOSPHORUS TRICHLORIDE

Phosphorus trichloride (PCl_3 , CASRN 7719-12-2), also called phosphorus chloride, is a clear liquid with a very pungent, hydrochloric acid-like smell. It is a corrosive mostly used in the production of organophosphorus compounds. Listed in schedule 3, it is controlled under the Chemical Weapons Convention. Phosphorus trichloride has a melting point of -93.6 °C, a boiling point of 76.1 °C, and a density of 1.57 g/cm³. It can react with water to form phosphoric acid, hydrochloric acid, and phosphorus oxides.

Phosphorus trichloride is an important intermediate in the production of insecticides, herbicides, and organophosphorus pesticides as well as other chemicals such as phosphoryl chloride, phosphorus pentachloride, thiophosphoryl chloride, and phosphonic acid. It is also used in the production of synthetic surfactants, phosphites, gasoline additives, flame retardants, and silver polish.

OSHA (USDOL, 2014) has set the PEL for phosphorus pentasulfide at 0.5 ppm while NIOSH (2005) and ACGIH (2008) have respectively set the REL and the TLV at 0.2 ppm. ACGIH has set a STEL of 0.5 ppm. The NIOSH IDLH of phosphorus pentachloride is 25 ppm (NIOSH, 2005). An irritant of the eyes, skin, nose, and throat, phosphorus trichloride can also cause eye and skin burns. Other ocular effects include lachrymation and loss of vision. Central nervous system effects include dizziness and headache. Exposure of the respiratory system to phosphorus trichloride can produce cough, sore throat, bronchitis, and

even pneumonia. Nausea, vomiting, and abdominal pain are common digestive tract effects.

PHOSPHORUS PENTASULFIDE

Phosphorus pentasulfide (P_2S_5/P_4S_{10} , also known as phosphorus persulfide, CASRN 1314-80-3) is a crystal solid that can be gray, yellow, or green in color with a strong rotten egg smell. It is extremely flammable and can spontaneously ignite because it is very hygroscopic in the presence of moisture. Chemical properties include a melting point of 285 °C (with a vapor pressure of 1 mm), a boiling point of 515 °C, and a density of 2.03 g/cm³. Phosphorus pentasulfide can be burnt to form phosphorus pentoxide and sulfur dioxide. In water, it will decompose forming H_3PO_4 and H_2S .

Phosphorus pentasulfide is used in the manufacture of lube oil additives, ignition compounds and safety matches, insecticides (e.g., parathion and malathion), and pesticides. It can also be used as a desiccant. OSHA (2014), NIOSH (2005), and ACGIH (2008) have respectively set the PEL, REL, and TLV for phosphorus pentasulfide at 1 mg/m³. OSHA and ACGIH have set a STEL of 3 mg/m³. The NIOSH IDLH for phosphorus pentachloride is 250 mg/m³ (NIOSH, 2005). Potential symptoms of overexposure are irritation of the eyes, skin, and respiratory system. Ocular effects include tearing, aversion to light, conjunctival pain or keratoconjunctivitis, and corneal vesiculation. Prolonged exposure can produce disturbances to the gastrointestinal tract and central nervous system effects such as headache, dizziness, fatigue, convulsions, apnea, and coma.

PHOSPHORUS OXYCHLORIDE

Phosphorus oxychloride (CASRN 10025-87-3, $POCl_3$) is a clear, colorless liquid, which can react with water vapor to form fumes in the air. It is remarkable with regard to its pungent and musky odor. Chemical properties include a melting point of 1.25 °C, a boiling point of 105.8 °C, and a density of 1.645 g/cm³. It reacts with water to produce products that rapidly corrode steel and most metals.

Phosphorus oxychloride is an important intermediate in the production of triarylphosphate esters (e.g., triphenyl phosphate and tricresyl phosphate), which have been used as flame retardants and plasticizers for PVC. It is acutely toxic to the eyes, throat, and respiratory tract. Phosphorus oxychloride is also used in nuclear reprocessing and the semiconductor industry. OSHA vacated a 1989 PEL of 0.6 mg/m³ (HSDB, 2008). NIOSH (2005) and ACGIH (2008) have respectively set the REL and TLV for phosphorus oxychloride at 0.6 mg/m³. NIOSH has also recommended a 15-min STEL of 0.5 mg/m³. A NIOSH IDLH for phosphorus oxychloride has not yet been determined (NIOSH, 2005).

Acute exposure to phosphorus oxychloride can irritate the eyes and cause conjunctivitis as well as burning of the cornea, skin, and mucus lining of the mouth. Phosphorus oxychloride is also a respiratory irritant that can acutely cause cough, dyspnea, lung edema, and bronchopneumonia. Meanwhile, chronic respiratory exposures cause bronchitis, bronchial pain, and emphysema. Headache, dizziness, abdominal pain, nausea, vomiting, and nephritis have also resulted from exposure.

PHOSPHORUS ANHYDRIDE/PHTHALIC ANHYDRIDE

Phosphorus anhydride (CASRN 85-44-9, $C_6H_4(CO)_2O$) is the anhydride of phthalic acid and is found as white flakes or needles used in the production of plasticizers. It has a mild, acrid odor with a melting point of 130.8 °C, a boiling point of 295 °C, and a density of 1.53 g/cm³ (as a solid). It reacts with water to form products that rapidly corrode steel and most metals.

In the plastics industry, phosphorus anhydride is important for the production of polyvinyl chloride (PVC) and flexible PVC products such as cables, pipes, and hoses. Other manufacturing uses for phosphorus anhydride include the production of polyester resins, dyes, urethane polyester polyols, rubber flame retarders, insecticides, other synthetic fibers, and leather processing. OSHA (USDOL, 2014) has set a PEL for phosphorus anhydride at 12 mg/m³ while NIOSH (2005) and ACGIH (2008) have respectively set their REL and TLV at 6 mg/m³. The NIOSH IDLH for phosphorus anhydride has been set at 60 mg/m³ (NIOSH, 2005). ACGIH has listed phosphorus anhydride as A4, not classifiable as a human carcinogen (ACGIH, 2008).

The environmental fate of phosphorus anhydride is dependent on the media into which it is mixed. In water, phosphorus anhydride hydrolyzes very rapidly (Towle et al., 1968) and has a half-life of <3 min (Hawkins, 1975). Due to its hydrolyzation in water, it is expected that phosphorus anhydride would also have a short half-life in moist and damp soils. In air, at ambient temperatures, phosphorus anhydride is found as a vapor that has a half-life of approximately 3 weeks (Bidleman, 1988; Meylan and Howard, 1993). Due to its short half-life in water, bioaccumulation of phosphorus anhydride is not likely to occur.

As discussed previously for many of the phosphorus-based compounds, phosphorus acid is an eye, skin, and respiratory irritant. Exposures can produce work-related rhinitis and conjunctivitis (Nielsen et al., 1988). However, workers exposed up to 17 mg/m³ of phosphorus anhydride did not have any measurable abnormal lung effects (Nielsen et al., 1991). First time exposures irritate the respiratory tract causing sneezing, burning sensations in the nose and throat, cough, and increased mucus secretion. Chronic exposures

cause inflammation of the respiratory tract, nose bleeds and ulcers, anosmia, and bronchitis.

Nielsen et al., (1988) also showed an effect on the immune system of exposed workers. Workers classified as having high levels of exposure to phosphorus anhydride had significantly higher levels of phosphorus anhydride-specific IgG than workers with lower exposure levels. There were no significant differences in levels of phosphorus anhydride-specific IgE or IgM. Subjects suffering from occupational asthma had significantly higher levels of phosphorus anhydride-specific IgG.

PHOSPHINE AND PHOSPHIDES

Distinct by its odor of strong garlic or that of rotting fish, phosphine (phosphorus trihydride, CASRN 7803-51-2, PH₃) is atypical of the other compounds described in this chapter. Phosphine can exist as a colorless liquid or as a colorless gas in air. As mentioned above, phosphine has a very distinct odor and has a half-life of about 24 h in air as a gas. It has a melting point of -133 °C, a boiling point of -87.7 °C, and a density of 1.529 g/l. Phosphine is a highly flammable gas that auto ignites at 38 °C. Denser than air, phosphine gas will collect in shallow areas and produce phosphorus pentoxide (which, as explained earlier in this chapter, is a respiratory irritant) when burnt. Upon hydrolysis of sodium phosphide, phosphine gas can be released. This reaction can result in fires because it is so exothermic. Phosphine can also be released when calcium phosphide comes in contact with acids or water.

Phosphine is not an actual product with much direct commercial value. Important in the production of semiconductors and plastics, phosphine is a rare source of phosphorus poisoning resulting from the accidental formation of the gas during different industrial applications. Prepared in a variety of ways, phosphine can be generated by reacting white phosphorus with sodium hydroxide. Phosphine can also be produced as a by-product generated during the synthesis of hydriodic acid from iodine and red phosphorus. When red phosphorus reacts with acids or caustics in the presence of a metal, phosphine gas is generated. Phosphine is also formed during the production of methamphetamine (Willers-Russo, 1999; Burgess, 2001).

Occupational phosphine exposure can occur via various forms of metallic phosphides. Aluminum phosphide is used as an insecticide fumigant and use in controlling of *Aspergillus* species, thereby decreasing aflatoxin content of certain grains (Leitao et al., 1987), in animal feeds, tobacco storage, processed foods, and other nonfood products. Aluminum, calcium, magnesium, and zinc phosphides are all used as fumigants in rodenticides. Zinc phosphide is used in the manufacture of photovoltaic cells. Indium phosphide is used in the manufacture of semiconductors and as an intermediate

in flame retardant production. Calcium phosphide is used in autogenous welding and signal flares. Finally, iron phosphide and titanium (III) phosphide are semiconductors used in high power, high frequency applications and in laser and other photo diodes.

OSHA (USDOL, 2014), NIOSH (2005,) and ACGIH (2008) have respectively set their PEL, REL, and TLV for phosphine at 0.3 ppm. The NIOSH IDLH for phosphorus anhydride has been set at 50 ppm (NIOSH, 2005). EPA has classified phosphine as a Group D, not classifiable as to human carcinogenicity (IRIS, 1999) and has recommended an RfD of 0.021 mg/kg/day and RfC of 0.0003 mg/m³.

Phosphine gas, phosphine derived from reactions using phosphides and phosphides themselves can all cause deleterious health effects in humans. The main route of exposure to phosphine is through inhalation but ocular and dermal effects due to contact and accidental ingestion have also been reported. Acute exposure to phosphine can cause a plethora of effects to the GI tract (e.g., nausea, vomiting, abdominal pain, diarrhea), cardiovascular system (e.g., chest pressure, arrhythmia), respiratory system (e.g., cough with fluorescent green sputum, dyspnea, pulmonary edema), central nervous system (e.g., stupor or syncope, headache, dizziness, fatigue, drowsiness, tremors, convulsions), integumentary system (e.g., chills and frostbite from liquid), numbness and paresthesia in fingers (from touching tablets) and burns. Chronic phosphine exposure is similar to that observed for chronic elemental phosphorus exposure and can produce toothache, phossy jaw, spontaneous fractures of bones, and anemia.

Phosphine gas inhalation can rapidly cause death due to cardiac collapse (Blanke 1970). Exposure to phosphine was shown to be genotoxic in humans. Applicators handling fumigant-containing phosphine were found to have an increase in stable chromosome rearrangements in the applicators (Garry et al., 1989). Exposure to grain that had been fumigated with aluminum phosphide caused the death of a pregnant worker (Garry et al., 1993).

Metal phosphide exposure can also provoke toxic effects in workers. Acute metal phosphide poisoning occurs from ingestion as a result of the formation of phosphine gas upon contact with fluids in the gut. Accidental aluminum phosphide ingestion has been shown to be more than 70% fatal in humans (Anand et al., 2011). Severe inhalation of aluminum phosphide can produce convulsions, acute respiratory distress syndrome (ARDS), heart arrhythmia and failure, and coma. Ntelios et al. (2013) reported a case of leukopenia induced in a worker after exposure to aluminum phosphide.

Phosphine degrades very quickly in all biota and does not bioaccumulate or biomagnify. When found in water, it will move quickly to air where it reacts to form less harmful chemicals. It has been estimated that phosphine in the troposphere has a half-life of <1 day (Fritz et al. 1982). In air, diphosphine (PH₂) can be produced as an intermediate from phosphine via a hydrogen abstraction reaction.

Diphosphine can then react with ozone to produce H₂PO from which hypophosphorus acid (H₂PO₂) may be produced. The hypophosphorus acid is ultimately oxidized to phosphorus and phosphoric acid.

Due to its low solubility in water, phosphine will either oxidize or volatize rapidly from water (Lai and Rosenblatt, 1977). It will even oxidize rapidly under anoxic condition and can form diphosphine (P₂H₄), phosphorus, hypophosphorous acid, phosphorus acid, and phosphoric acid (Kumar et al., 1985). In the presence of oxygen, phosphine will oxidize to form P₂H₄ and finally form phosphoric acid (Garry et al., 1993). Small traces of phosphine can adsorb or chemisorb to soil particles and sediments in water (Berck and Gunther, 1970; Hilton and Robison, 1972). However, volatilization is expected to be the most important loss process for phosphine in water.

SULFUR COMPOUNDS

FRANK STEPHEN AND M. RONY FRANCOIS

First aid: See text for each substance

Occupational exposure limits: *Sulfur dioxide*: 5.24 mg/m³ (OSHA PEL, NIOSH REL, ACGIH TLV); 261.76 mg/m³ (OSHA IDLH); *sulfuric acid*: 1 mg/m³ (OSHA PEL, NIOSH REL, ACGIH TLV); 15 mg/m³ (OSHA IDLH); 3 mg/m³ (ACGIH STEL); *hydrogen sulfide*: 13.91 mg/m³ (OSHA PEL, NIOSH REL, ACGIH TLV); 139.06 mg/m³ (NIOSH IDLH); 20.86 (ACGIH STEL)

Reference values: *Hydrogen sulfide*: 2×10^{-3} mg/m³ (IRIS RfC)

Hazard statements: *Sulfur dioxide*: H280—contains gas under pressure; may explode if heated; H314—causes severe skin burns and eye damage; H331—toxic if inhaled. *Sulfuric acid*: H314—causes severe skin burns and eye damage. *Hydrogen sulfide*: H220—extremely flammable gas; H280—contains gas under pressure; may explode if heated; H330—fatal if inhaled; H400—very toxic to aquatic life

Precautionary statements: *Sulfur dioxide*: P280—wear protective gloves/protective clothing/eye protection/face protection; P304+P340—if inhaled, remove victim to fresh air and give instructions to the victim to rest in a position comfortable for breathing; P305+P351+P338—if in eyes, rinse cautiously with water for several minutes. Remove contact lenses, if present and easy to do. Continue rinsing; P310—immediately call a poison center or doctor/physician; P410+P403—protect from sunlight; store in a well-ventilated place. *Hydrogen sulfide*: P210—keep away from heat/sparks/open flames/. . . /hot surfaces...no smoking; P273—avoid release to the environment; P284—wear respiratory protection; P310—immediately call a poison center or doctor/

physician; P410+P403—protect from sunlight. Store in a well-ventilated place; P501—dispose of contents/container

Risk phrases: *Sulfur dioxide*: R23—toxic by inhalation (>20%); R20—harmful by inhalation (>5%, <20%); R34—causes burns (>5%); R36/37/38—irritating to the eyes, respiratory system, and skin (>0.5%). *Sulfuric acid*: R35—causes severe burns (>15%); R36/38—irritating to eyes and skin (>5%, <15%). *Hydrogen sulfide*: R12—extremely flammable; R26—very toxic by inhalation; R50—very toxic to aquatic organisms

Safety phrases: *Sulfur dioxide*: S9—keep container in a well-ventilated place; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S36/37/39—wear suitable protective clothing, gloves, and eye/face protection; S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible). *Sulfuric acid*: S1/2—keep locked up and out of reach of children; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S30—never add water to this product; S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible). *Hydrogen sulfide*: S1/2—keep locked up and out of reach of children; S9—keep container in a well-ventilated place; S16—keep away from sources of ignition—no smoking; S36—wear suitable protective clothing; S38—in case of insufficient ventilation, wear suitable respiratory equipment; S45—in case of accident or if you feel unwell, seek medical advice immediately (show label where possible); S61—avoid release to the environment. Refer to special instructions/safety data sheets

HISTORY

Anyone familiar with the smell of rotting eggs or well water of poor quality can attest that they are familiar with brimstone. However, the common element to all these three is sulfur. In its raw form, this yellow, nontoxic crystal poses no general threat to humans. Known and used for over 2000 years, it has been used in fumigants, balms, and antiparasitics. Commercially, it is commonly used today in fertilizers, matches, insecticides, and fungicides. It is a nonmetal with a broad range of valence states (from -2 to +6), allowing it to form stable compounds with a large number of other elements, except the noble gases. Many of these compounds have very beneficial uses; however, some of these compounds produce deleterious health effects.

SULFUR DIOXIDE

BACKGROUND AND USES

Sulfur dioxide (CASRN 7446-09-5) is an irritant gas commonly found in the environment because of its production during petroleum refining and combustion as well as paper production. It is also known as sulfur oxide, sulfurous acid anhydride, sulfurous anhydride, and sulfurous oxide. It is a nonflammable and colorless gas that is heavier than air at room temperature. It possesses a strong, pungent odor that is a warning sign of its presence. Absorbed quite readily through the upper respiratory tract, sulfur dioxide does not appear to be absorbed dermally. Oral ingestion is possibly due to its presence in some foods. Some of the industrial uses for the approximately 300,000 tons of sulfur dioxide produced each year include oil, metal, and ore refining; refrigeration; waste and water treatment; wood pulp and paper bleaching, fumigation; tanning; metal casting; and the production of sodium sulfate and sulfuric acid. Sulfur dioxide is listed as a U.S. Environmental Protection Agency (EPA) priority air pollutant. The number of American workers potentially exposed occupationally to sulfur dioxide has been estimated at 600,000 (HSDB, 1998).

Naturally emitted from fires and volcanic eruptions, sulfur dioxide is always present in the earth's atmosphere and inhalation is the most common, yet harmless type of exposure. The highest levels of inhalation exposure would be expected to occur near industrial activities that involve fuel combustion. Historically, incidences of general population exposure from industrial activity occurred in London, Meuse Valley, Belgium and Donora, Pennsylvania. In each of these "fog" events, there was an increase in inhalation-induced mortality due to releases of sulfur dioxide, in the presence of other chemicals. Similar episodes occur frequently in winter,

especially in densely populated urban areas, possibly because of the higher demand for heat. "Smog" can also occur due to stagnant air masses and atmospheric inversion. During these episodes the sulfur dioxide reacted with the moisture found in fog. This reaction produces sulfurous acid (H_2SO_3), which can irritate the respiratory epithelium and mucous membranes upon inhalation.

PHYSICAL AND CHEMICAL PROPERTIES

Sulfur dioxide (SO_2) is a colorless gas that has a very strong pungent odor at room temperature detectable by most people at levels down to 0.3–1 parts per million (ppm). It is neither flammable nor combustible and has a melting point of -72 °C, a boiling point of -10 °C, and a vapor pressure of 3.2 atm. It is 2.26 times heavier than air. It is 10% soluble in water by weight and easily forms sulfurous acid and sulfuric acid on contact with water and moist surfaces. It is shipped as a liquefied compressed gas (NIOSH, 1994).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Due to the industrial uses of sulfur dioxide, releases are considered to be atmospheric (HSDB, 1998). Once emitted into the air, it remains in the gaseous phase and can move through various biota, including soil, water, grass, and vegetation (WHO, 1979). Oxidation of sulfur dioxide in the atmosphere with water forms sulfuric acid, which can fall as acid rain. Since it has high solubility in water, the oceans are considered to be a sink for sulfur dioxide (Kellogg et al., 1972). However, potential releases of sulfur dioxide from water would be expected to partition to the atmosphere (Kellogg et al., 1972; WHO, 1979). Soil can also be a site of fate for sulfur dioxide; however, the uptake levels would vary dependent on the soil pH and water content (HSDB, 1998). Falling acid rain will also cause increased soil mobility of heavy metals. Heavy metals form soluble sulfates in acidic soils and insoluble sulfate oxides or sulfate hydroxides when the pH of the soil is basic (Grzesiak et al., 1997).

MAMMALIAN TOXICOLOGY

Acute Effects

Due to the ability of sulfur dioxide to dissolve into the moisture on skin, eyes, and mucous membranes, the respiratory tract is the most likely target of effect. After exposure, sulfur dioxide dissolves in water to form sulfurous acid. At levels of 0.6–1.0 ppm, sulfur dioxide irritates the eyes, nose,

and throat (Summer and Haponik, 1981). At these relatively low concentrations, the majority of the sulfur dioxide is deposited in the nose and oropharynx. However, at higher exposures, bronchoconstriction can be induced when sulfur dioxide reacts with water in the conduction portions of the lungs to form a bisulfite ion. Symptoms such as sore throat, sneezing, shortness of breath, wheezing, and chest tightness can occur after sulfur dioxide inhalation. Edema and pneumonitis can develop after long-term exposure; and in cases of high acute exposure due to inhalation, sulfur dioxide can lead to reactive airway dysfunction syndrome (RADS). Irritation after sulfur dioxide dermal exposure can cause pain, redness, and blisters. Ocular effects due to sulfur dioxide vapor include corneal burns and conjunctivitis. Finally, sulfur dioxide-induced gastrointestinal effects include nausea, vomiting, and abdominal pain. An industrial accident involving five healthy men exposed to varying concentrations of sulfur dioxide can be used as an example of the range of effects that the gas has on humans. In this reported incident, two men died within 5 min of the exposure with pink, frothy fluid around the mouths. Acute symptoms of the three survivors included chest tightness, dyspnea, and soreness of their eyes, nose, and throat. Rhonchi and wheezing were heard in their lungs, and chest radiographs were normal. On follow-up, one of these individuals developed airway obstruction with associated dyspnea on exertion. Another man with a smoking history developed mild airflow obstruction 4 months after exposure, and the third man who had no smoking history developed no lung abnormalities (Charan et al., 1979). As a rule, individuals who survive an acute exposure recover completely.

Exposure to low concentrations of sulfur dioxide can result in a mild degree of bronchial constriction. This is especially apparent in asthmatic individuals (Linn et al., 1987). Studies of workers chronically exposed to lower levels of sulfur dioxide show little alterations in lung function. It has been proposed that workers who remain in such occupations may adapt to the gas (Ferris et al., 1979).

First Aid

Upon exposure, it is imperative that affected individuals be removed from the site immediately. Contaminated clothing and personal belongings must also be removed and exposed skin, hair, face washed with large amounts of water. Any eye exposure should be treated by 5-min washes with saline or water. Persons displaying any respiratory compromise may require a patent airway secured by endotracheal intubation or tracheotomy. Bronchospasms may be treated with aerosolized bronchodilators. Advanced life-saving protocols may have to be used should an exposed individual become hypotensive, have a seizure, or become comatose. Intravenous saline should be given for any casualty who goes into shock.

Chronic Effects

Very few chronic effects after sulfur dioxide exposure have been noted. As described above the respiratory system is the main target of effect. Altered or lost sense of smell, respiratory infection susceptibility, chronic bronchitis symptoms, and pulmonary function decline can all become chronic after exposure.

Workers exposed to acid mists in steel processing, refinery, and other chemical plants were found to have an increased risk of laryngeal cancer (Ahlborg et al., 1981; Forastiere et al., 1987; Soskolne et al., 1984; Steenland et al., 1988). Some of the highest exposures occur when sulfur dioxide is a by-product, as in the metal smelting industry and in the processing or combustion of high sulfur coal or oil (HSDB, 1998).

MODE OF ACTION(S)

The mechanism by which sulfur dioxide causes its effects on the lungs is still being investigated. Sulfur dioxide-induced reflexive bronchoconstriction during inhalation of sulfur dioxide was demonstrated in humans and in cats (Frank et al., 1962; Nadel et al., 1965). It causes smooth muscle contraction through a parasympathetically vagal-mediated reflex (Roberts et al., 1982). Tachykinin-induced bronchoconstriction was demonstrated using capsaicin to prevent release after exposure to sulfur dioxide (Bannenberg et al., 1994; Wang et al., 1996). Increased airway resistance was shown to result from reduced buffer and H^+ ion absorption capacity of the airway mucus (Holma, 1985). Various studies using atropine indicated a role for the muscarinic (cholinergic) mechanism of action (Snashall and Baldwin, 1982; Nadel et al., 1965; Sheppard, 1988a, 1988b). However, non-cholinergic mechanisms attributed to prostaglandins and leukotrienes have been demonstrated in humans (Field et al., 1996; Lazarus et al., 1997).

As sulfur dioxide is breathed through the nasal passages at low concentrations, it is predominantly deposited in the nose and oropharynx. As it comes in contact with the moist mucous membranes, it is converted, as mentioned previously, to sulfurous acid or sulfuric acid. This can cause local irritation. As this area's capacity to accept the gas is exceeded, it will pass down to the trachea, bronchi, and alveoli. There, the acidic ions will be neutralized by the endogenous production of ammonia by the lungs (Larson et al., 1977). When the buffering ability of the mucous proteins and ammonia is saturated, the acid formed will gain access to the surrounding tissue and initiate adverse reactions.

In studies of cows, intracellular and intercellular edema occurs at pH levels below 6.5, and epithelial cells

loosen from each other and the basement membrane at a pH below 6.0 (Holma et al., 1977). In other studies, H⁺ ion absorption in the mucus from acid exposure was found to increase mucous viscosity and decrease mucous velocity (Lippmann et al., 1979). In addition to decreased mucous transport, increased mucous viscosity has been demonstrated to correlate with increased airway resistance (Keal, 1974) and reduced pulmonary gas exchange (Pham et al., 1973).

INDUSTRIAL HYGIENE

NIOSH (1994) and the American Conference of Governmental Industrial Hygienists (ACGIH) (ACGIH, 1996) have respectively set the recommended exposure limit (REL) and threshold limit value (TLV) at 2 ppm and the short-term exposure limit (STEL) at 5 ppm. The Occupational Safety and Health Administration (OSHA) has set the permissible exposure limit (PEL) at 5 ppm. Sulfur dioxide gas is considered immediately dangerous to life and health (IDLH set at 100 ppm).

RISK ASSESSMENTS

WHO

The World Health Organization (WHO) has set a 24-h exposure limit for sulfur dioxide inhalation at 100–150 µg/m³.

ATSDR

The Agency for Toxic Substances and Disease Registry (ATSDR) has established a 0.01 ppm minimum risk levels (MRLs) for acute inhalation exposures to sulfur dioxide (ATSDR, 1998).

IARC

The International Agency for Research on Cancer (IARC) has classified sulfur dioxide as a Group 3, not classifiable as to human carcinogenicity.

ACGIH

The ACGIH has listed sulfur dioxide as an A4 carcinogen, not classifiable as a human carcinogen (ACGIH, 1996).

EPA

The EPA has established a 24-h exposure limit National Ambient Air Quality Standards (NAAQS) of 365 µg/m³ for sulfur dioxide.

CalEPA

In July 2011, the California Environmental Protection Agency (CalEPA) listed sulfur dioxide as a chemical known to cause reproductive toxicity for purposes of the Safe Drinking Water and Toxic Enforcement Act of 1986, as listed under Proposition 65.

SULFURIC ACID

BACKGROUND AND USES

One of the most widely used compounds in domestic industry, sulfuric acid (CASRN 7664-93-9) is a colorless to dark brown, odorless liquid. Most commonly, almost 70% of it is used in the fertilizer industry to convert phosphate rock to phosphoric acid (IARC, 1992). Other industrial uses include mineral and ore processing; petroleum refining; production of paper, synthetic rubber, and plastics; wastewater processing, pickling of steel and iron; manufacture of organic sulfonates used in detergents and lubricants; dehydration procedures; and charging of storage batteries (NIOSH, 1974; Budavari, 1989; IARC, 1992). It is also found in common household products such as drain cleaners and other cleaning agents, lead-acid batteries and has been used as a general food additive (HSDB, 1998). The National Institute for Occupational Safety and Health (NIOSH) estimated that approximately 750,000 Americans are occupationally exposed to sulfuric acid (NOES, 1990).

PHYSICAL AND CHEMICAL PROPERTIES

Sulfuric acid (H₂SO₄, CASRN 7664-93-9) is a colorless to dark brown, oily, odorless, and nonflammable liquid. It has a melting point of 10°C, a boiling point of 337°C, and a density of 1.84 g/cm³. Below 10.5°C, the pure compound is found in a solid form. Sulfuric acid is miscible in water.

ENVIRONMENTAL FATE AND BIOACCUMULATION

Upon entering the environment, sulfuric acid enters the natural sulfur cycle. As explained in the section on sulfur dioxide, sulfuric acid is formed when sulfur dioxide mixes with water in the atmosphere. Resident time in the atmosphere can last from 6 (surface air) to 14 days (15 km), and sulfuric acid is the main component of acid rain. Sulfur dioxide is oxidized to sulfur trioxide and then hydrolyzed in the atmosphere, forming sulfuric acid (Treon et al., 1950). Atmospheric sulfur oxides can acidify precipitation to a pH of <5.6 (Chaney et al., 1980). Sulfuric acid can be removed from the atmosphere through wet and dry deposition processes. Acid precipitation is most detrimental to the aquatic ecosystems, marine biota, and some terrestrial species of plants and trees. After falling on the earth and mixing with water, sulfuric acid will dissociate to form a sulfate anion that can combine with other cations. Once in soil, these ions will adsorb to the soil particles or can directly leach into surface

water and groundwater. Sulfates will then be taken up by and incorporated into the plant parenchyma. While sulfur is an important constituent found in proteins, food chain bioaccumulation of sulfuric acid is not considered important, and no reports were found.

MAMMALIAN TOXICOLOGY

Acute Effects

Human exposure to sulfuric acid occurs from dermal contact and inhalation with the preliminary targets being the skin, eyes, and respiratory tract. Exposure to sulfuric acid produces many of the same effects described above for sulfur dioxide but can be more severe. Interestingly, these effects occur at lower concentrations of sulfuric acid and shorter exposure times. Data from 905 industrial releases show that the most frequently reported effects were chemical burns, respiratory, and eye irritation (HSEES, 1997).

Ocular burns that resulted in coagulation necrosis, which limits deeper penetration into the cornea, occur after contact with high concentrations of sulfuric acid. However, blindness can still occur. Skin contact with high concentrations of sulfuric acid results in skin burns, the severity of which is directly related to the concentration and quantity of acid, the duration of skin contact, and the extent of skin penetration. Acids are water soluble and able to penetrate the subcutaneous tissue lowering the pH, affecting both the cells and intracellular matrices. Inhalation effects are comparable to those previously described for sulfur dioxide. Studies reporting any effect on the gastrointestinal tract, skin, or musculoskeletal system after inhalation of sulfuric acid have not been found.

First Aid

First aid procedures for exposure to sulfuric acid start with immediate removal of the victim from the source. Initial treatment protocols involve immediate removal of all contaminated clothing followed by continuous washing of exposed skin with water or normal saline for at least 15 min. Exposed persons should also be checked along the hairline and scalp, under the nails, and between the toes for affected areas. After washing to cleanse the area, treatment of minor burns can include application of a topical cream containing antibiotics and a tetanus immunization. If burns are severe, then consultation with a medical specialist may be necessary. After ocular exposure, any debris or particulate matter should be removed from the eye and, if possible, the pH of tears should be checked with litmus paper. Irrigate the eye, preferably with an eyewash, for at least 10 min. The eye pH should be monitored continuously. Ophthalmic antibacterial ointments will be needed after corneal burning. Exposed patients should be referred to an ophthalmologist.

Chronic Effects

Exposures to sulfuric acid mist have recently been observed to increase the risk of laryngeal and upper respiratory tract cancers (IARC, 1992). Workers in the Swedish steel pickling industry showed excess risk for laryngeal cancer (Ahlborg et al., 1981). Pickling operations workers in the U. S. steel industries also showed an elevated risk for laryngeal cancer (Steenland et al., 1988). Finally, it was reported that there were also some nested case-referent studies of workers with increased risk of cancer after exposure to sulfuric acid in a U.S. petrochemical plant (Soskolne et al., 1984). Erosion of incisor and canine teeth may occur after chronic exposure to sulfuric acid mist (Bruggen Cate, 1968).

MODE OF ACTION(S)

Sulfuric acid acts directly on the tissues by changing its pH. It might also act as a direct irritant, resulting in chronic ear, nose, throat irritation, and inflammation. Chronic inflammation may result and cause the release of free radicals, which may be genotoxic and result in an increased risk for some cancers. However, the connection between inflammation and carcinogenesis remains to be explored.

INDUSTRIAL HYGIENE

NIOSH (1997), ACGIH (1996), and OSHA (1998) have respectively set the REL, TLV, and PEL at 1 mg/m³, and the IDLH level at 15 mg/m³. A threshold limit value-time-weighted average (TLV-TWA) of 1 mg/m³ and a STEL of 3 mg/m³ (ACGIH, 1998) have been recommended by the ACGIH. Engineering controls and good ventilation should be used to minimize contact with the acid and minimize inhalation of acid mists. When this is not possible or when concentrations are high, personal protective equipment should be supplied to all employees. This equipment should include respirators, coveralls, gloves, and goggles (NIOSH, 1994).

RISK ASSESSMENTS

IARC

The IARC considers occupational exposure to strong inorganic mists containing sulfuric acid to be carcinogenic to humans (Group 1, IARC, 1992).

ACGIH

The ACGIH has listed sulfuric acid as an A2 carcinogen, a suspected human carcinogen (ACGIH, 1998).

EPA

The EPA has not classified sulfuric acid for carcinogenic effects but has placed it in the list of hazardous substances under the Clean Federal Water Pollution Control Act (EPA, 1998b) and the list of chemicals in "Toxic Chemicals Subject to Section 3.13 of the Emergency Planning and Community Right-to-Know Act" (EPA, 1998a). An oral reference dose (RfD) and an inhalation reference concentration (RfC) for sulfuric acid have not been derived by the EPA.

CalEPA

The CalEPA in March 2003 listed strong inorganic acid mists containing sulfuric acid as chemicals known to cause cancer for the purpose of the Safe Drinking Water and Toxic Enforcement Act of 1986 as listed under Proposition 65.

HYDROGEN SULFIDE

BACKGROUND AND USES

Hydrogen sulfide (sulfured hydrogen; symbol H₂S; CASRN 7783-06-4), when found at high concentrations in the air, is an extremely potent chemical asphyxiant that can result in sudden death. Much like the other sulfur compounds described above, it is also a respiratory and skin irritant. The industrial uses for hydrogen sulfide are numerous and can result in its release to the environment through operations involving petroleum (e.g., refining, petrochemical synthesis), production and manufacturing (e.g., coke, sulfur, natural gas, asphalt roofing, rayon, and pulp and paper), vulcanization of rubber-containing sulfur compounds, processing of human and animal waste

(e.g., landfilling, sewage pumping and treatment plants, swine containment, and manure handling), processing of animal products (e.g., pelt processing, animal slaughter facilities, leather tanneries), iron smelting, and food processing. It can also be an unwanted by-product formed naturally from the decay of organic sulfur-containing material. Finally, it can be released from natural sulfur deposits found in gypsum, sulfur, and coal mines.

PHYSICAL AND CHEMICAL PROPERTIES

Hydrogen sulfide is a colorless gas that smells like rotten eggs. It is corrosive, flammable, and explosive and has a melting point of -82°C , a boiling point of -60°C , and a vapor pressure of 17.6 atm. It is only slightly water soluble (0.4%) at 20°C (NIOSH, 1994).

ENVIRONMENTAL FATE AND BIOACCUMULATION

Upon release, hydrogen sulfide can partition to the air, surface- and groundwater, and moist soil. Once in the atmosphere, oxygen and ozone can oxidize hydrogen sulfide forming sulfur dioxide (see environmental fate discussed above). Hydrogen sulfide can dissociate in an aqueous solution to form either a bisulfide ion (HS^-) or a sulfide ion (S^{2-}). In soil, hydrogen sulfide enters into the natural sulfur cycle. It does not bioaccumulate or biomagnify in the food chain.

MAMMALIAN TOXICOLOGY

Acute Effects

The nervous system and cardiac tissues are particularly vulnerable to the disruption of oxidative metabolism and death is often the result of respiratory arrest. Hydrogen sulfide also irritates the skin, eyes, mucous membranes, and the respiratory tract. Pulmonary effects may not be apparent for up to 72 h after exposure.

Inhalation of hydrogen sulfide can produce a condition of "olfactory fatigue." In this condition, exposed individuals can no longer detect its presence at concentrations $>100\text{ ppm}$. Thus, they are susceptible to higher exposures more quickly. The inability to detect hydrogen sulfide leads to continued inhalation (dose) and can be followed by major central nervous system (CNS) injury, including, but not limited to, loss of consciousness, respiratory paralysis, and seizures. Coma and death can occur after only a few breaths following exposure to high concentrations. Prior to CNS depression, there may actually be an instance of CNS stimulation manifested as excitation, rapid breathing, and headache.

Hydrogen sulfide exposures can also affect several major organ systems, including the respiratory, cardiovascular, digestive, as well as the skin and eyes. Inhalation of concentrations as low as 50 ppm hydrogen sulfide can rapidly produce irritation of the nose, throat, and lower respiratory tract. Exposed persons may develop shortness of breath and cough, while prolonged exposures may produce bronchial or lung hemorrhage. Bronchitis and fluid accumulation can occur after an exposure to higher concentrations, and this effect may be seen up to 72 h post exposure. Exposures to high doses can produce irregular heartbeat and decreased cardiac output. Nausea and vomiting may also occur after exposure. Skin exposure to very high amounts of hydrogen sulfide can produce itching, redness, and burning. Liquefied hydrogen sulfide gas can cause frostbite. Finally, blurred vision, spasmodic blinking, conjunctivitis, and clouding of the cornea may occur after an exposure to hydrogen sulfide gas.

First Aid

Persons exposed to hydrogen sulfide should be immediately removed from the source. Any contaminated clothing should be removed and double bagged. Exposed skin and hair should be flushed with water for 5 min. Exposed eyes should be irrigated with plain water or saline for at least 5 min. In cases of respiratory compromise, secure the airway and respiration via endotracheal intubation. If not possible, perform cricothyroidotomy, if equipped and trained to do so. Victims who demonstrate bronchospasms should be treated with aerosolized bronchodilators.

Chronic Effects

Contrary to the effects listed above, very little data exist about potential effects of low or chronic exposure. Since hydrogen sulfide does not accumulate in the body, recovery from an initial exposure should not produce any long-term problems. However, a long-term or repeated exposure to hydrogen sulfide has been shown to produce a plethora of effects, including, but not limited to, chronic and possibly intense cough, hypotension, loss of appetite, weight loss, and ataxia. There were no studies found showing carcinogenic, reproductive, teratogenic, or developmental effects in humans.

MODE OF ACTION(S)

At high concentrations, hydrogen sulfide is a potent inhibitor of cytochrome oxidase resulting in an interrupted cellular metabolism when the cells' mitochondria cannot properly utilize oxygen (cytotoxic anoxia) (Sorbo, 1960).

INDUSTRIAL HYGIENE

NIOSH (2006), the ACGIH (2005), and OSHA (2006) have respectively set the REL, TLV, and PEL at 10 ppm. The ACGIH has determined a STEL of 15 ppm and NIOSH has designated an IDLH level of 100 ppm. The OSHA lists the acceptable ceiling limit of hydrogen sulfide at 20 ppm in the workplace.

RISK ASSESSMENTS

WHO

The WHO has set a 24-h exposure limit for hydrogen sulfide inhalation of 0.15 mg/m³ (WHO, 2000). At levels found in drinking water, WHO does not designate hydrogen sulfide as a human health concern (WHO, 2004).

ATSDR

The ATSDR has derived an acute-duration inhalation MRL of 0.07 ppm and an intermediate-duration inhalation MRL of 0.02 ppm for hydrogen sulfide (ATSDR, 2006).

IARC

The IARC has designated hydrogen sulfide as a Class 3 carcinogen, not classifiable as to its carcinogenicity to humans (IARC, 2006).

ACGIH

Due to the lack of data the ACGIH has not classified hydrogen sulfide as a human carcinogen (ACGIH, 2005).

EPA

The EPA has derived a chronic inhalation RfC of 0.001 ppm based on chronic exposures of rat olfactory mucosa to hydrogen sulfide (Brenneman et al., 2000). A previous RfD of 3×10^{-3} mg/kg/day was withdrawn from the Integrated Risk Information System (IRIS) database based on irreproducibility of effects, and a new RfD has not been derived (IRIS, 2006).

CalEPA

In 2008, the CalEPA established a REL for acute and chronic hydrogen sulfide inhalation at 42 and 10 µg/m³, respectively.

ORGANIC COMPOUNDS

SECTION EDITOR: RAYMOND D. HARBISON

53

ALIPHATIC HYDROCARBONS

MAYOWA AMOSU, NICOLE NATION, AND MARY ALICE SMITH

METHANE

Target organ(s): Skin and eyes, brain, heart, kidney
Occupational exposure limits (OEL): No OEL, simple asphyxiant
Reference values: No reference values reported for this compound

Risk/safety phrases:

Classification: F+

Risk phrases: +R12: Extremely flammable

Safety phrases: +S2: Keep out of the reach of children
+S9: Keep container in a well-ventilated place

+S16: Keep away from sources of ignition—no smoking

+S33: Take precautionary measures against static discharges

BACKGROUND AND USES

Methane gas (marsh gas; CASRN 74-82-8) is produced from a number of natural sources, most notably from anaerobic respiration in marshland areas and in rice production, volcanoes and other natural sources of fire, and from the rudiments of animals, particularly cattle and sheep. Methane is considered an important occupational hazard in farming and mining operations and in sewage treatment facilities because of its asphyxiant and explosive properties. As the principal constituent of natural gas, methane is widely used as a domestic fuel and is also used in chemical reactions due to its reductive properties (Harbison, 1998).

PHYSICAL AND CHEMICAL PROPERTIES

At room temperature, methane is a clear, colorless gas with a weak odor. The liquid form has a high vapor pressure at low temperatures, and will readily evaporate into the atmosphere. Methane maintains a vapor density of 0.554 at 0 °C (32 °F), which means that it is less dense than air and will rise to the upper levels of a contained space. It has a boiling point of -162 °C and a melting point of -183 °C. If a source of ignition is present while the atmospheric concentrations of methane are between 5 and 15%, an explosion can occur. Methane is incompatible with strong oxidizing agents such as chlorine and bromine.

MAMMALIAN TOXICOLOGY

Acute Effects

Methane has no known toxicity associated with chronic or acute exposures other than asphyxiation. People usually begin to experience symptoms of asphyxiation when oxygen levels in the environment are between 15 and 16%. More severe symptoms of toxicity will begin to develop as oxygen levels decrease to 6–8%. A few symptoms associated with severe methane gas poisoning due to asphyxiation result from respiratory distress and include loss of consciousness, dysrhythmias, myocardial ischemia, pulmonary edema, and seizures. Some clinical cases have reported headache, weakness, myalgia, ataxia, and light-headedness or fainting when confined to a room with a gas heater (Sherman and Harris, 1968).

Methane is one of the few compounds, where most overexposures result in either no adverse health effect or

death. Death produced by methane asphyxiation has been reported in all three major industries involving high concentrations of methane release: mining, wastewater treatment, and farming (Manning et al., 1981; Terazawa et al., 1985; CDC, 1989; Perry, 1995). There are no reports of any serious incapacitation or illness resulting from exposure to methane gas. However, an explosion of methane gas has occurred and the death of four workers who were killed in an accidental methane gas explosion in an urban tunnel was described by Nagao et al. (1997).

Liquid methane exposure can result in injury from frostbite, which can cause severe tissue burn and presents as a paling of skin color.

Chronic Effects

Methane has no known toxicity associated with chronic or acute exposures other than asphyxiation.

Mechanism of Action(s)

Asphyxiation from methane inhalation does not result from a direct biological interaction with the gas, but occurs as a simple displacement of oxygen. The metabolism of methane is similar to ethane in that most of the inhaled dose is exhaled unchanged. Absorbed methane is likely converted to its corresponding alcohol and subsequently broken down to carbon dioxide and excreted.

Chemical Pathology

Methane is not considered as a toxic agent and therefore there are no chemical pathologies associated with it.

SOURCES OF EXPOSURE

Occupational

The primary route of exposure to methane is through inhalation. Poor ventilation in a variety of settings is the main cause of an accumulation of hazardous concentrations of methane gas. The measurement of methane production by anaerobic degradation can be a useful indicator of the toxic effects of certain pollutants on the natural flora of bacteria (Vlaardingen and Beelen, 1992).

Environmental

Manure pits and other natural sources of natural gas can release enough methane to cause asphyxiation by displacing adequate concentrations of ambient oxygen. In coal mines, methane is referred to as marsh gas or fire damp and is the principal cause of explosions. Animal confinement areas can also be a hazardous source of methane.

INDUSTRIAL HYGIENE

Personal respirators are generally not required for methane because adequate ventilation is considered as enough protection in most instances, and is needed to avoid explosions.

The liquid form of methane may cause frostbite upon contact, and dermal protection is necessary when the liquid form is present. When liquid methane comes into contact with skin, severe frostbite can result.

Methane is extremely flammable; therefore, ignition sources should be kept away from high concentrations of the gas. Even something as "harmless" as a light bulb breaking when in use has been reported to cause serious explosions (Pettit, 1987). In the presence of light, methane may also react with compounds such as chlorine and bromine to form explosive mixtures. There are no occupational exposure regulations for methane.

While there are no exposure limits associated with concentrations of ambient methane; because of its asphyxiant property in displacing ambient oxygen, it is important to note the limits for oxygen concentration in the work area. Oxygen levels should be no lower than 18% to avoid extreme discomfort or danger. A new method for measuring methane in postmortem samples (Varlet, 2013) may help identify intentional and accidental deaths resulting from methane exposure in the future.

MEDICAL MANAGEMENT

Primary responders should immediately remove the victim to an area of fresh air or administer supplemental oxygen. Generally, individuals recover quickly once oxygen levels are brought back to normal in their environment.

Recently comatose survivors of asphyxia were treated with induced hypothermia with good survival (9 of 14; 65%) and those that survived had good neurological recovery. For asphyxia with methane, this may hold a promising new treatment (Baldursdottir et al., 2010).

In the case of an individual suffering from frostbite, warm water should be used to raise the temperature of the area; hot water should not be used. Digits can be warmed in the armpit and medical attention should be sought immediately.

ETHANE

Target organ(s): None; not irritating to eyes, nose, or throat

Occupational exposure limits: ACGIH: TWA–TLV: 1000 ppm

Reference values: No reference values reported for this compound

Risk/safety phrases:

Classification: F+; R12

Risk phrases: +R12: Extremely flammable

Safety phrases: +S2: Keep out of the reach of children
phrases:

- +S9: Keep container in a well-ventilated place
- +S16: Keep away from sources of ignition—no smoking
- +S33: Take precautionary measures against static discharges

BACKGROUND AND USES

Ethane (methylmethane; CASRN 74-84-0) is naturally occurring in mining operations and is a component of natural gas. It is not irritating to mucous membranes, eyes, or skin. Similar to methane, ethane is extremely flammable and is incompatible with chlorine. The production of some compounds, such as vinyl chloride and ethylene, requires ethane as a precursor. The vapor pressure is high at room temperature and has a

vapor density of 1.04. Ethane is produced endogenously as an end product of lipid peroxidation (de Ruiter et al., 1980; Sunderman, 1987; Rahimtula et al., 1988).

Inhalation exposures to ethane are most common. Ethane can act as a simple asphyxiant at high concentrations, but has no other reported adverse health effects.

PHYSICAL AND CHEMICAL PROPERTIES

Ethane is a colorless, odorless gas that is generally very stable and chemically inactive. However, in concentrations of 3–12% by volume, it has the potential to be very explosive. It is incompatible with chlorine, dioxygenyl tetrafluoroborate, oxidizing materials, heat, or flame.

MAMMALIAN TOXICOLOGY

Acute Effects

Ethane has no known toxicity associated with acute exposures other than asphyxiation, which can lead to unconsciousness and eventually death. People usually begin to experience symptoms of asphyxiation when oxygen levels in the environment drop between 15 and 16%. More severe symptoms of toxicity will begin to develop as oxygen levels drop to 6–8% (HSDB, 2009). Symptoms of acute asphyxiation due to the displacement of ambient oxygen by ethane include tunnel vision and reduced visual acuity, myocardial infarction due to hypoxia, bronchoconstriction, numbness, and dizziness.

Chronic Effects

Ethane has no known toxicity associated with chronic exposures.

Mechanism of Action(s)

Ethane absorbed by the respiratory tract is primarily excreted unchanged.

Chemical Pathology

Ethane is not considered as a toxic agent and therefore there are no chemical pathologies associated with exposure to ethane.

SOURCES OF EXPOSURE

Occupational

The general public may be exposed to ethane by inhalation of natural gas in crude oil emissions. It is also possible to be exposed through drinking water and food intake, but this exposure is minor in comparison to inhalation. The average daily intake of ethane by one person through breathing ambient air is 183 mg.

There are no reference values for exposures to ethane. However, because of its asphyxiant property in displacing ambient oxygen, it is important to note the limits for oxygen concentration in the working area. Oxygen levels should be no lower than 18% to avoid extreme discomfort and danger.

Environmental

Ethane is a component of crude oil and natural gas and naturally exists in the environment. It is most likely to be released into the environment through waste streams and into the atmosphere in gas form. The combustion of gasoline and the fumes created by waste incinerators might also release ethane into the atmosphere (HSDB, 2009).

INDUSTRIAL HYGIENE

Because ethane only exists as a liquid at below freezing temperatures (-172°C to -88°C) it is important to wear cold-insulating gloves to prevent frostbite or injury while handling the liquid form of ethane. In the case of high vapor concentration, self-contained breathing apparatuses may be worn. In industry a threshold limit value (TLV) at 1000 parts per million (ppm) is used for handling ethane. (Clough, 2005).

MEDICAL MANAGEMENT

In the case of asphyxiation, the victim should immediately be moved to an area with fresh air and medical attention should be sought. Supplemental oxygen can be administered, if necessary. Generally, individuals recover quickly once oxygen levels are brought back to normal. In the event of frostbite, the exposed area should be rinsed in warm water; hot water should not be used. Digits can be warmed in the armpit and medical attention should be sought immediately.

S2 keep out of the reach of children
S9 keep container in a well-ventilated place
S16 keep away from sources of ignition—no smoking
S33 take precautionary measures against static discharges

BACKGROUND AND USES

Propane, also called n-propane (CASRN 74-98-6), is a naturally colorless, odorless gas (Harbison, 1998). Because of the potential for explosion, odor is typically added to propane to make its presence more easily detectable. Propane has a wide variety of uses. It is a component of liquid petroleum gas utilized for both commercial and industrial purposes (HSDB, 2009). Propane is often used as a basic material in chemical and organic synthesis. It can be used as a household and industrial fuel, a solvent, a refrigerant, an aerosol propellant, and as a replacement for chlorofluorocarbons (HSDB, 2009). Propane has uses in the agricultural sector for crop drying, weed control, and as a fuel for farm equipment. The most significant negative health effects come from the potential for propane to explode, leading to burns, other injuries, and sometimes death.

PHYSICAL AND CHEMICAL PROPERTIES

Propane is typically found in industrial settings as a gas with a boiling point of -42°C (-43.6°F) and a freezing point of -189.7°C (-309.5°F). Propane has a vapor pressure of 8.4 atm and a vapor density of 1.6. The autoignition point of propane is 432°C (842°F), a lower explosive limit of 2.2% and an upper explosive limit of 9.5% (HSDB, 2009). Under normal conditions of storage and use, hazardous

decomposition or polymerization products are not produced. However, propane is extremely flammable when exposed to open flames, sparks, static discharge, and oxidizing materials.

MAMMALIAN TOXICOLOGY

Acute Effects

Propane is considered as a simple asphyxiant. This asphyxiant property is related to the direct displacement of oxygen, rather than toxic effects (Harbison, 1998). In confined spaces, high concentrations of propane vapor can accumulate, leading to irritation of the nose and throat, headache, nausea, vomiting, dizziness, and drowsiness. In extreme situations, unconsciousness and asphyxiation can result. However, at concentrations up to 10% or 100,000 ppm, propane has not been shown to cause noticeable irritation to the eyes, nose, or respiratory tract (Snyder, 1987). However, direct skin or mucous contact with liquid propane or with rapidly expanding gas can cause burns or frostbite to the exposed areas.

Chronic Effects

Propane is not considered carcinogenic or mutagenic, nor does it bioaccumulate. There are no known health effects associated with chronic exposure to propane.

Mechanism of Action(s)

As a simple asphyxiant, propane directly displaces oxygen, potentially leading to central nervous system depression, unconsciousness, and death.

Chemical Pathology

No long-term chemical pathologies of industrial exposure to propane have been reported.

SOURCES OF EXPOSURE

Occupational

The most common routes of occupational exposure occur through inhalation and dermal contact in workplaces where propane is present, due to either its production or use. This includes industries utilizing petroleum or natural gas or those using solvents, refrigerants, or aerosol propellants containing propane. Because propane can be used in the agricultural sector, farm workers using propane for crop drying, weed control, or as a fuel for equipment can also be exposed.

Environmental

due to its use in the petroleum industry, in outdoor gas grills, and as a heating fuel, propane may be released into the environment in multiple ways (HSDB, 2009). Additionally, disposal methods of the natural gas and petroleum industries may release propane into the atmosphere. Propane exists as a gas in the atmosphere. If present in the soil, propane is readily oxidized by soil bacterium into acetone (HSDB, 2009).

INDUSTRIAL HYGIENE

Where exposure might occur, appropriate personal protective equipment should be utilized. This includes goggles or other protective eyewear, chemical protective gloves, and protective clothing to prevent skin freezing in case of dermal contact. Quick-drench facilities and eyewash fountains should be readily available. If working with propane or propane-containing products within a contained area, self-contained breathing apparatuses or other respirator protection is recommended.

MEDICAL MANAGEMENT

If contact with the eyes occurs, contact lenses should be removed immediately. The eyes should be flushed with water for 15 min, and medical attention should be sought immediately.

If contact with the skin occurs, the area should be flushed with water for 15 min while medical attention should be sought. After contaminated clothing is removed, it should be soaked with water to prevent the risk of static discharges and subsequent gas ignition. Contaminated clothing and shoes should be washed thoroughly before reuse. If frostbite occurs, the frozen tissues should be warmed by rinsing in warmed water and medical attention should be sought.

If exposure through inhalation occurs, the person should be moved immediately to fresh air. If the person is not breathing, or if breathing is irregular or respiratory arrest occurs, trained personnel should deliver artificial respiration or oxygen. Medical attention should be sought. If an explosion occurs, seek medical attention.

BUTANE

Target organ(s): Brain, heart, liver

Occupational exposure limits: NIOSH: REL for 10 h TWA is 800 ppm

Reference values: None

Risk/safety phrases: R12: Extremely flammable

S2: Keep out of the reach of children
S9: Keep container in a well-ventilated place
S16: Keep away from sources of ignition—no smoking

BACKGROUND AND USES

Butane (CASRN 106-97-8) consists of a chain of four carbons. Like other hydrocarbons, it exhibits narcotic properties. It occurs naturally as a constituent of natural gas, from which it is then refined (HSDB, 2013). It is used as a fuel in disposable lighters, refrigerants, aerosol propellants, and as a gasoline additive. Most reported health effects due to butane result from intentional abuse of butane, primarily from “huffing” by teenagers. There are few reports of industrial health effects. The amounts of butane exposure during intentional abuse far exceed expected occupational exposures.

PHYSICAL AND CHEMICAL PROPERTIES

Butane is a colorless gas with a faint gasoline-like odor. It is a flammable gas, with a flash point of -69°C (-76°F) and an autoignition point of 287°C (550°F). Butane has a lower explosive limit of 1.6% and an upper explosive limit of 8.4%. It has a boiling point of -0.5°C (31.1°F). Butane is not considered soluble in water and is an explosion hazard when exposed to a nickel carbonyl/oxygen mixture; it should also be kept away from strong oxidizers.

MAMMALIAN TOXICOLOGY

Acute Effects

Butane is a simple asphyxiant; this asphyxiant property is related to the displacement of oxygen, not a toxic response

(Harbison, 1998). Exposure to high concentrations of butane, especially in confined spaces, can result in asphyxiation if the concentration of oxygen is reduced below 16%. Symptoms include those of oxygen deprivation, such as rapid breathing, dizziness, headache, mental confusion, muscular weakness, and numbness of the extremities. If oxygen concentrations fall below 6–8%, unconsciousness, central nervous system damage, and death are possible.

The vapor of butane is not considered to be irritating to the eyes, nose, or throat. However, contact with the liquid form of butane can cause frostbite, freeze burns, and permanent damage to tissues if it comes into contact with the eyes, skin, or mucous membranes.

Several case reports of intentional and unintentional direct butane inhalation have reported myocardial infarction and ventricular fibrillation (Sugie et al., 2004; Girard et al., 2008; De Naeyer et al., 2011; Senthilkumaran et al., 2012). One teenager died after butane abuse from multiple organ failure, which included the central nervous system, the cardiovascular system, the pulmonary system, and the liver (Rieder-Scharinger et al., 2000). Due to the direct nature of these exposures, similar exposures in an occupational setting are unlikely.

Chronic Effects

Because butane is a simple asphyxiant, chronic and carcinogenic effects are not expected. The International Agency for Research on Cancer (IARC), OSHA, and ACGIH do not consider butane to be carcinogenic. There are a few case reports indicating effects after chronic intentional use; one teenage butane abuser developed fatal fulminant hepatic failure after 3 years of butane abuse (McIntyre and Long, 1992). The extent of chronic effects noted in the literature is limited, suggesting that chronic effects are rare.

Mechanism of Action(s)

As a simple asphyxiant, negative effects are related to the displacement of oxygen, not to toxic responses; this lack of oxygen can result in hypoxia or anoxia. Biologically, butane is hydrolyzed by microsomal enzymes to its alcohol, butanol (Tsukamoto et al., 1985; Harbison, 1998). This butanol is exhaled or conjugated and excreted.

Chemical Pathology

Pathologies related to butane are limited. Myocardial infarction and ventricular fibrillation are the most commonly reported pathologies related to acute exposures. Other reported pathologies include fulminant hepatic failure and multiple organ failure after chronic intentional abuse.

SOURCES OF EXPOSURE

Occupational

The most common occupational exposures to butane occur through either inhalation or dermal contact in workplaces, where butane or petroleum- and natural gas-containing butane are used; this could include truck drivers, gas station attendants, and other workers where contact with petroleum and natural gas products are common (HSDB, 2013). One study in France detected butane in a hospital setting (Bessonneau et al., 2013), and a separate study in Poland detected butane in the occupational environment of a painting restorer (Jezewska and Szewczynska, 2012; Bessonneau et al., 2013). All levels detected in these studies were far below regulatory limits.

Environmental

Monitoring data indicate that butane is a widely occurring atmospheric pollutant (HSDB, 2013). The general population may be exposed to butane through the inhalation of ambient air and through contact with liquids containing this compound, such as crude oil, gasoline, and other liquid products.

INDUSTRIAL HYGIENE

Skin barriers and eye protection to prevent exposures to liquid butane are recommended. When working with potentially high concentrations of butane in enclosed spaces, self-contained breathing apparatuses or other respirator protection is recommended. Quick-drench facilities and/or eyewash stations should be located within the immediate work area for emergency use when working with butane.

The vacated 1989 OSHA PEL TWA of 800 ppm is still enforced in some states. National Institute for Occupational Safety and Health has a REL for a 10 h TWA of 800 ppm.

MEDICAL MANAGEMENT

The medical care required will be dependent upon the exposure. For mild to moderate inhalation exposure, removal of the individual away from the source of butane and administration of supplemental oxygen are typically sufficient. For severe inhalation exposure, supplemental oxygen should be administered and immediate medical care should be sought. Treatment will depend on the extent of symptoms, including ventricular fibrillation and central nervous system depression. If dermal exposure occurs,

rewarming of the area and topical treatments are recommended. Individuals with severe burns and frostbite should seek professional medical care. For eye exposure, the eyes should be washed with copious amounts of room temperature water for at least 15 min and medical attention should be sought.

BACKGROUND AND USES

n-Hexane is used as a solvent in glue, ink, rubber, and adhesives in shoe manufacturing. It is also used in the extraction of a variety of plant oils and in research laboratories. It is commonly found in petroleum products and, as a result of petroleum combustion, *n*-hexane is ubiquitous in ambient air at low concentrations. It may also be released from industrial sources as a result of evaporation.

PHYSICAL AND CHEMICAL PROPERTIES

n-Hexane (CASRN 110-54-3; hexane; hexyl hydride; normal-hexane) is a colorless liquid with a distinct gasoline-like odor. It is the most toxic member of the alkanes. It has a vapor pressure of 150 mmHg and a vapor density of 2.97. It is extremely flammable and easily ignited by heat or sparks. Its vapors are heavier than air; the vapors can accumulate in low areas and may form explosive mixtures with ambient air.

MAMMALIAN TOXICOLOGY

Acute Effects

Exposure to *n*-hexane affects the skin, eyes, and heart, as well as the respiratory and nervous systems. Some symptoms include headache, dizziness, nausea, vomiting, and irritation of the respiratory tract, nose and throat.

The primary route of exposure is inhalation. Symptoms of acute inhalation include numbness, cough, bloody-frothy sputum, tachycardia, and general weakness. Fifty-three workers in a vinyl sandal-manufacturing setting were exposed to *n*-hexane at an average of 118 ppm. They recorded sensory polyneuropathy (Takeuchi, 1993). Acute effects observed in other shoe factory workers included mild weakness and paresthesia of the lower limbs (Governa et al., 1987). Recent studies investigating nerve conduction in workers exposed to *n*-hexane report decreases in sensory nerve conduction in lower limbs when compared to workers not exposed to *n*-hexane (Najafi et al., 2011; Neghab et al., 2013; Neghab et al., 2012). These studies suggest that nerve conduction tests may be predictors of *n*-hexane effects before overt symptoms are seen in workers exposed to chronic low levels of *n*-hexane.

At very high concentrations, *n*-hexane can cause unconsciousness and even death from asphyxiation due to oxygen displacement. Polyneuropathy was observed in Taiwanese workers in a ball-manufacturing factory, where concentrations of *n*-hexane ranged from 89 to 109 ppm as a result of poor ventilation in the workspace (Huang et al., 1991).

Ocular exposure to *n*-hexane can cause corneal injury. Skin irritation and redness may result from dermal contact. Ingestion, though unlikely, can cause nausea and gastrointestinal irritation, as well as CNS depression.

Chronic Effects*

The chronic effects of *n*-hexane are rare in an industrial setting. When they do occur, it is usually in small factories. One example, described by Pezzoli et al. (1995), was of a man who had been complaining of motor impairment and feeling weak. This man had worked in a small, family

owned leather-processing factory for 30 years and had been exposed to high levels of *n*-hexane over this period. The chronic nature of this exposure was supported by urinary levels of 2,5-hexanedione (2,5 HD), a metabolite of *n*-hexane, of 785 mg/l. This is 75% higher than the normal population level of 450 mg/l (Pezzoli et al., 1995).

The most frequent and severe chronic effects are seen in cases of solvent abuse. Common products such as glues and correction fluids may be concentrated and inhaled (Ong et al., 1993). This results in high exposure to *n*-hexane and toluene, as well as other solvents. In 1990, volatile substance abuse resulted in the deaths of 118 young people in South Africa (Khedun et al., 1996). In a clinical study of inhalant abuse of *n*-hexane, researchers reported a decrease in nerve conduction, axonal swelling, and demyelination. The patients suffered from muscle weakness and numbness and partial motor conduction block that persisted for 2–4 months after withdrawal from hexane-containing inhalants (Kuwabara et al., 1999).

Mechanism of Action(s)

The oxidation of *n*-hexane forms the toxic metabolite 2,5-hexanedione that can result in both neurotoxicity and testicular toxicity, albeit by different mechanisms. In the brain, 2,5-hexanedione disrupts phosphorylation of neurofilaments, which allows neurofilament proteins to accumulate along the axon; this causes it to swell and results in axonopathy (Tshala-Katumbay et al., 2009). The testicular toxicity of 2,4-hexanedione is due to its effect on the Sertoli cells' ability to secrete seminiferous tubule fluid, which ultimately compromises germ cell viability (Boekelheide and Schoenfeld, 2001).

Chemical Pathology

Concentrations greater than 50 g may be lethal (Bingham et al., 2001).

SOURCES OF EXPOSURE

Occupational

The most common occupational exposure to *n*-hexane is by inhalation or dermal contact in industries where it is produced or used. These include automobile repair shops where gasoline tanks are handled, printing factories, manufacturing facilities, and a variety of refineries.

Environmental

n-Hexane is a component of crude oil and natural gas and naturally exists in the environment. Because of its widespread use and production, *n*-hexane is most commonly released into the environment through waste streams and into the atmosphere in vapor form.

INDUSTRIAL HYGIENE

The National Institute for Occupational Safety and Health (NIOSH, 2010) and the ACGIH (2012) have both set the TWA at 50 ppm (180 mg/m³). The OSHA permissible exposure limit is currently set at a TWA of 500 ppm.

Exposure to hexane is also a concern in the printing industry. Soon after application, the ink sets, and solvents are evaporated into the workroom air. To a large extent, exposure depends on the size and ventilation capabilities of the offset print shops (Wadden et al., 1995).

Health and safety precautions include proper ventilation to maintain exposure limits and proper protective clothing. The hazard of dermal exposure can be reduced through the use of polymeric-containing clothing material such as butyl nomex. This material has been shown to prevent exposure for time periods <21 min. This protection allows short-term contact with *n*-hexane at a reduced risk (Dillon and Obasuyi, 1985).

MEDICAL MANAGEMENT

In the case of acute exposure by inhalation, the affected person should be moved to a well-ventilated area or fresh air and medical attention should be sought to evaluate their respiratory distress. Inhaled corticosteroids (such as albuterol) can be given for severe coughing and wheezing and oxygen administered, if necessary. For skin exposures, contaminated clothing should be immediately removed and affected area should be washed with soap and water. In the case of eye contact, the eyes should be irrigated with plenty of water. Medical personnel should evaluate the treatment.

Recent research has promoted the use of new methods for early detection of *n*-hexane exposure. Mayan (2002) studied factory workers who had occupational exposure to hexane with no apparent health effects. Workspaces were monitored for *n*-hexane and post shift urine samples were collected and analyzed for the presence of 2,5-hexanedione. They found a significant correlation between levels of urinary 2,5-hexanedione and hexane detected in air samples. The authors suggest that urinary 2,5-hexanedione could be used as a biomarker for detection of *n*-hexane exposure and that this method is a more effective approach than air monitoring.

CUTTING OILS

Target organ(s): Skin, respiratory tract

Occupational exposure limits:	OSHA PEL—5 mg/m ³ TWA
	Oil mist, mineral:
	NIOSH REL—5 mg/m ³ TWA
	NIOSH REL—10 mg/m ³ STEL
	ACGIH TLV—5 mg/m ³ TWA

BACKGROUND AND USES

Cutting oils, also called metal-working fluids, is a term used to refer to a group of compounds that are used to aid in machine operations, specifically when metal pieces are being machined, ground, or milled. There are three main classifications of metal-working fluids: (1) straight oils, also called neat oils, which are insoluble and made up of mineral, animal, marine, vegetable, or synthetic oils; (2) soluble oils, which contain severely refined petroleum oils as well as emulsifiers; and (3) synthetic fluids, which do not contain petroleum oils.

Regardless of the type of fluid, various components, referred to as additives, can be added to the oil to provide or improve specific desirable properties. The hazardous effects of the specific cutting oil are highly dependent on these additives. Common additives include germicides such as formalin, mercurials, or phenolic compounds; emulsifiers such as soaps and sulfonates; corrosion inhibitors such as borates, dichromates, or amines; and extreme pressure compounds of sulfur, chlorine, or phosphorus. The oil–water emulsions tend to become rancid, but they are good coolants, economical, and noncombustible.

PHYSICAL AND CHEMICAL PROPERTIES

Physical and chemical properties are determined by the specific composition of the given cutting oil and thus vary between different oils. Information regarding the physical and chemical properties of particular cutting oil should be obtained from the manufacturer.

MAMMALIAN TOXICOLOGY

Acute Effects

Occupational irritant contact dermatitis is a commonly observed acute effect associated with cutting oil processes (Ramos, 1974; Grattan et al., 1989; Sakakibara et al., 1989; Goh and Gan, 1994). The severity and likelihood of contact dermatitis is dependent upon several factors. Cutting oils have various additives; these additives induce different degrees of inflammatory responses and can influence the absorption of components in the cutting fluid mixture (Baynes et al., 2002; Monteiro-Riviere et al., 2006). Small lacerations of the skin can be caused by sharp metal chips embedded in rags or clothing, increasing the likelihood of irritation or infection following dermal contact with cutting oils. The age of cutting oils may also impact the likelihood and severity of adverse health outcomes after exposure to cutting oils; the composition of the cutting oil, including the concentration of polycyclic aromatic hydrocarbons (PAHs) and the presence of microbes, changes over time (Evans et al., 1989; Apostoli et al., 1993).

Machinists who are prone to acne and seborrhea or are hirsute are relatively susceptible to blockage of hair follicles by insoluble oils and the consequent folliculitis, arising as a result of chemical irritation and mechanical plugging of the follicular canals. Individuals with a previously unresolved skin problem or who have a dry, atrophic skin are vulnerable to soluble fluids, especially clearly alkaline fluids or those containing wetting agents. Onset of the problem usually occurs soon after the first exposure and is marked by acute reactions starting on the dorsal surfaces of the hands and fingers, the extensor surfaces of the forearms and thighs, and the abdomen (i.e., those surfaces in contact with oil or oil-soaked clothing). Comedones and perifollicular papules and pustules ("oil boils") may develop with a possible latent development of melanosis. Secondary infections may occur, but the bacteria in the oil are rarely primary skin pathogens or the single cause of the folliculitis. Clinical manifestations clear rapidly with the termination of exposure and do not resolve if the exposure is continued. Hata et al. (2001) published a case study of a 48-year-old Japanese man who, after exposure to cutting oil on his forearms and dorsa of the hands, developed multiple erythematous lesions on areas that had no direct contact with the cutting oil (Hata et al., 2001). One explanation is that this reaction was mediated through an allergic response following initial contact with the cutting fluid, but this has not been verified. However, there are other reports of contact allergies developing after exposure to cutting fluids (Niklasson et al., 1993).

Exposures to mist sprays of insoluble oils used as coolants, cutting fluids, and lubricants in machine operations have been shown to have some impact on the respiratory tract. Mineral oil droplets <5 µg in diameter may be inhaled

and result in fibrotic nodules, paraffinomas, or lipoid pneumonitis (Waldron, 1977). A study of metalworking apprentices showed the development of asthma-like symptoms after exposure to metalworking fluids (Kennedy et al., 1999). Another study showed that 20% of workers exposed to metalworking fluids reported daily or weekly respiratory symptoms, such as bronchitis, shortness of breath, runny nose, and sore throat; these are suggestive of work-related asthma (Rosenman et al., 1997). A number of other studies have investigated hypersensitivity pneumonitis outbreaks in workers exposed to metalworking fluids, especially where mycobacterial contamination occurred (Fox et al., 1999; Shelton et al., 1999; Hodgson et al., 2001; Bracker et al., 2003; O'Brien, 2003; Gupta and Rosenman, 2006).

Chronic Effects

Due to the wide array of cutting oils, the chronic effects are dependent on the individual components of the mixtures. Certain components, or their metabolites or derivatives, are carcinogenic. Specifically, several studies have shown that the concentration of PAHs increases with the age of the cutting oil (Evans et al., 1989; Apostoli et al., 1993). Although neither of these studies found mutagenicity or increased health effects, PAHs are known to be carcinogenic.

The carcinogenicity of cutting oils as a complete mixture has been the subject of a number of studies. These studies typically investigate organs of the aerodigestive tract, including the larynx, esophagus, stomach, pancreas, rectum, and lungs. This pattern of digestive tract cancers in exposed populations has been observed in other epidemiological studies with some respiratory tract cancer links as well (Silverstein et al., 1988; Eisen et al., 1992). A study concentrating on a cohort of automobile-manufacturing workers found an association between cancers of the esophagus, larynx, rectum, skin, brain, liver, prostate, and pancreas and exposure to various metalworking fluids (Eisen et al., 2001). A different study, using data from the same cohort, found an association between cancer of the larynx and metalworking fluid exposure and no association between stomach cancer and the exposure (Zeka et al., 2004).

The carcinogenicity of cutting fluids on other organs has been studied as well. A case-control study involving workers exposed to metalworking fluids showed that dermal exposure was associated with an increased risk for non-seminomatous testicular cancer, particularly among workers with over 5000 h of exposure (Behrens et al., 2012). Another case-control study conducted among Canadian workers found an increased risk of bladder cancer among workers exposed to mineral, cutting, or lubricating oil (Ugnat et al., 2004). A different case-control study in Canada also found an increased risk of renal cell carcinoma after exposure to mineral, cutting, or lubricating oil (Hu et al., 2002).

Dermal lesions can become carcinogenic after chronic exposure to cutting oils. Tsuji et al. (1992) reported multiple keratoses and squamous cell carcinoma on the forearms of a patient, who had worked with cutting oils for 15 years (Tsuji et al., 1992). Excess risk of cancer of the skin and scrotum has also been reported (Jarvholt and Easton, 1990).

The irritant effects and carcinogenicity of cutting oils on the skin have also been demonstrated in animal models. Dermatitis were observed on guinea pigs after repeated exposure to cutting oil, and treatment with emollient creams was not effective for alleviating the response (Goh, 1991). Two different cutting oils were shown to cause skin tumors in mice (Gilman and Vesselinovitch, 1956), and the ability of cutting oil to initiate tumors in mouse skin has been demonstrated (Gupta and Mehrotra, 1989).

Mechanism of Action(s)

Because emulsion and synthetic fluids are potent defatting agents, the skin reaction may include maceration, dryness and "chapping," reddening, and vesiculation. Bacterial growths in the fluid do not appear to be directly injurious to workers, but rancid fluids and products of bacterial action can lead to skin disorders. Individual additives in cutting fluids can be a cause of either primary irritative or hypersensitive dermatitis. Detergents, soaps, and wetting agents defat the skin; and alkaline materials damage the keratin of the upper, protective skin layers. Formalin in germicides is a sensitizer. Additives containing sulfur and chlorine are direct irritants, although chloracne is not associated with cutting fluids. Nickel or chromates derived from materials being cut can be a source of allergic dermatitis. Harsh abrasive soaps and solvents, such as gasoline and kerosene, may contribute to chemical and traumatic dermatitis; these cleaning materials are common in machine shops. Although grime and grease can certainly be removed from the skin with these substances, it is safer to use less hazardous cleansers.

SOURCES OF EXPOSURE

Occupational

Occupational exposures occur among individuals who work with metal-cutting tools, which utilize cutting oils to facilitate machinery performance. The most probable routes of exposure to cutting fluids are dermal contact with the liquid and inhalation of the aerosols.

Environmental

Cutting oils are not naturally occurring and thus have limited environmental exposure. The environmental fate or transport of given cutting oil that has been accidentally or purposefully

introduced to the environment will depend heavily on the exact chemical composition of the cutting oil.

INDUSTRIAL HYGIENE

Contact dermatitis can be avoided through the use of appropriate control measures. Workers exposed to cutting fluids should be provided with adequate washing facilities. Machines should be enclosed to reduce the contact through splashing as well as to reduce potential inhalation of aerosolized cutting oil droplets. Sufficient clean clothing and protective garments should be provided. Cutting fluids should be replaced according to manufacturer recommendations to avoid harmful contaminants that increase over time.

MEDICAL MANAGEMENT

The appropriate medical response depends on the route of exposure. For inhalation exposures, the individual should be moved to fresh air, away from the exposure, and help from a medical professional should be sought if breathing difficulties arise. For skin contact, the exposed areas should be washed with soap and water immediately. If the fluid comes into contact with clothing, the clothing should be removed and laundered before the next wear. Medical attention should be sought if irritation or rash appears after contact with skin. If the fluid comes into contact with the eyes, they should be flushed with water for at least 15 min and immediate medical attention should be sought. If the fluid is ingested, medical assistance should be sought before taking any action.

LUBRICATING OILS

Risk/safety phrases:	R12: Extremely flammable
	R45: May cause cancer
	R46: May cause heritable genetic damage
	R53: May cause long-term adverse effects in the aquatic environment
	R65: Harmful, may cause lung damage if swallowed
	S45: In case of accident or if you feel unwell seek medical advice immediately (show the label where possible)
	S53: Avoid exposure—obtain special instructions before use

BACKGROUND AND USES

Lubricating oils are based on aliphatic hydrocarbon molecules containing 17 or more carbon atoms. The wide array of lubricating oil mixtures are used to reduce the friction and heat produced when mechanical parts

come into contact with one another. Similar to cutting oils, there are two major classifications: (1) mineral, which are made from refined petroleum, and (2) synthetic, which are made from other oil sources. The exact composition of lubricating oils varies, as lubricating oils are complex mixtures that contain small amounts of aromatic and polycyclic substances and a broad variety of dissimilar materials known collectively as additives. Additives serve a variety of functions, including inhibiting corrosion or oxidation, preserving integrity of the oil film, altering the viscosity of the mixture, suppressing bacterial growth within the mixture, or acting as a detergent. The presence of the additives determines the toxicity and possible adverse health outcomes of lubricating oils.

PHYSICAL AND CHEMICAL PROPERTIES

Physical and chemical properties are determined by the specific composition of given lubricating oil and thus vary between different oils. Information regarding the physical and chemical properties of particular lubricating oil should be obtained from the manufacturer.

MAMMALIAN TOXICOLOGY

Acute Effects

Because of the similarity in the two types of mixtures, any adverse health effects seen after exposure to lubricating oils will be similar to those seen after exposure to cutting oils. However, fewer studies have been completed on lubricating oils than on cutting oils, and most of the studies characterize the effects of chronic exposure to lubricating oils. It should be noted that the additives found in lubricating oil mixtures pose the greatest risk for toxicity.

Chronic Effects

There have been a few studies conducted on the chronic effects of lubricating oils. One group found evidence of dermal irritation in mice following chronic application of a lubricating compound (Arfsten et al., 2005). Another study exposed Sprague-Dawley rats to aerosols of base stocks used to create lubricating oils; after exposure, there were a few effects seen in the lungs of the rats, but the limited effects at high doses suggest a relatively low toxicity for these base stock aerosols (Dalbey et al., 1991).

Lubricating oils have also been shown to cause DNA adducts to form in mouse and human skin exposed to these oils (Carmichael et al., 1991). A case-control study conducted among Canadian workers found an increased risk of bladder cancer among workers exposed to mineral, cutting, or lubricating oil (Ugnat et al., 2004). A different case-

control study in Canada also found an increased risk of renal cell carcinoma after exposure to mineral, cutting, or lubricating oil (Hu et al., 2002). However, as with cutting oils, the carcinogenic effects of lubricating oils are likely due to specific compounds found within the mixtures. One study found that after lubricating oils had been treated to significantly reduce PAH levels, the ability of the oil to cause skin tumors in mice was ablated (McKee et al., 1989).

Mechanism of Action(s)

The mechanism of action will depend on the nature of the additive responsible for the adverse health effect. For studies concerning adverse health outcomes following general lubricating oil exposure, mechanisms have not been well characterized.

SOURCES OF EXPOSURE

Occupational

Occupational exposures occur among individuals who work with machines utilizing lubricating oils to enhance machine performance; due to the nature of lubricating oils and modern industry, lubricating oils are likely present in nearly all industrial settings. The most probable routes of exposure to lubricating oils are dermal contact with the liquid and inhalation of the aerosols.

Environmental

Lubricating oils are not naturally occurring and thus have limited environmental exposure. The environmental fate or transport of given lubricating oil that has been accidentally or purposefully introduced to the environment will depend heavily on the exact chemical composition of the lubricating oil.

INDUSTRIAL HYGIENE

The most effective industrial hygiene measures are engineering controls. Adequate ventilation should be ensured, and the fluid should be kept away from ignition sources. Eye and face protection, along with protective clothing such as boots, gloves, and apron or coveralls, should be provided.

MEDICAL MANAGEMENT

Medical action following exposure will depend on the nature of the exposure and the severity of health effects. For inhalation exposures, the individual should be removed from the area, and oxygen should be provided if breathing

is difficult; if breathing is not occurring, artificial respiration should be performed. Medical attention should be sought immediately following difficulty or cessation of breathing. For skin exposures, the area should be washed with soap and water. Contaminated clothing should be removed and washed before reuse. Medical attention should be sought immediately. If contact with the eyes, eyes should be flushed immediately with water for at least 15 min. Medical attention should be sought immediately. If swallowed, medical attention should be sought immediately.

1-PENTANOL

First aid: See text

Target organ(s): Central nervous system (CNS), lungs, nerves, skin

Occupational exposure limits: Derived no effect level (DNEL, inhalation, systemic/local effects, long term): 73.16 mg/m³; DNEL, inhalation, systemic/local effects, short term: 292 mg/m³

Reference values: DNEL, systemic/local effects, long term: 15.4 mg/m³; DNEL, systemic/local effects, short term: 256.4 mg/m³; DNEL, oral, systemic effects, long term: 25 mg/kg-bw/day.

Hazard statements: H226—flammable liquid and vapor; H315—causes skin irritation; H319—causes serious eye irritation; H332—harmful if inhaled; H335—may cause respiratory irritation

Risk phrases: R10—flammable; R20—harmful by inhalation; R37/38—irritating to the respiratory system and skin

Safety phrases: S1/2—keep locked up and out of reach of children; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S36/37—wear suitable protective clothing and gloves; S46—if swallowed, seek medical advice immediately and show this container or label

BACKGROUND AND USES

Pentanols are irritating, narcotic, and have produced illnesses and fatalities upon ingestion. However, this class of alcohols

is of a low order of toxicity in an industrial setting. As the carbon chain lengths of the alcohols increase, the toxicity decreases. Higher chain alcohols are not able to penetrate the skin as readily as smaller molecular weight alcohols and are less likely to be inhaled. There are no current regulations regarding occupational exposures to pentanols.

1-Pentanol (pentyl or amyl alcohol; “fusel oil”; CASRN 71-41-0) is the most common pentanol and exhibits the more prevalent hazards of these compounds. It is a colorless liquid with a pleasant odor.

PHYSICAL AND CHEMICAL PROPERTIES

More soluble in organic solvents than water, 1-pentanol has a vapor pressure of 2.8 mmHg at 20 °C (68 °F) and a vapor density of 3.0. Although reagent grade pentanol can be obtained, a mixture of three isomers is usually present in commercial grade formulations. It is used as an industrial solvent and is also a synthetic flavoring agent. In nature, pentanol is detected in animal waste and in some plant essential oils.

MAMMALIAN TOXICOLOGY

Acute Effects

Acute effects commonly experienced upon exposure to 1-pentanol vapor include irritation of the eyes with lacrimation and corneal disturbances. No significant or permanent damage has been reported as a result of 1-pentanol overexposure. Respiratory tract irritation at high concentrations and some

CNS effects, including vertigo, double vision, and headache may occur.

Female rats exposed to 3900 parts per million (ppm) of 1-pentanol vapor for 7 days during gestation did not exhibit any maternal or fetal toxicity (Nelson et al., 1990). Interestingly, the authors intended to test an exposure to a higher concentration of 1-pentanol vapor, but they could not generate high enough concentrations to produce maternal toxicity.

Chronic Effects

Chronic exposure to this chemical has not yielded any significant health hazards except for infrequent mild dermatitis (Fregert et al., 1963).

Mechanism of Action(s)

1-Pentanol can produce irritation and inflammation to the pulmonary, gastrointestinal, and dermal tissue. This chemical may also act as a neurological depressant.

SOURCES OF EXPOSURE

Occupational

1-Pentanol is not considered a significant occupational hazard, except under conditions of high exposure. This chemical is produced in processes in which fractional distillation of mixed alcohols resulting from the chlorination and alkaline hydrolysis of pentane occurs.

Environmental

Environmental exposure to 1-pentanol comes occurs due to the inhalation of ambient air and consumption of drinking water in contaminated areas. Substantial quantities of this chemical are not commonly found in the environment.

INDUSTRIAL HYGIENE

1-Pentanol is not considered a significant occupational hazard, and minimal precautions are required to prevent exposures. Barrier creams and protective clothing should be worn to prevent dermal contact. Any standard organic vapor adsorbent is an appropriate respirator choice. At high concentrations, a self-contained oxygen supply may be necessary.

MEDICAL MANAGEMENT

In case of contact with the eyes, flush with warm running water for at least 20 min, holding the eyelids open during

flushing. Take care not to flush contaminated water into unaffected eye or onto skin. In case of skin contact, immediately remove contaminated clothing under running water. Flush exposed area with large amounts of warm running water for at least 20 min. Decontaminate clothing before reuse or discard. For inhalational exposures, remove to fresh air. Give oxygen and get immediate medical attention for any breathing difficulty. If ingested, do not induce vomiting. If the casualty is alert and not convulsing, give 2–4 glasses of water to drink to dilute 1-pentanol. If spontaneous vomiting occurs, have the casualty lean forward to avoid breathing in of emesis. Rinse mouth and administer more water. Get medical attention immediately (ECHA 2013).

ALLYL ALCOHOL

First aid: See text

Target organ(s): Liver, lungs

Occupational exposure limits: American Conference of Governmental Industrial Hygienists (ACGIH, 1996) threshold limit value (TLV) 0.5 ppm (1.25 mg/m³), Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) 2 ppm (5 mg/m³), recommended exposure limit (REL) 2 ppm (5 mg/m³) and 4 ppm, short-term exposure limit (STEL) 9.5 mg/m³ (skin)

Reference values: Reference dose (RfD) -5×10^{-3} mg/kg/day

Hazard statements: H225—highly flammable liquid and vapor; H301—toxic if swallowed; H311—toxic in contact with skin; H331—toxic in contact with skin; H319—causes serious eye irritation; H335—may cause respiratory irritation; H400—very toxic to aquatic life

Precautionary statements: P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking; P280—wear protective gloves/protective clothing/eye protection/face protection; P303—if on skin (or hair), rinse skin with water/shower and remove immediately all

contaminated clothing; P305—if in eyes, rinse cautiously with water for several minutes. Remove contact lenses, if present and easy to do. Continue rinsing; P501—dispose of contents/container to . . . in accordance with local/regional/national/international regulations.

Risk phrases: R23/24/25—toxic by inhalation, in contact with skin, and if swallowed; R36/37/38—irritating to the eyes, respiratory system, and skin; R50—very toxic to aquatic organisms; R10—flammable

Safety phrases: S1/2—keep locked up and out of reach of children; S36/37/39—wear suitable protective clothing, gloves, and eye/face protection; S38—in case of insufficient ventilation, wear suitable respiratory equipment; S45—in case of accident or if you feel unwell, seek medical advice immediately (show the label where possible); S61—avoid release to the environment. Refer to special instructions/safety data sheets

BACKGROUND AND USES

Allyl alcohol ($\text{H}_2\text{C}=\text{CH}-\text{CH}_2-\text{OH}$; 2-propanol, 1-propen-3-ol; CASRN 107-18-6) is a chemical intermediate with potent irritant properties. Existing as a colorless liquid at room temperature, allyl alcohol has a pungent, mustard-like odor. It is used widely as a chemical intermediate in resins, flavorings, epoxies, and reagent grade herbicide.

PHYSICAL AND CHEMICAL PROPERTIES

Of the olefinic alcohols (those with a double bond), allyl alcohol is considered the most important in the industry. It is miscible with water and organic solvents. At 25 °C (77 °F), allyl alcohol has a vapor pressure of 23.8 mmHg and a vapor density of 2.0. It is not known to occur naturally.

MAMMALIAN TOXICOLOGY

Acute Effects

Inhalation of allyl alcohol vapors produces dose-related effects on the respiratory system and mucous membranes. Signs and symptoms of acute, high concentration exposures may include coughing, dry throat, and irritation of the eyes and nose. Lacrimation, retrobulbar pain, photophobia, and blurring vision may also result from exposures to vapors (Dunlap et al., 1958).

McLaughlin (1952) treated six cases of eye irritation or burns and reported no permanent damage. Resolution of five cases occurred within 48 h. Absorption through the skin leads to deep muscle pain, presumably caused by spasm. Allyl alcohol and many of its esters are hepatic toxicants that cause

periportal necrosis and other liver injury in laboratory animals (Kodama and Hine, 1958; Taylor et al., 1964). Occupational exposure to allyl alcohol has not been associated with human liver toxicity.

Although allyl alcohol and its metabolite, acrolein, have been reported to be mutagenic in some assays (Smith et al., 1990), their carcinogenicity has not been established.

Chronic Effects

There have been no signs or symptoms of chronic allyl alcohol exposure reported in the literature.

Mechanism of Action(s)

The metabolism of allyl alcohol to acrolein has been demonstrated in rat liver and may be the cause of hepatotoxicity (Reid, 1972; Patel et al., 1983). The hepatotoxicity of allyl alcohol is apparently dependent on glutathione depletion, followed by lipid peroxidation, which produces free radicals and subsequent liver damage (Pompella et al., 1988; Maellaro et al., 1990). Reports of human organ damage are not available in the literature.

SOURCES OF EXPOSURE

Occupational

Inhalation and dermal exposure where allyl alcohol is produced or used are the main occupation exposures.

Environmental

There are no data on environmental exposures of allyl alcohol as it does not occur naturally.

INDUSTRIAL HYGIENE

Allyl alcohol can be produced from a dehydration and reduction reaction of glycerol. The most likely route of an occupational exposure is inhalation, though dermal contact is also considered an occupational hazard. When allyl alcohol is used in an open system, exhaust ventilation is essential and cleanup of spills requires the use of personal protective equipment. The strong odor of allyl alcohol is a good warning for workers about a potential exposure. Ruth (1986) reported an odor threshold of 1.95 mg/m³ (800 parts per billion (ppb)), well below the allowable workplace levels, which are in the order of ppm. The irritation concentration is 12.5 mg/m³ (5 ppm). Workers experiencing eye and nose irritation produced by allyl alcohol would be alerted to possible overexposure and would be able to exit a hazardous environment.

High air concentrations will be highly irritating to the skin, eyes, and respiratory system.

Allyl alcohol can be absorbed through the skin in lethal amounts. Dermal protection should be worn. Butyl rubber, Viton®, and Teflon® have been tested against permeation by allyl alcohol and demonstrated acceptable protection for more than 8 h. Safety glasses, goggles, or face shields should be worn during operations in which allyl alcohol might contact the eyes (Anon, 1996).

MEDICAL MANAGEMENT

Tissue destruction and blindness may result from an exposure to the eye area. The eyes should be flushed gently with large amounts of water. If there is dermal exposure, severe burns, skin corrosion, and absorption of lethal amounts may result. The skin should be washed with soap and water if the skin is intact, or just water if the skin is not intact. For an exposure by ingestion, do not induce vomiting.

METHANOL

First aid: See text

Target organ(s): CNS, ocular

Occupational exposure limits: OSHA PEL 200 ppm (260 mg/m³), NIOSH TWA 200 ppm (260 mg/m³), 250 ppm (325 mg/m³ skin)

Reference values: RfD 0.5 mg/kg/day reference concentration (RfC) (inhalation) 298 mg/m³

Hazard statements: H225—highly flammable liquid and vapor; H331—toxic if inhaled; H311—toxic in contact with skin; H301—toxic if swallowed; H370—causes damage to organs <or state all organs affected, if known> <state route of exposure if it is conclusively proved that no other routes of exposure cause the hazard>. Additional text: Target organs: Optic nerve (nervus opticus), CNS

Precautionary statements: P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking; P233—keep container tightly closed; P240—ground/bond container and receiving equipment; P241—use explosion-proof electrical/ventilating/lighting/ . . . /equipment; P242—use only non-sparking tools; P243—take precautionary measures against static discharge; P260—do not breathe dust/fume/gas/mist/vapors/spray; P261—avoid breathing dust/fume/gas/mist/vapors/spray; P264—wash . . . thoroughly after handling; P270—do not eat, drink, or smoke when using this product; P271—use only outdoors or in a well-ventilated area; P280—wear protective gloves/protective clothing/eye protection/face protection; P301 + P310—if swallowed, immediately call a poison center or doctor/physician; P302 + P352—if on skin, wash with plenty of soap and water; P303 + P361 + P353—if on skin (or hair), remove/take off immediately all contaminated clothing. Rinse skin with water/shower; P304 + P340—if inhaled, remove the victim to fresh air and make him rest in a position comfortable for breathing; P308—if exposed or concerned, +P311—call a poison center or doctor/physician, +P312—call a poison center or doctor/physician if you feel unwell; P321—specific treatment (see . . . on label); P330—rinse mouth; P361—remove/take off immediately all contaminated clothing; P370 + P378—in case of fire, use . . . for extinction;

P403 + P235—store in well-ventilated place. Keep cool; P405—store locked up; P501—dispose of contents/container to . . . hazardous or special waste collection point.

Risk phrases: R11—highly flammable; R23/24/25—toxic by inhalation, in contact with skin, and if swallowed; R39/23/24/25—toxic: danger of very serious irreversible effects through inhalation, in contact with skin, and if swallowed.

Safety phrases: S1/2—keep locked up and out of reach of children; S7—keep container tightly closed; S16—keep away from sources of ignition . . . no smoking; S36/37—wear suitable protective clothing and gloves; S45—in case of accident or if you feel unwell, see medical advice immediately (show label where possible)

BACKGROUND AND USES

Methanol (symbol CH₃OH; methyl alcohol; wood alcohol; CASRN 67-56-1) is used extensively as a solvent for lacquers, paints, varnishes, cements, inks, dyes, plastics, and various industrial coatings. Large quantities are used in the production of formaldehyde and other chemical derivatives such as acetic acid, methyl halides and terephthalate, methyl methacrylate, and methylamines. Methanol is also used as a gasoline additive, as a component of lacquer thinners, in antifreeze preparations of the “nonpermanent” type, and in canned heating preparations of jellied alcohol. It is also used in duplicating fluid, in paint removers, and as a cleaning agent. The potential for methanol as a future alternative for gasoline indicates that the use of this chemical will most likely increase rather than decrease. At room temperature, methanol is a colorless liquid with a pungent odor. It is relatively volatile, with a vapor pressure of 96 mmHg and a vapor density of 1.11. It is miscible with water and soluble with other organic solvents. It is found in nature as a fermentation product of wood and as a constituent of some fruits and vegetables. Some endogenous metabolic reactions, such as a methyltransferase enzyme system, result in methanol formation. Aspartame, an artificial sweetener, may form up to 10% methanol by weight in the gut (Kavet and Nauss, 1990). In the past, methanol was produced from the distillation of wood, leaving a mixture with some additives that made consumption distasteful. Most of the methanol produced in the United States is now prepared synthetically by the reduction of carbon monoxide with hydrogen.

PHYSICAL AND CHEMICAL PROPERTIES

Methanol (CASRN 67-56-1) is a clear, colorless liquid with a characteristic pungent odor (NTP NIEHS web

accessed 2/16/2013). Methanol has a molecular weight of 32.04 g/mol and a boiling point of 79 °C. The air odor threshold has been reported as 1500 ppm (approximately 2000 mg/m³), much higher than the occupational guidelines.

MAMMALIAN TOXICOLOGY

Acute Effects

The most important routes of occupational exposure are inhalation and dermal contact. Accidental or intentional ingestion is also of some concern. Nearly all of the information on methanol toxicity in humans is from acute exposures. Cases of intoxication following oral consumption are the most frequently reported. The minimal lethal dose in humans has not been determined, but it has been suggested that ingestion of about 1 g/kg can cause death if the patient is untreated. Ingestion of methanol causes ataxia, drowsiness, dysarthria, and nystagmus within 30 min, followed by a latent period of 12–24 h before metabolic toxicity becomes apparent. Severe metabolic acidosis occurs after the latent period. Symptoms include nausea, vomiting, and headache. Ocular toxicity generally develops 12–48 h after ingestion. Blurring of the vision, occasionally with changes in color perception and scotomata, and constriction of visual fields also typically develop suddenly with little warning. Poor prognosis includes convulsions, coma, shock, persistent acidosis, bradycardia, and renal failure.

Acute exposures to high concentrations of methanol vapors have been reported to cause primarily headache, dizziness, and nausea (Frederick et al., 1984). Two firefighters exposed to concentrations of vaporized methanol complained only of mild headache, although the exposure concentrations were unknown (Aufderheide et al., 1993). Downie et al. (1992) reported effects in a worker involved in cleaning a methanol tank wearing a respirator but no protective clothing. After a few hours of continuous dermal contact, visual symptoms similar to ingestion exposures were noted. The systemic toxicity of methanol is similar regardless of the route of exposure. The effects of high levels of exposure by inhalation or dermal contact resemble the effects of low level exposure by ingestion.

Chronic Effects

The effects of chronic methanol exposure are not well characterized, as few epidemiological studies have been reported. Information suggests that prolonged exposure to methanol may have similar effects as high concentrations in an acute exposure (Kavet and Nauss, 1990). A series of case reports published by Wood and Buller (1904) and

Zeigler (1921) examined chronic occupational and nonoccupational inhalation, as well as dermal and ingestion exposure to methanol. Visual deterioration, headache, and nausea were commonly reported. The few epidemiological reports by Tyson (1912) and Frederick et al. (1984) revealed similar health effects in chronically exposed worker populations. These investigations revealed no association between the cancer mortality and methanol exposure. One case report linked chronic methanol exposure to multiple sclerosis-like symptoms, and autopsy revealed plaques and lesions of the CNS similar to this disease (Henzi, 1984). There have been no significant findings in animal and human studies of developmental or teratogenic effects in populations exposed to concentrations allowable in the workplace. Lee et al. (1992) have shown in humans that the PEL of 200 ppm does not produce formate accumulation endogenously and therefore does not produce toxicity.

Mechanism of Action(s)

The metabolic pathway and subsequent mechanism of toxicity of methanol in humans have been identified as a series of stepwise oxidation reactions, first to formaldehyde and then to formic acid (Roe, 1943). Methanol oxidation to formaldehyde is catalyzed by alcohol dehydrogenase, a zinc metal enzyme, which oxidizes other alcohols as well (Li and Vallee, 1969). The formic acid formed in humans must be oxidized to carbon dioxide to prevent toxicity. The enzyme responsible for this conversion is hepatic tetrahydrofolate (THF). Tetrahydrofolate is found in lower concentrations in human and nonhuman primates than in rodent species, indicating this deficiency as the cause for the toxicity differences noted between species. Johlin et al. (1987) reported two possible mechanisms for formic acid accumulation in primates, including low THF levels (up to 50% less in primates) and reduced activity of 10-formyltetrahydrofolate dehydrogenase.

Martin-Amat et al. (1978) described the accumulation of formate as the cause of the ocular injury associated with methanol. More recent reports have indicated the Müller cell as the primary target for ocular toxicity in folate-deficient rats (Garner et al., 1995). Similar animal studies have indicated direct retinal damage as the primary effect in acute methanol exposures resulting from formic acid accumulation (Murray et al., 1991).

Animal studies have been conducted using methanol vapor. Inhalation studies with rodents at high concentrations indicate a narcotic effect with methanol similar to other organic solvents but no severe, overt pathological changes systemically or locally in the lung (White et al., 1983; Andrews et al., 1987; Poon et al., 1995; Stanton et al., 1995). Nonhuman primate models have provided more valuable data for identifying methanol hazards. Andrews et al. (1987) exposed

cynomolgus monkeys to methanol vapor at up to 5000 ppm and did not identify specific target organ effects.

Chemical Pathology

Blood and urine samples should be collected for methanol and formic acid determination. Quantitation can be performed by colorimetry or gas chromatography. Normal blood concentration of methanol derived from endogenous production and dietary sources are in the range of 2–30 mg/l. (Baselt, 1982).

SOURCES OF EXPOSURE

Occupational

The most important routes of occupational exposures are inhalation and dermal contact. Accidental ingestion of methanol is also of some concern. The absorption and distribution of methanol by any of these routes occur rapidly.

Environmental

Reese and Kimbrough (1993) indicated a higher incidence of vapor exposure from vehicle-specific emissions as methanol replaces conventional gasoline. Exposures in parking garages, traffic, and at service stations during refueling may present significant inhalation exposures.

INDUSTRIAL HYGIENE

Proper ventilation and protective equipment should be worn when worker exposure is likely to exceed RELs. Frederick et al. (1984) demonstrated the effectiveness of simple exhaust and ventilation engineering controls in decreasing airborne concentrations of methanol near duplicating machines up to 96%. These airborne concentrations of methanol can be monitored using a personal diffusive sampler designed for formaldehyde with an absorbent matrix of water (Kawai et al., 1990).

Unlike many other solvents, concentrations likely encountered in the workplace may not be easily detected by the average worker. Scherberger et al. (1958) found that the average minimum identifiable odor level for methanol was 1500 ppm (roughly 2000 mg/m³), much higher than the occupational guidelines. Protective gloves and clothing should be worn when a dermal contact is probable. Proper labeling and awareness of ingestion hazards should be sufficient to avoid an accidental methanol intake. This alcohol is designated by the National Institute for Occupational Safety and Health (NIOSH, 1994) as a Class IB flammable compound.

MEDICAL MANAGEMENT

Acute methanol ingestion is likely to be life threatening at high concentrations and should be treated immediately. Methanol has similar CNS depressant effects as ethanol and produces the same euphoria and light-headedness. Because the metabolic acidosis and eye injury resulting from methanol poisoning are related to the metabolites of methanol rather than to the alcohol itself, treatment of methanol intoxication attempts to impair this enzymatic metabolism. Ethanol can compete with methanol for active sites of this enzyme, and in fact the enzyme has a greater affinity for the former than the latter. Consequently, the therapeutic administration of ethanol permits it to be preferentially oxidized and diminishes the production of methanol metabolites. Roe (1943) suggested that sufficient ethanol must be administered to produce a blood level of at least 0.1%. The efficacy of ethanol treatment for methanol intoxication was reported by Bergeron and Cardinal (1982).

In cases of methanol intoxication, the pupils may be dilated and unreactive. Visual loss is associated with hyperemia of the optic disc, and blurring warns of at least some degree of permanent loss of vision. Atrophy of the disc is observed in some 30–60 days after excessive exposure. Pathological changes noted in fatal cases of methanol ingestion were primarily edema, hyperemia, and necrosis of the stomach, intestines, brain, and retinas (Menne, 1938).

Control of acidosis is essential in the treatment of methanol poisoning. The use of intravenous sodium bicarbonate when blood pH drops below 7.2 is recommended and has frequently been lifesaving. The value of hemodialysis or peritoneal dialysis has been emphasized (Cowen, 1964; Keyvan-Larijarni and Tannenberg, 1974). The availability of one or the other form of dialysis and of rapid determinations of blood methanol levels and acid-base balance has dramatically improved the prognosis of methanol intoxication.

Computed tomography of the skull can be helpful in the diagnosis by demonstrating symmetrical areas of low attenuation in the putamens (Aquilonius et al., 1978; McLean et al., 1980).

Occupational exposure limits: OSHA PEL: 1000 ppm (1900 mg/m³), 15 min STEL: 1000 ppm; NIOSH 10-h YWA: 1000 ppm, IDLH: 3300 ppm

Reference values: RfD 0.67 mg/kg-bw/day (proposed)

Hazard statements: H225—highly flammable liquid and vapor; H319—causes serious eye irritation ($\geq 50\%$)

Precautionary statements: P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking; P233—keep container tightly closed; P240—ground/bond container and receiving equipment; P241—use explosion-proof electrical/ventilating/lighting/ . . . /equipment; P242—use only non-sparking tools; P243—take precautionary measures against static discharge; P264—wash . . . thoroughly after handling. Additional text: Hands; P280—wear protective gloves/protective clothing/eye protection/face protection; P370 + P378—in case of fire, use . . . for extinction. Additional text: Dry chemical, alcohol foam, all-purpose AFFF, carbon dioxide, or water spray; P305 + P351 + P338—if in eyes, rinse cautiously with water for several minutes. Remove contact lenses, if present and easy to do. Continue rinsing; P337 + P313—if eye irritation persists, get medical advice/attention; P403 + P235—store in well-ventilated place. Keep cool; P405—store locked up; P501—dispose of contents/container to . . . hazardous or special waste collection point

Risk phrase: R11—highly flammable

Safety phrases: S2—keep out of the reach of children; S7—keep container tightly closed; S16—keep away from sources of ignition . . . no smoking

BACKGROUND AND USES

Ethanol (C₂H₅OH; ethyl alcohol; CASRN 64-17-5) used in industry is synthesized almost entirely by the hydration of ethylene. It is used as a starting material for the synthesis of a wide variety of organic compounds used in industry and is second only to water as an industrial solvent. Beverage alcohol is derived from the fermentation of carbohydrates, and the supply for this purpose is not augmented by synthetic ethanol.

PHYSICAL AND CHEMICAL PROPERTIES

At room temperature, ethanol is a clear, colorless, volatile liquid with an odor similar to that of wine and whiskey. It is volatile, with a vapor pressure of 59.3 mmHg at 25 °C, and is miscible with water and other organic solvents.

MAMMALIAN TOXICOLOGY

Acute Effects

Although exposure to ethanol is common, it is not of great importance as an industrial hazard. Most of the literature on ethanol toxicity is concerned with the consumption of alcoholic beverages. High inhalation exposures to ethanol may cause dizziness, headache, and drowsiness. At high concentrations of ethanol vapor, there may be some irritation of the upper respiratory system, including coughing and dryness of the throat, but no permanent damage. Irritation of the eye in response to ethanol vapors or liquid may occur as well. Contact allergic reactions have been reported, but these were neither occupational exposures nor identified as significantly irritating (Fregert et al., 1969; Phillips et al., 1972; van Ketel and Tan-Lim, 1975).

Lester and Greenberg (1951) computed the absorption via the respiratory tract that would be necessary to cause any continuous increase in blood ethanol levels. They concluded that a workman exposed to 1000 ppm would have to breathe at a rate of 65 l/min. This more than doubles the ventilation rate of 30 l/min associated with hard work; thus, the hazard of systemic effects from airborne ethanol is unlikely. At air concentrations of 5000–10,000 ppm, there may be mild transient coughing or eye irritation. Concentrations of 20,000 ppm are intolerable. Workers sometimes drink ethanol, on hand

for manufacturing or other nonbeverage purposes, a practice that adds to the total dose absorbed and increases susceptibility to accidents. Ethanol absorption, regardless of the route of administration, induces hepatic enzymes and has been known to contribute to the toxicities of some chemicals. Coexposures to trichloroethylene, carbon tetrachloride, vinyl chloride, and in workers taking prescription drugs such as disulfiram have been the subject of some discussion of ethanol potentiation (Hills and Venable, 1982; Wilcosky and Simonsen, 1991).

Chronic Effects

Reports of chronic exposures to ethanol in the workplace have not shown an association with any adverse health effect. Specific links to ethanol exposure would be extremely difficult to establish considering the high prevalence of recreational ethanol consumption among the general population. Teta et al. (1992) studied a population of an ethanol production facility. Although small excesses in some cancers were noted, the process of ethanol production and not ethanol itself was examined. An occupational study by Wilcosky and Tyroler (1983) found a modest excess of ischemic heart disease associated with ethanol exposure.

Human epidemiological studies and maternal animal studies have not found any association between the inhalation of ethanol vapors and abnormal fetal development. Chronic ingestion of ethanol in alcoholic beverages by pregnant women has been definitively associated with developmental abnormalities collectively termed fetal alcohol syndrome. However, occupational exposures to ethanol are not of the same magnitude as those required for teratogenicity.

Mechanism of Action(s)

Regardless of the exposure route, ethanol is metabolized primarily in the liver. It is first oxidized to acetaldehyde by the hepatic enzyme alcohol dehydrogenase. The product acetaldehyde is quickly broken down by aldehyde dehydrogenase to acetate. This product is excreted from the body via exhalation and urinary discharge. Genetic variability creates interindividual differences in ethanol metabolism. Certain populations lack adequate aldehyde dehydrogenase activity and may experience a buildup of acetaldehyde. This is especially prevalent in Asian populations and accounts for the low tolerance and reddening or flushing of the face after consumption. Some unchanged ethanol can be detected in the urine and blood, but occupational exposures are likely not to be high enough to significantly change these concentrations from baseline levels.

SOURCES OF EXPOSURE

Occupational

The primary routes of an occupational exposure to ethanol are inhalation and dermal contact. Accidental ingestion of ethanol can occur, but it is usually not reported to be fatal. Inhalation exposure to vapors can be minimized with simple engineering controls. Vapor generation can be detected at many levels of ethanol use, from production to its use as a glaze in confections (Wadden et al., 1994). Monitoring of airborne concentrations of ethanol in the workplace is successfully completed with standard protocols (Langvardt and Melcher, 1979; Mueller and Miller, 1979).

INDUSTRIAL HYGIENE

Dermal contact is of concern when exposure time is lengthy and can be minimized with gloves. The glove material must be evaluated because some rubbers, such as neoprene, have longer breakthrough times than others. Ethanol is used as a hand cleanser in some instances, and a short-term exposure is not associated with adverse effects. The strong odor of ethanol is a good warning property. Ruth (1986) reported an odor threshold of 0.342 mg/m^3 for ethanol, with an irritation concentration of 9500 mg/m^3 (4950 ppm). Although some tolerance for ethanol is expected, reports of inhalation overexposures are infrequent. Because of its flammability, ethanol should be shielded from open flames and conditions where ignition is possible (i.e., reactive chemicals and high temperatures). NIOSH (1994), OSHA, and the ACGIH (1996) have set their respective exposure limits and TLVs for ethanol at 1000 ppm. The ACGIH has also designated ethanol with an A4 classification, not classifiable as to its carcinogenicity.

PROPANOL

First aid: Inhalation: Keep patient calm, remove to fresh air, seek medical attention. Skin: Wash thoroughly with soap and water. Eyes: Immediately wash affected eyes for at least 15 min under running water with eyelids held open, consult an eye specialist. Ingestion: Rinse mouth immediately and then drink plenty of water, seek medical attention.

Occupational exposure limits: DNEL; DNEL inhalation, systemic effects, long term: 268 mg/m³; DNEL inhalation, systemic effects, short term: 1723 mg/m³; DNEL dermal, systemic effects, long term: 136 mg/m³

Reference values: DNEL inhalation, systemic effects, long term: 80 mg/m³; DNEL inhalation, systemic effects, short term: 1036 mg/m³; DNEL dermal, systemic effects, long term: 81 mg/kg-bw/day; DNEL oral, systemic effects, long term: 61 mg/kg-bw/day

Hazard statements: H225—highly flammable liquid and vapor; H318—causes serious eye damage; H336—may cause drowsiness or dizziness

Risk phrases: R11—highly flammable; R41—risk of serious damage to eyes; R67—vapors may cause drowsiness and dizziness

Safety phrases: S7—keep container tightly closed; S16—keep away from sources of ignition . . . no smoking; S24—avoid contact with skin; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S39—wear eye/face protection

BACKGROUND AND USES

The propanols are a minor toxicological hazard in industry. Propanol is more toxic to humans than ethanol, probably because of its slower metabolism. The main route of exposure for both alcohols is inhalation and dermal contact, and both are widely used in industry as well as in household products.

PHYSICAL AND CHEMICAL PROPERTIES

Propanol (n-propyl alcohol; CASRN 71-23-8) is a clear, colorless liquid with an odor resembling ethanol. It is primarily used as a specialty solvent in applications such as printing ink and polymer production. It is miscible with water and has a vapor pressure of 15 mmHg at room temperature and a vapor density of 2.1. It occurs naturally in animal wastes and as a product of volcanoes.

MAMMALIAN TOXICOLOGY

Acute Effects

The hazards associated with this compound are low. Propanol produces some effects similar to ethanol on ingestion or inhalation of high concentrations. The concentrations expected in the workplace are unlikely to be high enough to cause any harmful effects. Dermal contact with propanol may have a drying effect on the skin after chronic exposure, but it is not associated with systemic toxicity. There have been no reports of carcinogenicity or teratogenicity among populations exposed to this chemical.

Nelson et al. (1989) reported maternal toxicity and a low incidence of teratogenicity in laboratory animals associated with inhalation of propanol vapors. However, the level required to produce minimal toxicity was 7000 ppm, far above what would be expected in the workplace. The esterification of some fatty acids was observed in rats after administration of propanol (Carlson, 1993). Animal studies have not associated any carcinogenic effects with propanol exposure.

Chronic Effects

There are no studies of chronic effects in humans.

Mechanism of Action(s)

Once absorbed, propanol is oxidized to propionic acid and excreted (Kamil et al., 1953). The intermediate step in this pathway is the conversion of propanol to propanaldehyde by alcohol dehydrogenase.

INDUSTRIAL HYGIENE

Propylene oxide undergoes a hydrogenation reaction over nickel to produce propanaldehyde, which is subsequently reduced to propanol. The odor of this compound can be detected at concentrations as low as 30 ppm (75 mg/m^3) (Ruth, 1986), alarming workers of potential overexposures. This compound is flammable and may react with strong oxidizers, such as tertbutoxide to form an explosive mixture. Protective clothing and adequate ventilation are recommended to protect from overexposures.

The NIOSH (1994), OSHA, and ACGIH (1996) have set their respective REL, PEL, and TLV for propanol at 200 ppm (500 mg/m^3) with a STEL/ceiling of 250 ppm (625 mg/m^3).

BACKGROUND AND USES

Isopropanol (isopropyl alcohol; CASRN 67-63-0) is a commonly used industrial solvent and the main ingredient in rubbing alcohol. It is a colorless liquid that is miscible with water and has a characteristic odor that is detectable

at concentrations as low as 7.84 mg/m³ (3 ppm) (Ruth, 1986).

PHYSICAL AND CHEMICAL PROPERTIES

At room temperature, this compound has a vapor pressure of 44 mmHg and a vapor density of 2.08. Isopropanol is produced endogenously as a metabolite of other compounds and is also an indirect food additive.

MAMMALIAN TOXICOLOGY

Acute Effects

The health effects associated with isopropanol are primarily the result of irritation. Inhalation overexposures may cause respiratory, eye, and mucous membrane irritation and some CNS depression. Extremely high concentrations may cause dizziness, nausea, hypotension, and hypothermia. A rare instance of allergic sensitivity to isopropanol was encountered in a cosmetic patch testing program (Ludwig and Hausen, 1977). Ito et al. (1979) described a case of polyneuropathy caused by a mixture of organic solvents, the main ingredient being isopropanol. Similar to ethanol, isopropanol stimulates the mixed function oxidase system of the liver and therefore may alter the toxicity of other industrial compounds, such as carbon tetrachloride (Ueng et al., 1983). Concomitant exposures to other chemicals should be evaluated in an environment where the potential for isopropanol exposure exists.

The low toxicity associated with isopropanol has been demonstrated in animals as well. Acute toxicity studies have reported some neurotoxicity and a kidney change but only at extremely high concentrations (Teramoto et al., 1993; Burleigh-Flayer et al., 1994; Gill et al., 1995). Developmental and mutagenic studies have not found any adverse effects associated with isopropanol exposure (Kapp et al., 1993; Tyl et al., 1994).

Chronic Effects

Chronic dermal contact with isopropanol has a drying effect on the skin. No other long-term effects have been found in the literature.

Mechanism of Action

Isopropanol has been found to be quickly metabolized to acetone once it is absorbed (Laham et al., 1980). Acetone is excreted in the urine and exhaled in the breath. Alveolar isopropanol concentrations and acetone levels in the blood

and urine have been correlated with workplace concentrations (Brugnone et al., 1983).

INDUSTRIAL HYGIENE

Starting with propylene, production of isopropanol may be accomplished with a strong acid (H₃SO₄), weak acid, or nonacid process. Historically, the strong acid process was favored in the past. More recently, some health effects associated with this process have encouraged the use of other processes. Airborne concentrations of this chemical can be monitored with charcoal desorption tubes and gas chromatography (Langvardt and Melcher, 1979; Mueller and Miller, 1979). When overexposures are likely, protective gear, including an air-purifying respirator with a full face piece and protective clothing, should be worn. This compound is designated a Class IB flammable liquid, indicating caution in areas of open flames and other possible ignition sources. The ACGIH (1996) and NIOSH (1994) have set their TLBA and REL at identical values of 400 ppm (980 mg/m³) with a 15-minute STEL of 500 ppm (1225 mg/m³). ASHA has set a similar PEL at 400 mg/m³.

n-BUTANOL

Target organ(s): Eyes, CNS

Occupational exposure limits: 20 ppm (ACGIH TLV); 100 ppm (OSHA PEL); 50 ppm (OSHA ceiling); 50 ppm (NIOSH ceiling)

Reference Values: RfD 1×10^{-1} mg/kg-bw/day

Hazard statements: H226—flammable liquid and vapor; H302—harmful if swallowed; H335—may cause respiratory irritation; H315—causes skin irritation; H318—causes serious eye damage; H336—may cause drowsiness or dizziness

Precautionary statements: P210—keep away from heat/sparks/open flames/ . . . /hot surfaces . . . no smoking; P233—keep container tightly closed; P240—ground/bond container and receiving equipment; P241—use explosive-proof electrical/ventilating/lighting/ . . . /equipment; P242—take precautionary measures against static discharge; P280—wear protective gloves/protective clothing/eye protection/face protection; P303 + P361 + P353—if on skin (or hair), remove/take off immediately all contaminated clothing. Rinse skin with water/shower; P370 + P378—in case of fire, use . . . for extinction; P403 + P235—store in a well-ventilated place. Keep cool; P501—dispose of contents/container to . . .

Risk phrases: R11—highly flammable; R22—harmful if swallowed; R37/38—irritating to the respiratory system and skin; R41—risk of serious damage to eyes; R67—vapors may cause drowsiness and dizziness

Safety phrases: S2—keep out of the reach of children; S7/9—keep container tightly closed and in a well-ventilated place; S13—keep away from food, drink, and animal feeding stuff; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S37/39—wear suitable gloves and eye/face protection; S46—if swallowed, seek medical advice immediately and show the container or label

BACKGROUND AND USES

Of the butanols, *n*-butanol (*n*-butyl alcohol; CASRN 71-36-3) is the most important in industries and the most extensively studied. *n*-Butanol is a colorless liquid with a strong, mildly alcoholic odor. It is used in chemical derivatives and as a solvent for paints, waxes, brake fluid, and cleaners.

PHYSICAL AND CHEMICAL PROPERTIES

At room temperature, *n*-butanol has a vapor pressure of 6 mmHg and vapor density of 2.6. *n*-Butanol is soluble in water 9% by weight and is a Class IC flammable liquid. Naturally occurring sources of this alcohol include peppermint oil, some teas, and apple aromas.

MAMMALIAN TOXICOLOGY

Acute Effects

Eye irritation, with corneal inflammation, burning sensation, lacrimation, photophobia, and blurred vision, was reported in workers exposed to 200 ppm or more of *n*-butanol (Sterner et al., 1949). This study followed *n*-butanol exposure in a population of workers for 10 years and found no systemic effects with exposures below 100 ppm. Dermatitis of hands and fingers was reported by Tabershaw et al. (1994) but could not be prevented by protective ointments. The apparently specific formation of minute vacuoles in the cornea has been observed in workers coating raincoats with material containing this solvent (Cogan and Grant, 1945). Vacuolar keratopathy was reported to be most significant in the morning immediately upon opening the eyes after waking up. The other butyl alcohols have similar irritative properties.

Animal studies have also demonstrated the low toxicity of *n*-butanol. Wallgren (1960) showed that of the alcohols, the butanols appeared to be the most intoxicating to rats. Of those tested, *n*-butanol was found to be excreted quicker than most but exhibited its intoxicating effects the fastest. Similar to other short-chain aliphatic alcohols, *n*-butanol was not found to be maternally toxic at high concentrations (6000 ppm) and did not produce teratogenicity (Nelson et al., 1989).

Carlson (1994) reported the ability of *n*-butanol to esterify fatty acids in experimental animals.

Chronic Effects

n-Butanol has not been associated with any chronic effects and is not considered classifiable as to its carcinogenicity.

Mechanism of Action(s)

The metabolic pathway for *n*-butanol is similar to other alcohols. First, it is oxidized to its aldehyde via alcohol dehydrogenase. Further oxidation yields butyric acid, which is broken down further and excreted mostly as carbon dioxide and water.

SOURCES OF EXPOSURE

Occupational

In occupations where *n*-butanol is synthesized or used, there is a potential for exposure. The primary routes of exposure to workers are inhalation and dermal contact.

Environmental

No known environmental exposure has been found in the literature.

INDUSTRIAL HYGIENE

n-Butanol may be synthesized from ethanol or acetaldehyde. Inhalation and dermal contact are the primary routes of worker exposure. The odor detection limit for this compound is low, reported at 0.36 mg/m³ (Ruth, 1986). Workers coming into contact with *n*-butanol should be provided with protective clothing, including gloves, goggles, and boots and, if necessary, personal respirators with face masks. NIOSH (1994) and the ACGIH (1996) have set similar ceiling values at 50 ppm (150 mg/m³). OSHA has a less stringent PE for *n*-butanol of 100 ppm (200 mg/m³).

MEDICAL MANAGEMENT

Anyone exposed to vapors should be removed from the area. Symptoms of overexposure usually disappear when the exposure is removed.

PROPYLENE GLYCOL

Occupational exposure limits: DNEL; DNEL inhalation, systemic effects, long term: 168 mg/m³; DNEL inhalation, local effects, long term: 10 mg/m³

Reference values: DNEL inhalation, systemic effects, long term: 50 mg/m³; DNEL inhalation, local effects, long term: 10 mg/m³

Hazard statement: None

Precautionary statement: None

Risk phrase: None

Safety phrase: None

BACKGROUND AND USES

Propylene glycol is used for similar applications as other glycols. It is also used in cosmetics and as a heat transfer fluid in solar energy applications (Marshall et al., 1981; Gupta et al., 1987).

PHYSICAL AND CHEMICAL PROPERTIES

Propylene glycol (1,2-dihydropropane; CASRN 57-55-6) is an odorless, colorless, and tasteless liquid. It has a vapor

pressure of 0.129 mmHg at 25 °C (77 °F) and is soluble in water and alcohol.

MAMMALIAN TOXICOLOGY

Acute Effects

In one study, rats were exposed to 0.1–2.2 mg/l propylene glycol for 90 days by inhalation (nose only) (Suber et al., 1989). Researchers reported significant differences in some hematological parameters, enzyme activities, and organ weights, but these findings did not reveal a clear dose-response relationship. Another study found that the activity of human natural killer cells was depressed when they were exposed to propylene glycol *in vitro* (Denning and Webster, 1987). Female rats fed dietary levels of propylene glycol up to 2.5 g/kg/day did not have any apparent adverse effects (Gaunt et al., 1972).

Irritant and allergic skin reactions have been associated with propylene glycol exposure (Hannuksela et al., 1975). Propylene glycol may produce effects similar to other glycols at extremely high levels of exposure. In cases of acute exposure, gas chromatography may be used to measure propylene glycol serum and blood levels to confirm a diagnosis and monitor the patients (Houze et al., 1993).

Chronic Effects

No chronic effects of propylene glycol exposure are found in the literature.

Mechanism of Action(s)

Propylene glycol is metabolized by alcohol and aldehyde dehydrogenases to lactaldehyde and then lactic acid (Anonymous, 1994).

INDUSTRIAL HYGIENE

There are no exposure limits or TLVs for propylene glycol from OSHA, NIOSH, or the ACGIH.

ETHYLENE GLYCOL

Target organ(s): CNS, renal

Occupational exposure limits: ACGIH 100 mg/m³ aerosol; DNEL; DNEL inhalation, local effects, long term: 35 mg/m³; DNEL dermal, systemic effects, long term: 106 mg/kg-bw/day;

Reference values: DNEL inhalation, local effects, long term: 7 mg/m³; DNEL dermal, systemic effects, long term: 53 mg/m³

Hazard statements: H302—harmful if swallowed; H373—may cause damage to organs such as kidneys through prolonged or repeated oral exposure

Risk phrase: R48/22—harmful: danger of serious damage to health by prolonged exposure if swallowed

Safety phrases: S2—keep out of the reach of children; S45—in case of accident or if you feel unwell, seek medical advice immediately (show label where possible)

BACKGROUND AND USES

Ethylene glycol (1,2-ethanediol; glycol alcohol; CASRN 107-21-1) is a colorless, odorless, clear, syrupy liquid. It has a vapor pressure of 0.06 mmHg at room temperature and is miscible in water. The most common and well-known use of ethylene glycol is as an antifreeze in automobiles. It is also widely used in other cooling and heating systems, in hydraulic brake fluids, in electrolytic condensers, as a solvent in paint and plastics, and in many types of inks.

MAMMALIAN TOXICOLOGY

Acute Effects

An accidental or intentional consumption of ethylene glycol is the most common form of an acute overexposure. The first signs and symptoms are associated with CNS depression. They may include ataxia, prostration, cyanosis, stupor, convulsions progressing to coma, and death (Winek et al., 1978). In serious poisonings, CNS depression typically progresses to cardiovascular symptoms and then renal failure over 48 h. The mean lethal dose for an adult has been estimated at about 100 ml (Milles, 1946).

In the first hours after an exposure, up to 1/5th of ethylene glycol may be excreted unchanged. Most is metabolized by alcohol dehydrogenase to glycol aldehyde. Glycol aldehyde is oxidized by aldehyde dehydrogenase to glycolic and glyoxylic acid. Glyoxylic acid is metabolized to oxalic acid. Unmetabolized ethylene glycol is responsible for CNS depression, whereas oxalic acid is the cause of renal toxicity. However, recent studies indicate that metabolites other than oxalic acid contribute to renal toxicity.

The developmental toxicity of ethylene glycol in animal assays differs drastically with the route of exposure. Studies of rats and mice exposed orally have supported the conclusion that ethylene glycol may cause developmental abnormalities (Marr et al., 1992). Nepper-Bradley et al. (1995) established the no observable effect level (NOEL) for developmental effects at 500 mg/kg/day in CD rats and 150 mg/kg/day in CD-1 mice dosed with ethylene glycol via gavage. However, another study of ethylene glycol's developmental toxicity in CD-1 mice concluded that dermal doses of up to 3549 mg/kg did not cause maternal or developmental effects (Tyl et al., 1995c). A third study by Tyl et al. (1995a) investigated the developmental effects of ethylene glycol aerosol in CD-1 mice exposed by nose-only. This study found a NOEL for developmental toxicity (including teratogenicity) of 1000 mg/m³ and a NOEL for maternal toxicity of 500 mg/m³. Whole-body exposure of CD-1 mice and CD rats to ethylene glycol aerosol greatly modified the NOEL (Tyl et al., 1995b). The NOEL for maternal toxicity and developmental toxicity in mice was reduced to 150 mg/m³. The NOEL for rats was 1000 mg/m³ for maternal toxicity and 150 mg/m³ for developmental toxicity. The authors suggest that the differences between whole-body and nose-only NOELs could be a result of ingestion during grooming activities. Combined, these studies support the conclusion that a dermal exposure to ethylene glycol is least likely to cause developmental effects, whereas ingestion is most likely to cause adverse effects.

Animal studies indicate that developmental effects are more likely to result from one high dose exposure to ethylene

glycol than from several smaller doses (Carney, 1994). The highest peak blood level of ethylene glycol is strongly associated with the degree of the developmental toxicity. This also explains why ingestion, which would create a relatively rapid peak, is potentially more dangerous than a dermal exposure, which is characterized by slower absorption and a lower peak.

Mechanism of Action(s)

The alcohol dehydrogenase pathway has 30–40 times greater affinity for ethanol than for ethylene glycol. This is the basis for the use of ethanol as an antidote for ethylene glycol poisonings. When ethylene glycol metabolism is blocked by ethanol, ethylene glycol is excreted in the urine unchanged.

A recent study investigated the effect of ethanol on ethylene glycol metabolism using Sprague-Dawley rats as an animal model (Kukielka and Cederbaum, 1995). Microsomal preparations from rats given high levels of dietary ethanol had a much greater capacity to metabolize ethylene glycol to formaldehyde and a higher production of hydrogen peroxide. The authors concluded that this effect is most likely the result of ethanol induction of cytochrome P4502E1.

Gas chromatography may be used for determining the serum levels of glycolic acid or ethylene glycol and urine levels of ethylene glycol (Aarstad et al., 1993; Fraser and MacNeil, 1993).

INDUSTRIAL HYGIENE

Occupational injuries associated with ethylene glycol are extremely rare considering its widespread use. Skin contact is the most likely route of worker exposure. Ethylene glycol is poorly absorbed through the skin, and therefore the absorbed dose by this route is low. Inhalation of aerosols may occur, but exposure to ethylene glycol vapor is rare unless it is heated or sprayed as a mist. Ingestion is highly unlikely unless gross negligence is used in handling and labeling this compound. Ethylene glycol is not considered an eye or skin irritant.

MEDICAL MANAGEMENT

Ethanol has been used to block the metabolism of ethylene glycol. Cox et al. (1992) suggest that 1,3-butylene glycol may be a more effective antidote to ethylene glycol intoxication. 1,3-Butylene glycol is more efficient at blocking ethylene glycol metabolism than ethanol, and it is less toxic. Hemodialysis may be used to remove unmetabolized ethylene glycol. Severe acidosis may be treated with sodium bicarbonate or sodium lactate.

BACKGROUND AND USES

Ethylene chlorohydrin ($\text{CH}_2\text{Cl}-\text{CH}_2\text{-OH}$; 2-chloroethyl alcohol, CASRN 107-07-3) is used for its special solvent properties. It is a chemical intermediate in the production of ethylene glycol and, in the past, ethylene oxide. This alcohol is used in the manufacturing of insecticides and as a cleaning agent for machines. Indirect exposure can result from release as a by-product in applications involving ethylene oxide and its accumulation in some foodstuffs as a result of sterilization or packaging.

PHYSICAL AND CHEMICAL PROPERTIES

Ethylene chlorohydrin is a colorless liquid with a faint ether-like odor and is miscible with water. At room temperature, it has a vapor pressure of 5 mmHg and a vapor density of 2.78. Among the halogenated alcohols, ethylene chlorohydrin is the most prominent, along with the chloropropanols.

MAMMALIAN TOXICOLOGY

Acute Effects

Dermal contact is the most concerning route of exposure as ethylene chlorohydrin readily penetrates the skin. There is

ETHYLENE CHLOROHYDRIN

Target organ(s): Respiratory system, liver, kidneys, CNS, skin

little skin irritation with this compound, decreasing the warning potential of a skin exposure. Inhalation overexposures may produce mucous membrane irritation, but they are usually not sufficient to produce serious systemic poisoning, although there is a potential for these effects. The CNS is especially susceptible, with muscle incoordination and convulsions resulting from exposure (Goldblatt and Chiesman, 1944; Bush et al., 1949). Corneal swelling and irritation may occur upon eye exposure, but no permanent damage has been reported. A primary hazard with ethylene chlorohydrin is its rather small margin of safety. Death may occur as a result of pulmonary edema or edema of the brain. Ingestion of this compound is not likely but has been described as fatal in low doses (Miller et al., 1970).

Chronic Effects

Epidemiological studies of ethylene chlorohydrin exposure have been reported. Greenberg et al. (1990) first reported an increase in pancreatic cancer and leukemia in the chlorohydrin section of an ethylene oxide production facility. Exposure to ethylene chlorohydrin was reported, along with other chlorinated hydrocarbons that occur as by-products or are involved in asynchronous operations. An increase in some cancers, particularly pancreatic cancer and leukemia, was observed in a population of workers in an ethylene chlorohydrin facility (Benson and Teta, 1993). The authors noted that other research in addition to their own has indicated ethylene dichloride as the probable causative agent, along with other chlorinated hydrocarbon by-products.

Animal studies have not shown any associations of carcinogenicity (Allavena et al., 1992) or developmental effects with exposure to ethylene chlorohydrin.

Mechanism of Action(s)

The metabolism of ethylene chlorohydrin has not been well established in humans. Most studies indicate that ethylene chlorohydrin is metabolized to chloroacetaldehyde and chloroacetic acid, which act as inhibitors of the tricarboxylic acid cycle. Orally dosed rats have shown that most of the radiolabeled ethylene chlorohydrin is excreted as cysteine metabolites or other conjugation products of the reactive metabolites (Grunow and Altman, 1982). Alcohol dehydrogenase and glutathione are hypothesized to be important in the metabolism of ethylene chlorohydrin.

INDUSTRIAL HYGIENE

Ethylene chlorohydrin is produced upon addition of hypochlorous acid to ethylene gas. The most probable route of

exposure is via inhalation and dermal contact. This is one of the more hazardous alcohols, and caution should be taken during its use. Personal protective gear is necessary when overexposure is likely. Rubber gloves are not recommended because this alcohol can penetrate most glove materials. Adequate ventilation and respiratory protection are recommended for high vapor concentrations, as well as chemical fume hoods. Detection of ethylene chlorohydrin by capillary gas chromatography was shown to be linear (Danielson et al., 1990). Two methods for degrading ethylene chlorohydrin to its less hazardous reduction product, ethanol, are described by Lunn and Sansone (1991). This compound can react with steam and strong caustics to produce corrosive fumes, including phosgene. Engineering controls and informing workers of potentials hazards are essential when using this chemical in an industrial setting. Ethylene chlorohydrin has been given a Class IIIB combustible rating.

Skin exposure is the primary hazard associated with ethylene chlorohydrin. The ACGIH (1996) and NIOSH (1994) have both set the TLV and REL at 1 ppm (3.3 mg/m^3). The OSHA has regulated this compound less stringently, with a PEL of 5 ppm (16 mg/m^3). This compound is not classifiable as to its carcinogenicity (ACGIH, 1996).

DIETHYLENE GLYCOL

Target organ(s): Kidney

Occupational exposure limits: DNEL; DNEL inhalation, local effects, long term: 60 mg/m³; DNEL dermal, systemic effects, long term: 106 mg/kg-bw/day

Reference values: DNEL inhalation, local effects, long term: 12 mg/m³; DNEL dermal, systemic effects, long term: 53 mg/kg-bw/day

Hazard statements: H302—harmful if swallowed; H373—may cause damage to the kidneys through prolonged or repeated oral exposure

Risk phrases: R22—harmful if swallowed

Safety phrases: S2—keep out of the reach of children; S46—if swallowed, seek medical advice immediately and show the container or label.

BACKGROUND AND USES

Diethylene glycol (DEG; CASRN 111-46-6) is a colorless, odorless, syrupy liquid with a sharp sweet taste.

PHYSICAL AND CHEMICAL PROPERTIES

It has a vapor pressure of 1 mmHg at 92 °C (198 °F) and is miscible in water, alcohol, acetone, ether, and ethylene glycol. It is a condensation product of ethylene glycol production. Structurally, DEG is two ethylene glycol moieties joined by an ether linkage.

MAMMALIAN TOXICOLOGY

Acute Effects

Unfortunately, DEG has been the agent of several mass poisoning incidents. The first occurred early this century

in the United States and is sometimes referred to as the “Massingale Disaster” (Gelling and Cannon, 1938). Sulfa-nilamide, an antibacterial “elixir,” was prepared with 70% DEG and ingested. Over 100 deaths were attributed to this incident. This incident was largely responsible for the passage of the 1938 Federal Food, Drug and Cosmetic Act (Wax, 1995). More recent mass poisonings have occurred in South Africa, India, Nigeria, and Bangladesh (Okuonghae et al., 1992; Hanif et al., 1995; Wax, 1996). In many of these incidents, DEG was used in pharmaceuticals as an inexpensive substitute for the less toxic propylene glycol.

The most recent incident involved a children’s elixir of acetaminophen in Haiti (Scalzo, 1996). A locally made preparation contained imported glycerin contaminated with DEG. Eighty-six children developed a nonspecific febrile illness followed by acute renal failure (Malebranche et al., 1996). Signs and symptoms from DEG intoxication include vomiting, abdominal pain, lethargy, and malaise. Neurological symptoms, including pupil dilation, optic neuritis, and cerebral atrophy, were typically delayed (Scalzo, 1996).

Pregnant rabbits that were treated with up to 1000 mg/kg DEG on days 7 through 19 of gestation showed no statistically significant incidence of fetal abnormalities (Hellwig et al., 1995).

Mechanism of Action(s)

The mechanism of action of DEG is poorly understood. It was once presumed that DEG would first undergo cleavage of the ether bond into two ethylene glycol molecules and then be further metabolized. Although many have concluded that DEG is metabolized similarly to ethylene glycol, clinical findings do not support this conclusion. Patients with confirmed DEG poisoning have not shown oxalate formation or metabolic acidosis characteristic of ethylene glycol poisoning (Scalzo, 1996). Animal studies of DEG metabolism have found only trace amounts of oxalic acid in the urine, suggesting a different primary metabolism. Animal studies have demonstrated that up to 96% of DEG is rapidly excreted in the urine (Mathews et al., 1991; Heilmair et al., 1993). It is primarily excreted unchanged; however, studies on rats indicate that 2-hydroxyethoxyacetic acid and glycolic acid are urinary metabolites (Lenk et al., 1989). 2-Hydroxyethoxyacetic acid is a product of DEG oxidation by alcohol dehydrogenase (Wiener and Richardson, 1989).

Chemical Pathology

Pathological examination of DEG-exposed livers in human necropsy cases revealed central hydropic degeneration with ballooned hepatic cells (Scalzo, 1996). Interestingly, studies of hepatotoxic effects of DEG in rats and dogs do not show hydropic changes in livers.

INDUSTRIAL HYGIENE

Diethylene glycol is poorly absorbed through the skin and is not expected to be an inhalation hazard unless it is heated. There are no occupational exposure limits for DEG from the NIOSH, OSHA, or ACGIH.

Risk phrases: R60—may impair fertility (EGME, EGEE); R61—may cause harm to the unborn child (EGME, EGEE); R36/38—irritating to the eyes and skin (EGBE); R20/22—harmful by inhalation and if swallowed (EGEE); R20/21/22—harmful by inhalation, in contact with skin, and if swallowed (EGME, EGBE); R10—flammable (EGME, EGEE).

Safety phrases: S2—keep out of the reach of children (EGBE); S36/37—wear suitable protective clothing and gloves (EGBE); S53—avoid exposure, obtain special instructions before use (EGME, EGEE); S45—in case of accident or if you feel unwell, seek medical advice immediately (show label where possible) (EGME, EGEE); S46—if swallowed, seek medical advice immediately and show the container or label

BACKGROUND AND USES

The three main types of ethylene glycol derivatives are EGME (CASRN 109-86-4), EGEE (CASRN 110-80-5), and EGBE (CASRN 111-76-2). These compounds are important industrial cosolvents used in a variety of applications, including protective coatings, paints, varnishes, domestic and industrial cleaning agents, inks, dyes, some pesticides, and in the semiconductor industry. These glycols are entirely manufactured and are not known to occur naturally.

PHYSICAL AND CHEMICAL PROPERTIES

All three of the ethylene glycol derivatives are liquid at room temperature with mild ether-like odors. The physical

properties are similar among these compounds; as a representative example, EGBE has a vapor pressure of 0.6 mmHg, a flash point of 72 °C, a lower flammability limit of 1.1%, and an upper flammability limit of 10.6%.

MAMMALIAN TOXICOLOGY

Acute Effects

The majority of information regarding the toxicity of the monoalkyl glycols is extrapolated from animal data. Recent work has concentrated on evaluating dermal absorption, as it is the primary route of exposure. Historically, alkylated ethylene glycols were first associated with hazardous effects in the shirt collar industry in the 1930s (Greenberg et al., 1938; Parsons and Parsons, 1938). The exposures to EGME resulted in CNS depression and hemolytic anemia. Current regulations have kept workplace exposures sufficiently low to prevent these effects. Zavon (1963) reported cases of workers exposed to EGME exhibiting similar neurological effects, including drowsiness, fatigue, general malaise, and tremors. Eventual recovery was noted in all cases after cessation of the exposure. Routes of exposure in these cases were not characterized. Ohi and Wegman (1978) observed the development of encephalopathy, bone marrow injury, and pancytopenia in two cutaneously exposed workers at a textile printing plant in Massachusetts. The workers additionally developed hematological changes; both suffered bone marrow insult. More recent reports of industrial exposures of EGME have observed similar CNS and hematological effects from dermal and inhalation exposures (Cohen, 1984; Larese et al., 1992). It has also been shown to cause hemopoietic effects in rats after 4 days of oral exposure to 100–500 mg/kg (Grant et al., 1985).

Severe hemoglobinuria has been noted in rats after an exposure to EGBE (Ghanayem et al., 1987a, 1987b). Ingestion of a household product containing EGBE reportedly resulted in hemoglobinuria, metabolic acidosis, hypokalemia, elevated serum creatinine levels, and increased urinary excretion of oxalate crystals (Rambourgh-Schepens et al., 1988).

Ethylene glycol monoethyl ether has reportedly caused teratogenic effects in rats exposed by gavage below levels that were maternally toxic (Weir et al., 1987). In the same study, EGBE produced teratogenicity only at levels that were maternally toxic. Teratogenicity has also been reported subsequent to a dermal exposure to EGEE (Hardin et al., 1982).

The testicular toxicity of alkyl derivatives of ethylene glycol has been examined by many researchers. Molsen et al. (1995) reported significant differences in the testicular metabolism of EGME between species and strains. Foster et al. (1983) reported no observed adverse effect level (NOAELs) for testicular effects in rats treated 11 days with EGME and EGEE at 50 and 250 mg/kg, respectively.

Researchers have investigated energy metabolism and hormonal responses as possible mechanisms for male reproductive toxicity (Oudiz and Zenic, 1986; Reader et al., 1991). Dermal exposure to EGME has also reportedly produced a reduction in fertility, reduced testis spermatid count, reduced epididymal sperm count, and increased the sperm count with abnormal morphology in male rats (Feuston et al., 1989).

Chronic Effects

An epidemiological study found no significant health changes in a group of workers exposed to EGME at currently acceptable workplace exposure concentrations (Cook et al., 1982).

The potential reproductive effects of alkylated ethylene glycols have been investigated based on findings of studies of male rat reproduction. Ratcliffe et al. (1989) found a weak association between lowered sperm count and exposure to EGEE in a cross-sectional study. Unfortunately, potentially confounding variables could not be controlled. A similar association with EGEE and EGME exposure and low sperm count in shipyard painters was also reported by Welch et al. (1988). Although both compounds were present, the authors indicated that EGEE exposure was more likely to occur at this facility.

No chronic human carcinogenicity or teratogenicity data were available for these compounds.

Mechanism of Action(s)

Hemoglobinuria in rats correlates closely with the EGBE urinary metabolite butoxyacetic acid (Ghanayem et al., 1987a, 1987b). Ethylene glycol monobutylether requires metabolic activation by alcohol or aldehyde dehydrogenase to exert this effect (Ghanayem, 1989).

Studies of the pharmacokinetics of EGBE have noted significant interspecies differences. Rats have higher predicted peak blood concentrations than humans when receiving the same relative dose (rog/kg) (Corley et al., 1994). In addition, human blood was found to be much less susceptible than rat blood to potential hemolytic effects of EGBE (Ghanayem, 1989; Corley et al., 1994).

The primary urinary metabolite in rats exposed to up to 46 ppm EGEE via inhalation was ethylene glycol monoethyl ether acetate (EGMEA) (Kennedy et al., 1993). Approximately 38% of EGEE was exhaled during or after exposure, and almost half of the retained dose was excreted in the urine.

SOURCES OF EXPOSURE

Occupational

Workers are exposed to these compounds where they are included in solvents for cleaning or manufacturing, as well as

the production of these chemicals during solvent manufacture. The most common route of exposure is dermal.

Environmental

Environmental exposure is rare except in cases of sites that have been contaminated by solvents containing these compounds.

INDUSTRIAL HYGIENE

The primary precursor for all alkyl derivatives of ethylene glycol is ethylene oxide. Exposures to these compounds may occur via inhalation, but the low vapor pressures make airborne concentrations low in industrial facilities. Workplace air concentrations of these glycol vapors can be detected through standardized procedures, but the low volatility of these compounds may lead to incomplete assessments of total workplace exposures (Piacitelli et al., 1990). Recent biomonitoring studies indicate that dermal contact contributes to the majority of the absorbed dose (Vincent et al., 1993). One study of percutaneous absorption estimated that it would be possible to absorb enough EGBE by this route to produce acute effects (Johanson et al., 1988). Vapors are easily controlled through engineering and ventilation. During expected high concentration exposures, personal respirators should be worn. Protective clothing, including rubber gloves, should be worn to prevent dermal contact. These controls, in addition to worker education and awareness of these compounds, should provide adequate protection in the workplace.

MEDICAL MANAGEMENT

Flush exposed area with large amounts of warm running water for at least 20 min. Decontaminate clothing before reuse or discard. For inhalational exposures, remove to fresh air. Give oxygen and get immediate medical attention for any breathing difficulty.

Measurement of the metabolites present in the urine is the most common method of monitoring worker exposure to these chemicals, as the parent compound is comparatively undetectable. Determination of 2-ethoxyacetic, 2-methoxyacetic acid, and 2-butoxyacetic acid in the urine was found to correlate well with known exposure levels (Smallwood et al., 1988; Groeseneken et al., 1989; Sakai et al., 1994). The latter report involves detection of these acids as pentafluorobenzyl esters. The amino acid conjugate of butoxyacetic acid, *N*-butoxyacetylglutamine, was identified as a viable means of monitoring exposure, correlating well with 2-butoxyacetic acid measurements (Rettenmeier et al., 1993).

ALKYL DERIVATIVES OF DIETHYLENE GLYCOL

First aid: See text

Occupational exposure limits: *Diethylene glycol monomethyl ether* (diEGME): DNEL; DNEL inhalation,

systemic effects, long term: 50.1 mg/m³; DNEL dermal, systemic effects, long term: 0.53 mg/kg-bw/day; *diethylene glycol monoethyl ether* (diEGEE): DNEL inhalation, systemic effects, long term: 37 mg/m³; DNEL inhalation, local effects, long term: 18 mg/m³; DNEL dermal, systemic effects, long term: 50 mg/kg-bw/day; *diethylene glycol monobutyl ether* (diEGBE): DNEL inhalation, systemic effects, long term: 67.5 mg/m³; DNEL inhalation, local effects, long term: 67.5 mg/m³; DNEL inhalation, local effects, short term: 101.2 mg/m³; DNEL dermal, systemic effects, long term: 20 mg/kg-bw/day

Reference values: diEGME: DNEL inhalation, systemic effects, long term: 25 mg/m³; DNEL dermal, systemic effects, long term: 0.27 mg/kg-bw/day; DNEL oral, systemic effects, long term: 1.5 mg/kg-bw/day; diEGEE: DNEL inhalation, systemic effects, long term: 18.3 mg/m³; DNEL inhalation, local effects, long term: 9 mg/m³; DNEL dermal, systemic effects, long term: 25 mg/kg-bw/day; DNEL oral, systemic effects, long term: 25 mg/kg-bw/day; diEGBE: DNEL inhalation, systemic effects, long term: 34 mg/m³; DNEL inhalation, local effects, long term: 34 mg/m³; DNEL inhalation, local effects, short term: 50.6 mg/m³; DNEL dermal, systemic effects, long term: 10 mg/kg-bw/day; DNEL oral, systemic effects, long term: 1.25 mg/kg-bw/day

Hazard statement: H361—suspected of damaging fertility or to the unborn child (diEGME); H319—causes serious eye irritation (diEGBE)

Precautionary statements: P201—obtain special instructions before use (diEGME); P202—do not handle until all safety precautions have been read and understood (diEGME); P264—wash . . . thoroughly after handling (diEGBE); P280—wear protective gloves/protective clothing/eye protection/face protection (diEGBE); P281—use personal protective equipment as required (diEGME); P305 + P351 + P338—if in eyes, rinse cautiously with water for several minutes; remove contact lenses, if present and easy to do; continue rinsing (diEGBE); P308 + P313—if exposed or concerned, get medical advice/attention (diEGME); P405—store locked up; P501—dispose of contents/container to . . . (diEGME)

Risk phrases: R63—possible risk of harm to the unborn child (diEGME); R36—irritating to the eyes (diEGBE)

Safety phrases: S2—keep out of the reach of children (diEGME, diEGBE); S24—avoid contact with skin (diEGBE); S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice (diEGBE); S36/37—wear suitable protective clothing and gloves (diEGME)

BACKGROUND AND USES

The three important alkyl derivatives of DEG are diEGME (CASRN 111-77-3), diEGEE (CASRN 111-90-0), and diEGBE (CASRN 112-34-5). In general, monoalkyls of DEG are less toxic than monoalkyls of ethylene glycol. As a result, they have been substituted for the monoalkyls of ethylene glycol in many industrial processes.

Diethylene glycol monomethyl ether is used in textile dye pastes, in lacquer industrial for thinners and quick drying varnishes; solvent for wood stains, hydraulic brake fluid diluent, and as a coupling agent for miscible organic aqueous systems.

Diethylene glycol monoethyl ether is used as a solvent in lacquer, varnishes, and enamels. It is also used in cosmetic products and dermatological preparations and as a solvent in some medicine products. It enhances the percutaneous absorption through the skin and mucosal barriers. It is used in some drugs to enhance absorption.

Diethylene glycol monobutyl ether is used as a solvent in paints, dyes, inks detergents, and cleaners.

PHYSICAL AND CHEMICAL PROPERTIES

The alkyl derivatives of diethylene glycol are all colorless liquids. The odor of diEGME is mild and pleasant. It has a vapor pressure of 0.2 mmHg at 20 °C (68°F) and is miscible with water, glycerol, alcohol, acetone, and ether. Because of its low vapor pressure, exposure to diEGME via inhalation is unlikely to occur unless it is heated. Diethylene glycol monoethyl ether has an odor that is mild and pleasant. It has a vapor pressure of 0.14 mmHg at 25 °C (77°F) and is soluble in water and alcohol. It has been selected as a replacement for EGME for many uses. Exposure to diEGEE via inhalation is unlikely to occur under normal conditions.

Diethylene glycol monobutyl ether has a faint odor. It has a vapor pressure of 0.02 mmHg at 20 °C (68°F). It is miscible with water and soluble in alcohol, acetone, and ether. Exposure to diEGBE is unlikely to occur via inhalation unless it is heated.

MAMMALIAN TOXICOLOGY

Acute Effects

Rats exposed to up to 216 ppm diEGME vapors for a equivalent of 13 workweeks had no hematological or clinical findings associated with exposure (Miller et al., 1985), nor were there any significant pathological findings.

Rats dosed orally with 2000 mg/kg diEGME for 20 days had significantly reduced absolute and relative liver weights (Kawamoto et al., 1990b). They also had significantly increased microsomal protein and hepatic cytochrome P-450 concentrations. Decreased testes weight (80% of controls) and thymus weight (60% of controls) were also observed after 20 days (Kawamoto et al., 1990a). In another study, rats were dosed with 2000 mg/kg diEGME and the effect on gamma-glutamyl-transpeptidase (GGT) was measured (Kawamoto et al., 1992). Diethylene glycol monomethyl ether exposure caused a 50% increase in brain levels of GGT, but no effect was noted on levels in other organs.

Developmental studies in rats exposed to diEGME orally suggest that it is fetotoxic to rats at levels that are not maternally toxic (Hardin et al., 1986). No toxic or fetotoxic effects were produced by doses up to 720 mg/kg. Another study of the teratogenic potential of diEGME established 50 mg/kg/day as the NOAEL for maternal and developmental toxicity (Scorticchini et al., 1986).

In one study, pregnant rats orally exposed to diEGME had offsprings with malformations at levels below those that caused maternal toxicity (Yamano et al., 1993). The NOAEL for fetal and maternal toxicity was reported to be 200 mg/kg.

Various tests of mutagenicity have indicated that diEGBE does not present a genetic or teratogenic risk to humans (Thompson et al., 1984; Nolen et al., 1985). A dose of 2 mL/kg has been shown to produce cyanosis, tachypnea, and slight uremia.

Chronic Effects

Dermal exposure of rats to 1.0 g/kg/day for 3 months resulted in decreased spleen weights and significantly increased serum creatinine kinase and lactate dehydrogenase activity (Hobson et al., 1986).

Mechanism of Action(s)

The mechanism of action of these compounds are poorly characterized but may be related to CYP-P450 enzyme induction and the production of metabolites from enzyme systems not normally associated with ethylene glycols (Bowden et al. 1995).

SOURCES OF EXPOSURE

Occupational

Occupational exposures can potentially occur in settings where DEG-based solvents are used.

Environmental

Environmental exposure could potentially occur from accidental contamination of environmental media with DEG-based solvents.

INDUSTRIAL HYGIENE

No OSHA regulations exist for these compounds. Industrial hygiene guidance for DEG should be observed.

MEDICAL MANAGEMENT

In case of contact with the eyes, flush with warm running water for at least 20 min, holding eyelids open during flushing. Take care not to flush contaminated water into unaffected eye or onto skin. In case of skin contact, immediately remove contaminated clothing under running water. Flush exposed area with large amounts of warm running water for at least 20 min. Decontaminate clothing before reuse or discard. For inhalational exposures, remove to fresh air. Give oxygen and get immediate medical attention for any breathing difficulty. If ingested, do not induce vomiting. If the casualty is alert and not convulsing, give 2–4 glasses of water to drink to dilute. If spontaneous vomiting occurs, have the casualty lean forward to avoid breathing in of emesis. Rinse mouth and administer more water. Get medical attention immediately.

FORMALDEHYDE

Target organ(s): Eyes, respiratory system

Occupational exposure limits: NIOSH—TWA 0.016 ppm, Ceiling 0.1 ppm; OSHA—TWA 0.75 ppm, STEL 2 ppm; ACGIH—STEL 0.3 ppm

Reference values: RfD—0.2 mg/kg/day; TDI—150 µg/kg; MRL—0.003 ppm

Hazard statements: H301—toxic if swallowed; H311—toxic in contact with skin; H314—causes severe skin burns and eye damage; H317—may cause allergic skin reaction; H331—toxic if inhaled; H351—suspected of causing cancer by inhalation

Risk phrases: R23/24/25—toxic by inhalation, in contact with skin and if swallowed; R34—causes burns; R43—may cause sensitization by skin contact

Safety phrases: S1/2—keep locked up and out of reach of children; S26—in case of contact with eyes, rinse immediately with plenty of water and seek medical advice; S36/37/39—wear suitable protective clothing, gloves, and eye/face protection; S45—in case of accident or if you feel unwell, seek medical advice immediately (show label where possible); S51—use only in well-ventilated areas

BACKGROUND AND USES

Formaldehyde (methyl aldehyde, methylene oxide; CASRN 50-00-0) is a ubiquitous compound found endogenously in the body and environment. It is a colorless, flammable gas with a distinct, pungent odor and is most commonly available in aqueous solutions under the name formalin (37% formaldehyde in water). Formaldehyde has been used as a disinfectant, an embalming agent, and in industry as a precursor in the fabrication of complex compounds. Since scientific research has identified links between formaldehyde and adverse health effects, precautions and protections must be considered during use.

PHYSICAL AND CHEMICAL PROPERTIES

Formaldehyde is colorless gas with a very distinct, pungent odor. It is highly soluble in water and in a variety of organic solvents. It has the potential to react explosively with peroxides and nitrogen oxide. The gas has a molecular weight of 30.0, a boiling point of −6 °F, and a freezing point of −134 °F. The lower explosive limit is 7.0% and the upper explosive limit is 73%. This compound has a vapor pressure of 10 mm Hg at −88 °C and a vapor density of 1.075 as a gas. NIOSH (2010)

Formalin, the aqueous form of formaldehyde, is a colorless liquid with a very distinct, pungent odor. It is incompatible and may react with strong oxidizers, alkalis,

and acids. The liquid has a variable molecular weight, which is dependent on the specific aqueous formulation. Formalin has a boiling point of 214 °F, a vapor pressure of 26 mm Hg at 25 °C, and a specific gravity of 1.08. The flash point of formalin is 185 °F with the lower explosive limit being 7.0% and the upper explosive limit being 73%.

MAMMALIAN TOXICOLOGY

Acute Effects

Due to high water solubility, acute exposure to formaldehyde results primarily in irritant effects of the upper respiratory tract, including the eyes, nose, and throat. These acute effects are avoidable, as the odor threshold is fairly low for this compound (1–2 ppm). Irritant symptoms and slight pulmonary changes were reported in clinical anatomy students and found to be reversible once exposure to formaldehyde (i.e., laboratory experience) was terminated (Kribel et al., 1993). It has been estimated through human nasal computational fluid dynamic models that there would be around 85.3% uptake of 1 ppm formaldehyde (Schroeter et al., 2014). While formaldehyde uptake occurs with little resistance, it does not appear to severely impact the respiratory system once subjects are removed from exposure. Pulmonary function has been the subject of a number of studies, and no significant decreases in lung function were observed (Schacter et al., 1986; Witek, 1987). Even in cases of asthmatic individuals and where exposure to formaldehyde is in resin form, there were no adverse effects on lung function, such as peak expiratory flow (PEF) rate (Imbus and Tochilin, 1988; Harving et al., 1990). Although no systemic effects are normally associated with formaldehyde exposure, four cases of membranous nephropathy occurred months after severe acute effects were observed (Breysse et al., 1994). This association has not been confirmed in other cases or through biochemical analysis, therefore these case reports remain unique.

The most numerous observed health effects during acute and subacute animal testing were related to the upper respiratory tract. Using computational fluid models similar to those described for humans, rats, and monkeys were also considered. Nasal uptake of 1 ppm formaldehyde was determined to be 99.4% for rats and 86.5% for monkeys (Schroeter et al., 2014). Rats exposed to 15 ppm formaldehyde for 3 weeks had decreased mucociliary function in local nasal regions (Morgan et al., 1986a, 1986b). Exposure to 3–4 ppm formaldehyde in one study was associated with rhinitis, degeneration, hyperplasia, and squamous metaplasia of the nasal epithelium (Cassee and Feron, 1994). Prolonged exposure in Rhesus monkeys to 6 ppm formaldehyde in a study by Monticello et al. (1989) resulted in lesions of the transitional and respiratory epithelia of the nasal passages and upper airways. Airway hyperreactivity, although not

observed in human studies, was induced by low levels of formaldehyde in guinea pigs after 8-h inhalation exposures (Swiecichowski et al., 1993). Time-dependent results of these studies implicate the duration of exposure as a possible factor for evaluating formaldehyde inhalation hazards. In most cases, elimination of exposure to formaldehyde led to a reduction in symptoms. Exposure to formaldehyde may alter warning effects produced by other chemicals and compounds. Chang and Barrow (1984) first demonstrated in rats the ability of formaldehyde to induce cross-tolerance to the irritant effects of chlorine gas. This was later confirmed also for the aldehydes acrolein and acetaldehyde for formaldehyde-pretreated rats (Babiuk et al., 1985). Cross-tolerance due to formaldehyde exposure may weaken the natural warning signs that help guard workers from hazardous concentrations.

Chronic Effects

The signs, symptoms, and etiology of documented chronic effects of formaldehyde exposure are varied. There is debate whether formaldehyde is the sole cause of observed health effects or whether it is the result of several chemical exposures occurring at the same time. Depending on route and duration of exposure, workers have reported health effects ranging from dermal eczema to reproductive hazards and neurological disorders. Formaldehyde can act as both an irritant and an allergen. Cases of allergic contact dermatitis have been reported among formaldehyde-exposed employees in many industries, such as printing (Reid and Rycroft, 1993; Koch, 1995). In one study, for 10 out of 11 patients with formaldehyde-induced eczema, about 2/3 reported healing or improvement of the affected areas (Flyvholm and Menne, 1992). No systemic effects in humans have been reported after dermal exposures.

Respiratory effects are more commonly reported, as inhalation is a more prominent occupational exposure route. An *in vitro* study observing tracheal ciliary activity and aldehyde exposure determined formaldehyde to be one of the most potent inhibitors of ciliary activity (Dalhamn and Rosengren, 1971). Chronic exposure to lower levels of formaldehyde may produce irritant effects similar to acute exposure and impaired respiratory function. Numerous studies have reported formaldehyde exposure in various industries with decreased pulmonary function and disease. A study of funeral service workers by Holness and Nethercott (1989) reported more frequent cases of chronic bronchitis, dyspnea, and general irritation among these workers than unexposed controls.

It should be recognized that a water-soluble, low molecular weight compound such as formaldehyde would not typically penetrate the lower respiratory system. However, when individuals are exposed simultaneously to larger molecules, such as wood dust, formaldehyde may adhere to these particles deposit deep in the respiratory tract, causing effects not typically seen with formaldehyde exposure alone.

Hence, studies involving products of woodworking industries, particularly particle board and oriented strand board, which are held together with formaldehyde resins, indicate respiratory hazards associated with these activities. Self-reported cases of asthma and coughing and abnormal tests of lung function were identified and dose-response relationships with formaldehyde exposure were suggested (Alexandersson and Hedenstierna, 1989; Herbert et al., 1994). These studies also examined pulmonary signs, such as forced expiratory volume per 1 s and forced vital capacity, and found decreases. Nasal obstruction and mucosal swelling were observed, and mucociliary clearance and olfactory function were significantly reduced in a population of workers with long term exposure to formaldehyde and wood dust (Holström and Wilhelmsson, 1988). Malaka and Kodama (1990) concluded that chronic exposure to formaldehyde in plywood workers induces signs and symptoms similar to those seen in chronic obstructive pulmonary disease. Similar effects are seen in other industries in which formaldehyde is used, such as in application of acid-curing paints and lacquers (Alexandersson and Hedenstierna, 1988).

Unique cases of other respiratory effects are also seen in the literature. A case of lymphocytic alveolitis was reported by Schauble and Rich (1994) in a crematorium worker. The authors concluded that exposure to formaldehyde fumes upon cremation of preserved bodies is a possible explanation for their findings. Some cases of occupational asthma due to formaldehyde gas and dust exposure have also been reported (Lemière et al., 1995). While respiratory effects are seen, no permanent cases of lung impairment or increased severity of symptoms have been documented as a result of occupational formaldehyde exposure. Tolerance to the effects of formaldehyde is not observed among chronically exposed workers.

Systemic effects after inhalation exposure have been reported. Baj et al. (1994) reported formaldehyde and other solvent exposure produced changes in the immune and hematopoietic systems in 22 office workers. Adverse neurobehavioral responses to formaldehyde exposure have been reported, although infrequently. Disturbances in equilibrium, mood, and sleep patterns, as well as memory loss, headache, and in a few cases, occurrence of seizures, have been reported (Kilburn et al., 1985; Kilburn, 1994). Reproductive function in males and congenital birth defects are not associated with formaldehyde exposure, although an increase in spontaneous abortions was reported significant in a study by Taskinen et al. (1994).

The carcinogenicity of formaldehyde is a regularly debated topic. Numerous studies have been unable to establish a definite link between specific cancers and occupational exposures. A vast amount of literature for human and animal data currently exists. Earlier studies demonstrated, particularly in rats, a significant increase in nasal carcinomas after inhalation exposure to formaldehyde (Swenberg et al., 1980; Albert et al., 1982; Kerns et al., 1983). Further investigations

identified the nasoturbinate and nasal septum as primary targets for tumor initiation (Morgan et al., 1986a, 1986b). An article published in 2013 confirmed a possible link between formaldehyde exposure and autophagy in male rats. The study determined a dose-dependent relationship between formaldehyde exposure and abnormal testicular morphology and mass (Han et al., 2013). These animal studies prompted evaluation of similar effects in humans. There have been some case reports of sentinel nasal cancer in humans who were occupationally exposed to formaldehyde for long periods, but these isolated cases cannot be used to definitively establish the carcinogenicity of this compound (Halperin et al., 1983; Holstrom and Lund, 1991). Conflicting studies in the past for this type of cancer have reported significant excesses of sinonasal cancers (Olsen et al., 1984; Hayes et al., 1986) and no associations between these sites and formaldehyde exposure (Vaughn et al., 1986; Roush et al., 1987). A recent study by Hansen and Olsen (1995) noted a relationship with formaldehyde exposure and sinonasal cancers in the absence of a wood dust confounding exposure. A more recent case control study of nasal and paranasal carcinomas found no conclusive evidence to implicate formaldehyde other than as a possible potentiator of the effects of wood dust exposure (Luce et al., 1993). Reviews of epidemiological literature by Blair et al. (1990a, 1990b) and Partanen (1993) calculate some risk associated with sinonasal and nasopharyngeal cancer and formaldehyde exposure, although unequivocal proof has yet to be published.

A study was conducted by the National Cancer Institute to evaluate formaldehyde exposure in workers employed at 10 formaldehyde-producing facilities. The findings did not identify any significant associations with any cancer at the levels of exposure estimated to occur (Blair et al., 1986). This study, the largest of its kind for assessment of formaldehyde exposure, has been the subject of an ongoing debate on the interpretation of the data collected. National Cancer Institute researchers conducted a follow-up study in 2013 and explained that when combined with data from previous investigations, the overall results suggest a link between formaldehyde exposure and nasopharyngeal cancer (Beane Freeman et al., 2013). Sterling and Weinkam (1988) first criticized the original work as possibly masking an association of lung cancer through the design of the study. Reanalysis of the data with particular attention to the "healthy worker effect" and short- and long-term employees shows an increased risk of lung cancer with cumulative exposure to formaldehyde, although some calculation errors were present. Comments from both sides of the issue rebut the opposing position and data interpretation, leading to conflicting opinions among the professional community (Blair and Stewart, 1989; Sterling and Weinkam, 1989). A similar study published in the same year found no association between formaldehyde exposure and cancers (Vaughn et al., 1986). Another study a few years later reported no

significant association with respiratory cancers, but there was a possible relationship between formaldehyde exposure and cancers of the buccal cavity and connective tissue in garment workers (Staynor et al., 1988).

Attributing chronic health hazards to occupational formaldehyde exposure is difficult to determine in humans because of coexposures to other compounds such as phenol and particulates such as wood dust. Also, it is important to note that professional exposures (e.g., embalmers) and industrial exposures have shown different mortality patterns. Additional analyses by Blair et al. (1990a, 1990b) are in agreement with the original paper, finding no specific link of formaldehyde to lung cancer. The authors concluded that, although formaldehyde cannot be ruled out, it is more probable that other exposures, such as to phenol and wood dust, are responsible for the excess lung cancer observed in exposed populations. Sterling and Weinkam (1994) reanalyzed the data to show an increased risk of lung cancer with increased formaldehyde exposure. The differences of these two approaches illustrate the difficult task of assigning carcinogenic risk to a compound as common as formaldehyde. An independent analysis of this additional data was performed by Marsh et al. (1992), taking into account coexposures to a variety of substances. In the presence of the coexposures, significant increases in lung cancer were observed, but these were not evident in the analyses that did not include the coexposures. Similar studies showed an increase of lung or nasopharyngeal cancers among occupationally exposed workers and could not conclude, with any certainty, that formaldehyde was the exclusive causative agent for the disease (Bertazzi et al., 1986; Marsh et al., 1994). Andjelkovich et al. (1994) studied mortality of iron foundry workers. An increase in lung cancers was identified, but researchers could not find an association with formaldehyde. Overall, the literature does not seem to support a link between occupational formaldehyde exposure and cancers of the respiratory system. In addition, formaldehyde has not been directly associated with other cancer risks. In a study by Gerin et al. (1989), other cancer sites were examined, including stomach, colon, rectum, liver, and many other systemic sites and no correlation was found with formaldehyde exposure.

This inconclusive and contradictory information regarding this compound has led the ACGIH (2013) to give formaldehyde an A2 designation (probable human carcinogen). The International Agency for Research on Cancer (IARC [1995]) has a similar rating for formaldehyde as probably carcinogenic in humans, Group 2A.

Mechanism of Action(s)

Formaldehyde is an intermediate in a number of metabolic interactions, particularly those involving amino acids and the demethylation of N-, O-, and S-methyl compounds. In a

study of mice, the liver was identified as having the highest content of formaldehyde after exposure, with the kidney being second (Johansson and Tjalve, 1978). The fate of formaldehyde can vary, depending on the molecule it comes into contact with after absorption. If it is not quickly metabolized, there is an opportunity for formaldehyde to react with nucleophilic molecules in the cell. Almost all cells are able to metabolize formaldehyde via formaldehyde dehydrogenase and aldehyde dehydrogenase (ADH). The presence of these enzymes in erythrocytes (Uotila and Koivusalo, 1987) may account for the relatively few systemic effects associated with formaldehyde. After inhalation exposure, these enzymes may oxidize the formaldehyde to formate or carbon dioxide and water. This is the major pathway for formaldehyde metabolism. This reaction also involves a glutathione-hemiacetal intermediate (hydroxymethylglutathione), an NAD⁺ cofactor, and the presence of S-formylglutathione hydrolase, which frees the glutathione molecule from the intermediate. Formate can also be directly incorporated into macromolecules by a tetrahydrofolate-dependent pathway via the one carbon pool. Peroxisomal catalase is capable of oxidizing formaldehyde to formate in the presence of hydrogen peroxide. Production of H₂O₂ is the rate-limiting step in this reaction, which does not account for a great deal of formaldehyde metabolism.

Chemical Pathology

The potential of formaldehyde-induced damage is greatest prior to metabolism. The high reactivity of the compound makes it quite toxic, and is more likely to be hazardous at high exposure concentrations. A review of formaldehyde reactivity by Auerbach et al. (1977) indicates that reactions with amino groups in biological molecules are the ones of most concern. These amino groups form methylol adducts, which can react with a second amino group, producing a molecule of water in the process. A methylene bridge is formed, which may be responsible for deoxyribonucleic acid (DNA) crosslinks, single strand breaks, and mutagenic activity. Induction of nasal carcinomas in rats has been linked to mutation of the p53 tumor suppressor gene (Recio et al., 1992; Wolf et al., 1995). This mechanism of action has been identified in human cancers as well, but not specifically with formaldehyde exposure (Nigro et al., 1989). Since no association of formaldehyde-induced cancer has been noted in humans, the mechanism of action for human carcinogenicity is highly speculative. The biological plausibility of formaldehyde-associated cancers has not been explored in the epidemiologic literature. Data on cell proliferation in humans exposed to formaldehyde have not been reported, although cell proliferation has been observed in the nasal tissue of exposed rats and mice (Chang et al., 1983).
